Malignant catarrhal fever (MCF) has a sporadic worldwide distribution. It mainly affects single animals, although outbreaks have occurred. The wildebeest strain is seen in Africa and in zoological gardens. The sheep-associated strain occurs when sheep associate with cattle, which are considered 'dead-end' hosts. The African form is more easily transmitted, transferred via the placenta into the fetus. Soon after birth, the wildebeest calf sheds infection which can be contracted by other species. Transmission of the sheep form is not known, although cattle have usually been in contact with pregnant or lambing sheep. The virus is fragile and does not survive more than a day outside the host. There may be many distinct MCF virus forms.

The incubation period is shorter for the African form. Following infection, there is an eclipse phase of nine to seventeen days, then viraemia continues until death. After a further three to fifteen days, signs develop, followed by death five to ten days after their onset. Transmission is probably by inhalation or possibly blood transfusion.

Signs

Cases are sporadic. Animals are very ill with anorexia, pyrexia (40.5–41.5°C; 105–107°F), depression and loss of condition. An early pathognomonic sign is an intense scleral congestion with bilateral keratitis and corneal opacity starting at the edge of the sclera, causing blindness. Early lesions also involve the buccal mucosa, with reddening of the lips, gingivae and muzzle. Erosions develop, including necrosis of the tips of the labial papillae and the mouth corners.

Other signs vary. They can include nervous signs such as muscle tremors and hyperaesthesia. The superficial lymph nodes are grossly enlarged. There is profuse mucopurulent oculo-nasal discharge which can encrust around the nostrils and eyes. There is often excessive salivation, followed by dyspnoea and stertor due to exudate accumulation. Faeces vary between profuse diarrhoea and soft, scanty faeces. Laminitis and dermatitis can occur in the sheep-associated form.

At later stages, more prominent nervous signs may occur, such as incoordination, leg weakness and nystagmus followed finally in some by head pressing, convulsions or paralysis.

Uncommonly, a mild form occurs with mild, transient fever and some oral and nasal mucosal erosions. These animals can recover.

Necropsy

Lesions occur in many parts of the body including the respiratory, alimentary and urinary tracts. They include varying degrees of haemorrhage, hyperaemia and discrete or extensive erosions. The eyes show scleral congestion and keratitis. The lymph nodes show marked enlargement. The skin around the coronets may show lesions. Histologically, the epidermis shows extensive hydropic degeneration and vesicle formation with rupture. The dermis shows vasculitis with proliferation and necrosis and marked lymphoid cuffing.

Diagnosis

History helps with a record of other species contact and one animal affected. Nervous signs, lymph node enlargement, scleral congestion, corneal opacity and

diffuse mucosal erosion are indicators. At necropsy the histological presence of vasculitis confirms diagnosis. There is leukopenia. Serological tests can be used in the African form. Viral isolation or transmission can be attempted.

Differential diagnosis

Differential diagnosis includes mucosal disease, but ocular lesions are not severe and there is no lymph node enlargement. Rinderpest and foot-and-mouth disease are herd problems with no severe ocular lesions. Infectious bovine rhinotracheitis usually affects several animals, with mainly respiratory signs. Calf diphtheria does not produce ocular signs.

Treatment and control

There is no treatment or suitable vaccine. Infected animals should be separated from others. Cattle should not be grazed with sheep, particularly at the time of lambing, nor near wildebeest. Bought-in sheep should come from disease-free farms.

Introduction

The nature of many farming practices such as the widespread and increasing use of agrochemicals and the wide variety of potentially toxic plants, coupled with the innate inquisitiveness of cattle to investigate (often by licking) new or unusual substances, means that many cattle live in a potentially toxic environment. It is perhaps surprising therefore that despite this, incidents of poisoning remain comparatively uncommon in cattle. Most toxic dangers to cattle are well understood and documented. This fact, together with the usually responsible and diligent approach to the handling of toxic chemicals and the correct and proper management of pasture, considerably reduces the risk of cattle gaining access to poisonous substances. Most instances of poisoning arise, therefore, by accident, usually as the result of human error, ignorance, neglect or, rarely, malice. Such errors, of course, may not always be under the direct control of the stockworker, for it may be the actions of a third party, often unconnected with livestock that are to blame for a poisoning incident. As an example, the environment and feed of cattle, like all livestock and indeed humans, may be subjected to the effects of industrial pollution. However, incidents where there is gross contamination of the environment or where an accident results in the release of highly toxic substances are very uncommon and for the maintenance of such a state the livestock farmer, like the population

in general, must rely on the vigilance and safety standards of industry and the monitoring authorities.

Most instances of poisoning in cattle therefore are not the result of large-scale incidents but arise from accidental access by cattle to toxic substances at the local farm level either by cattle moving from a safe to a toxic environment or by the inadvertent introduction by man of a toxicant into the animals' previously safe environment.

Poisoning in cattle can vary greatly in severity, morbidity and mortality. In the most severe cases, where a large number of cattle have consumed toxic quantities of poison very high morbidity and mortality can result. In contrast, mild episodes occur where the clinical effects are transient and few animals suffer harmful effects. Some of such cases are often so insignificant that they are missed or misdiagnosed.

Diagnosis of poisoning

The diagnosis of poisoning in cattle is not easy, as often it is the last thing a clinician will consider when presented with an outbreak of disease and not infrequently it is a subject about which he knows little. In many cases the evidence of intoxication is merely circumstantial, the materials required to establish a definitive diagnosis have long disappeared and in many cases the clinical signs are vague and confusing. However, poisoning incidents are often serious, potentially litigious and hence must always be handled with care and vigilance.

There are essentially three stages in establishing a diagnosis of poisoning:

- (1) Recognition that the incident is probably a case of intoxication.
- (2) Reaching a presumptive diagnosis of the toxicant or class(es) of toxicant.
- (3) Establishing a definitive diagnosis of the intoxication.

It is not possible in many cases for all three stages to be accomplished.

Recognition of apparent intoxication

Rarely is an outbreak of disease in cattle immediately attributable to poisoning on clinical or pathological

grounds alone. Before the clinician comes to such an opinion he needs to consider fully the history, epidemiology and clinical signs presented and consider carefully the differential diagnosis in order to exclude the more common non-toxic causes of the condition.

Poisoning incidents should be suspected in the following circumstances:

- The onset of disease is clearly associated with a change in management of the affected animals, for example a change in feed, movement to a new environment or a concurrent agricultural management practice, e.g. spraying or dipping.
- The epidemiology of the disease is not that expected of an infectious disease, for example the condition may quite obviously arise simultaneously in several animals or groups rather than appear to be the result of spread.
- The clinical signs as presented are not typical of the more common infectious, parasitic or metabolic diseases with broadly similar clinical pictures.
- There is circumstantial evidence that animals may have had access to unusual materials.
- The differential diagnosis of the disease as determined by clinical and post-mortem examination includes poisoning as a possible cause.

Presumptive diagnosis of the toxicant

Having established the incident may be a case of intoxication the clinician needs to consider what agent or type of agent might be responsible. In some cases this may be straightforward as the history and circumstantial evidence of poisoning may direct the clinician immediately to the probable cause. More frequently, however, it is far from obvious and requires a detailed consideration of the clinical signs, the post-mortem findings (if appropriate) and the circumstantial evidence. The overall aim should be to answer the question: What possibly could the cattle have had access to that could account for the signs and post-mortem picture as observed? This inquiry needs to be wide-ranging. A full history should always be taken; the clinician should examine the animals in the housing or pasture in which they developed the condition but should not merely concentrate on the animals themselves as it is necessary also to inspect the environment for possible sources of toxicants. It is vital, of course, always to inspect the feed but this should not automatically be viewed as the prime suspect source, although a recent change in feed is strong supportive circumstantial evidence that it may be the source of intoxication. In grazing animals the pasture should be thoroughly inspected for the presence of known toxic plants.

Any recent use of agrochemicals should elicit questioning of farm staff as to their correct usage and the disposal and storage of concentrate. Anything in the environment of the cattle that would not normally be present should be investigated with suspicion; for example, old farm machinery or rubbish left in fields, lead from old batteries and discarded sump oil may be the sources of various toxicants. The water supply must always be critically examined, especially if the supply is provided by means other than a piped mains supply. Could the supply have been contaminated by local dumping of toxic rubbish, or run-off from nitrogenous fertilizers from fields? Only when there is no known indication of local contamination should more distant sources, e.g. industrial sites, be considered.

The clinician's best initial guide to the type of toxicant involved is detailed appraisal of the clinical signs and post-mortem findings, where appropriate, and to correlate these with the known effects of the major types of toxicant (Table 54.1). However, few toxicants produce a clinical picture not shared with other poisons or non-toxic causes and several can produce a wide array of clinical signs.

Establishing a definitive diagnosis

Having attempted to form an opinion as to the type of toxicant involved, the veterinary clinician is now in a position to attempt to reach a definitive diagnosis. To achieve this, in most cases, especially when chemical rather than plant toxicants are involved, he will require the assistance of a diagnostic laboratory. In some cases a routine thorough gross and histological examination by the laboratory may provide strong supportive evidence of the toxicant as may the botanical examination of rumen contents in cases of plant poisoning, but in the majority of instances a definitive diagnosis of poisoning is dependent on the finding, by chemical analysis, of toxicant in the tissues, ruminal or intestinal contents or food of the poisoned animal. The results of such chemical analyses must always be interpreted carefully and in conjunction with the history, clinical picture and post-mortem findings. The question to be answered is: Would the observed level of chemical (as determined by analysis) in the particular tissue at the time of examination account for the signs and disease picture originally observed? Only when this question can be answered in the affirmative can a definitive diagnosis result. This is not always possible, especially with the economic constraints usually imposed on veterinary laboratory examination, and the clinician must view attempts at establishing a definitive diagnosis in this light. The required evidence is often not available; for example, a suspect batch of feed may have long since disappeared and despite a diligent examination the analyst is unable

Table 54.1 Initial linking between clinical abnormality and type of poisoning.

| System | Abnormality | Suspected class of poison | |
|------------------------|--|--|---|
| | | Chemical | Plant |
| Alimentary | Diarrhoea | Heavy metals, organophosphates, ionophores | Solanine containing, oak, GI irritants, ragwort |
| | Colic abdominal pain | Heavy metals, formaldehyde, urea | Oak, GI irritants |
| | Hypersalivation, vomiting | Organophosphates, urea | GI irritants, rhododendron |
| Central nervous system | Depression, coma | Ionophores | Oxalate containing, solanine containing |
| | Hyperexcitability, hyperaesthesia, convulsions | Heavy metals, nitrofurans, organochlorines | Atropine containing |
| Eye | Mydriasis | Lead | Atropine containing, Hemlock, <i>Cicuta</i> sp. |
| | Miosis | Organophosphates | |
| | Blindness | Lead | |
| Respiratory | Dyspnoea | Nitrate/nitrite | Cyanide containing |
| | Photosensitization | | St John's wort, ragwort |
| Skin | Gangrene | | Ergot |
| | Lameness | Fluoride | Ergot |
| | Haematuria | | Bracken |
| Locomotor | Haemoglobinuria | Copper | <i>Brassica</i> spp. |
| | | | <i>Allium</i> spp. |
| Urinary | | | Pyrrolizidine containing |

GI, gastrointestinal.

to determine a chemical cause of the signs observed. The veterinarian at this stage must conclude the case, after referral if necessary, as merely one of *suspected* intoxication.

Relationship between the veterinary clinician and the diagnostic laboratory

If a significant number of investigations are to be concluded beyond the stage of 'suspected intoxication' by the clinician, a working cooperation must develop between the veterinary clinician and the diagnostic laboratory. Once intoxication is suspected the golden rules are to contact the laboratory earlier rather than later and to take too much material for examination rather than too little. When the clinician suspects intoxication and has concluded the initial clinical and environmental assessments contact should be made with a laboratory experienced in diagnostic toxicology. The clinician should inform the laboratory of the following: history, clinical signs, post-mortem findings (if appropriate) and the results of the environmental assessment, indicating an opinion as to possible toxicants. The clinician must then be guided by the laboratory as to what samples to submit, the size of specimens, how they

Table 54.2 Specimens submitted for toxicological examination.

| Tissue | Amount usually required |
|---|-------------------------|
| Serum (separated from clot, not haemolysed) | up to 10 ml |
| Urine | 50 ml |
| Liver | 100 g |
| Kidney | 100 g |
| Other tissues | 100 g |
| Rumen contents | 500 ml |
| Feed | minimum 100 g |

should be packaged or sent and any special instructions. Accompanying all specimens must be the clinical information as above together with details of any treatments given and the time of death. As a general rule, containers should be glass or plastic and tightly sealed, different organs should be packaged separately and no preservative added. As tests for different toxicants require different samples the need for prior discussion between the clinician and the laboratory is paramount. Detailed discussion is not warranted here. Table 54.2 serves as a guide.

Principal toxicoses

There are a vast array of potentially toxic chemical compounds and toxic plants which can, theoretically at least, cause poisoning in cattle due to the fact that they contain known toxic agents and/or have been proven as toxic by experimental observation. In practice, a few principal toxicoses are commonly observed in a given region or country and the majority are rarely, and a few almost never, encountered.

Local, regional and geographic factors greatly influence the importance of the various toxicoses in different regions and countries, so much so, particularly with toxic plants, that attempting to define the principal toxicoses is fraught with difficulty. Nevertheless, certain types of toxicant are encountered much more frequently than others. These common toxicoses, based generally on the position in the UK, are accorded detailed treatment in the text, whereas for those considered of lesser importance a summary of the principal facts is given in Table 54.3.

Organophosphate and carbamate poisoning

The organophosphate compounds are widely-used agrochemicals in agriculture, horticulture and livestock production, and accidental overdosage or overexposure can lead to toxicosis.

Source of toxicant

The principal uses of organophosphates are as insecticides and acaricides, and preparations are made for animal treatment (dusting powders, sprays, washes, dips, pour-on, etc.), sprays for application to plants and granules for application to soil. Carbamates, which have a similar mode of action, are used as molluscicides and herbicides.

Cattle may become poisoned by a variety of methods, principally due to human error, negligence or ignorance. The compounds can be absorbed orally, dermally or by inhalation. Cattle may gain access to stored compounds, they can be mistaken as feed ingredients, and they may also consume treated seed. Containers may be used for feed or water without cleaning. Sprays for pest control in crops may directly contaminate animals or pollute feed or water courses. Inadvertent overdosage can occur with insecticidal sprays, dips or topical pour-on preparations or by a combination of topical and oral therapy or by rapid retreatment.

Signs

The organophosphates and carbamates block the action of cholinesterases (by phosphorylation or carboxyla-

tion, respectively) at cholinergic nerve endings and myoneural junctions. The continued presence of acetylcholine at these sites produces continued nerve stimulation and accounts for the clinical signs observed. The time of onset of clinical signs varies with the dose and route of absorption from five minutes to a few hours. Clinical signs are similar for both organophosphate and carbamate toxicoses and are broadly threefold, namely stimulation of the parasympathetic nervous system (muscarinic effects), stimulation of the skeletal muscles (nicotinic effects) and central nervous effects. The muscarinic effects in general precede the nicotinic. The first effects are excessive, followed by profuse salivation. This is accompanied by nasal discharge, cough, dyspnoea, colic, diarrhoea, excessive lacrimation, frequent urination and miosis. These are then joined by the nicotinic signs, muscle fasciculations, stiffness, adoption of a 'saw-horse posture', which then progresses to muscle paralysis. Cattle usually show marked central depression although rarely they may show central nervous excitation. As the condition progresses the muscarinic signs become very pronounced with profuse salivation, severe colic, sweating and dyspnoea progressing to collapse and death. Death is the result of hypoxia due to severe bronchoconstriction with respiratory hypersecretion and irregular slowing of the heart.

Diagnosis

The history and characteristic clinical signs of parasympathetic stimulation are suggestive of poisoning. This will be reinforced if there is circumstantial evidence of exposure to organophosphates or carbamate compounds. Particular attention should be paid to the possibility of inadvertent therapeutic overdosage, for example by combinations of oral and topical exposure. Chemical analysis of blood or tissue for the toxicant is usually of no value due to the fast breakdown of organophosphates; the analysis of contaminated feed or rumen contents is likely to be more successful. However, the preferred method of confirmatory diagnosis is by the determination of the reduction in cholinesterase activity. This test is often performed, for convenience or necessity, on whole blood, but examination of brain tissue is better. The test is a specialized laboratory procedure and the testing laboratory should preferably be consulted before the submission of samples.

Principal differential diagnoses

The respiratory signs may resemble fog fever (p. 866) in which the muscle fasciculations are not, however, usually observed. The syndrome is similar to acute urea

Table 54.3 Summary of the less commonly observed toxicoses of cattle.

| Poison | Usual source(s) | Clinical signs | Management guidelines |
|---|---|--|---|
| Aflatoxin | Feeds containing groundnut, cottonseed or maize contaminated with the toxicogenic fungi <i>Aspergillus flavus</i> and <i>A. parasiticus</i> . Growth of toxicogenic fungi is only possible when moisture content of stored grain exceeds 15%, feed levels should not exceed 50 ppb. | Reduced feed intake, poor weight gain (or decreased milk yield), inappetence, rough hair coat, reduced resistance to infectious disease. Less commonly acute severe signs may be observed especially in calves less than 6 months, including nervous signs, circling, blindness, convulsions, death. | No specific treatment. Remove all suspect feed, submit samples of feed for analysis (permitted levels of dietary aflatoxin controlled). |
| Arsenicals | Accidental contamination of feed with inorganic arsenicals or organic (herbicides, pesticides). Formerly in dips and weedkillers, industrial chemicals, horticultural sprays. | Often sudden death. Acute – severe colic, salivation, teeth grinding, weakness, incoordination, rapid collapse and death. Subacute – similar with ruminal stasis, diarrhoea, severe thirst, dehydration, collapse and death. | Rarely successful. Adsorbents orally, sulphur compounds, e.g. dimercaprol (4 mg/kg im) or sodium thiosulphate 15–30 g in 100–200 ml water i.v. and up to 60 g orally (adult). |
| Atropine-containing plants | Deadly nightshade (<i>Atropa belladonna</i>), black or stinking henbane (<i>Hyoscyamus niger</i>), thorn apple (<i>Datura stramonium</i>). | Those of atropinization, dilation of pupils, dryness of mouth progressing to excitement, incoordination, convulsions and death. | Uncommon, often little can be done; pilocarpine can be given by injection but is not widely available and can itself be dangerous. |
| Brassica | Conversion of S-methyl cysteine sulphoxide in the plants to dimethyl disulphide. Kale (<i>Brassica oleracea</i>) fed as fodder crop, rape (<i>B. napus</i>) and cultivated cabbages. Usually need to eat kale as sole fodder for about three weeks. | Peracute – collapse and death; acute – haemaglobinuria, pallor, weakness, jaundice, tachycardia, diarrhoea, low haematocrit. Heinz–Ehrlich bodies in RBCs. Can be fatal. Within a group usually a high prevalence of subclinical anaemia. | Stop feeding kale, blood transfusion, vitamin injections, iron. Feed good quality hay before and as well as kale. |
| Cyanide | Cyanide release by hydrolysis from cyanogenetic glycosides in plants including cherry laurel (<i>Prunus laurocerasus</i>), linseed cake, sudan and sorghum grasses, couch grass, white clover. | Dyspnoea, bright red mucosae, recency, convulsions, opisthotonus, rapid death. Often less acute; depression, staggering, muscle tremor, dyspnoea, death within 2 h, fresh blood is bright red. | Inject sodium nitrite 16 mg/kg iv followed by sodium thiosulphate (40 mg/kg iv). Repeat only thiosulphate, 30 g doses of sodium thiosulphate orally. |
| Ergot | Ergots (sclerotia of <i>Claviceps purpurea</i>) are found on rye and also on other cereal grains and rye grasses particularly in warm wet seasons. | Acute (convulsive) rare – depression, staggering, blindness, convulsions. Chronic (gangrenous) – lameness, abnormal gait, extremities swollen, reddened, gangrenous, particularly tail, ear tips, distal limbs. | Remove from feed source, avoid heavily ergotized pastures or uninspected stored grain following warm wet summers. |
| Formaldehyde (formalin) | Formalin used for agricultural purposes, e.g. foot baths. Usually associated with a lack of available drinking water. | Mild – salivation, inflammation of buccal mucosae. Severe – dullness abdominal pain, weak pulse, coma, death. | Do not leave cattle unattended near source of diluted formalin. Symptomatic therapy. |
| Furazolidone (see p. 260) | Accidental over dosage following therapeutic or prophylactic use, improper mixing in milk substitute. | Acute – hyperaesthesia, convulsions, death. Chronic – haemorrhages, necrotic lesions in mouth, dysentery. | Stop administration of furazolidone, sedatives to control hyperaesthesia. |
| Hemlock; spotted hemlock, <i>Conium maculatum</i> | Umbelliferous plant common in wasteland and neglected pasture, characterized by permanganate-coloured spots on stems and mousey odour when crushed. May be eaten when grazing is sparse; palatability decreases as plant gets woody in late summer. | Dilation of pupils, weakness, staggering, muscle tremor, death from respiratory failure. | Avoid contact with plant and overgrazing, especially in early part of the grazing season. |

contd.

Table 54.3 *Continued*

| Poison | Usual source(s) | Clinical signs | Management guidelines |
|---|--|--|---|
| Hemlock; water hemlock, cowbane, <i>Cicuta virosa</i> | Plant grows in wet ditches and on edges of ponds and swamps. Contains the very toxic cicutoxin, the roots being the most dangerous. | Dilated pupils, frothing at the mouth, abdominal pain, violent convulsions, rapid death. | None, awareness of the potential danger. |
| Mercury | Organic mercury compounds from grain dressed with fungicide, no longer common due to control of seed dressings. | May not appear for three to four weeks after feeding dressed grain; inappetence, blindness, staggering, weakness, nervous signs. | Poisoned animals can be treated with sodium thiosulphate (20 mg/kg i.v. and orally) or dimercaprol (BAL) 2.5–5 mg/kg iv 4× daily. |
| Metaldehyde | Molluscicide for slug/snail control. | Incoordination, hyperaesthesia, salivation, tremor, dyspnoea, fever, ataxia, convulsions, opisthotonus, cyanosis, death. | Sedation or anaesthesia to control hyperaesthesia and convulsions. Consider rumenotomy. |
| Molybdenum | High soil levels on teart pastures, exacerbated by low copper and high sulphate levels. Induces a relative copper deficiency; high dietary molybdenum and low available copper are interlinked. | Diarrhoea, often green or black with offensive odour, depigmentation, poor condition, stiff gait in young, anaemia, osteoporosis, fractures, poor milk yield. | Test group for low blood copper, careful administration of copper supplements or injections. A perennial problem on known pastures and prophylactic measures should be introduced. |
| Ionophores (monensin, salinomycin, lasalocid) | Accidental overdosage or incorrect mixing in cattle diets. | Anorexia, depression, diarrhoea, ataxia, recumbency, dyspnoea, can be fatal. Signs develop in up to two days or longer with lower toxic doses. | History of recent access to changed feed useful in presumptive diagnosis. Feed assays, remove ionophore from feed of affected group, ensure correct levels in feed. |
| Onion, wild garlic, <i>Allium</i> sp. | Large quantities of unwanted onions fed to stock, access to wild garlic in woodlands. | Haemolytic anaemia, haemoglobinuria, pallor, possibly jaundice. Can be fatal. | Remove from source, feed well, multivitamin and iron by injection. |
| Organochlorine compounds | Accidental access or overexposure to insecticides for animal or agricultural use. | Acute and chronic syndromes occur – abdominal problems and typically salivation, incoordination, muscle tremor, clonic spasms, convulsions, possibly aimless or frenzied movements, clonic-tonic convulsions, collapse, death. | Give adsorbents orally and/or wash skin contamination with soap and water. Control excitation with pentobarbitone or sedatives. Exposure of food-producing animals to these chemicals may result in high and persistent tissue residues, particularly in fat. |
| Oxalate-containing plants | Unwilted leaves of sugar beet, fodder beet, mangels, also fat hen (<i>Chenopodium album</i>), docks and sorrels (<i>Rumex</i> sp.). Oxalate is detoxified by ruminal microflora and hence previous sublethal exposure will increase tolerance to oxalate. Large quantities of unwilted leaves need to be consumed over a short period. | Rapid ingestion of soluble oxalates induces hypocalcaemia, paresis, muscle tremor, recumbency, coma, death. Ill-thrift due to chronic renal damage. | Treatment of clinical cases with calcium borogluconate as in milk fever. The response is not as certain and is often unsuccessful. Affected forage should be introduced gradually, is best fed wilted, and not as the sole feed source. |
| Plants causing gastrointestinal signs | In addition to those described elsewhere there are a large number of hedgerow and wild plants which will induce salivation, colic and diarrhoea, these include: cuckoo pint (<i>Arum maculatum</i>), black bryony (<i>Tamus communis</i>), autumn crocus (<i>Colchicum autumnale</i>), monkshood (<i>Aconitum napellus</i>), hellebores (<i>Helleborus</i> sp.), buttercup (<i>Ranunculus</i> sp.), spindle tree (<i>Euonymus europaeus</i>), white bryony (<i>Bryonia dioica</i>), dog's mercury (<i>Mercurialis perennis</i>), box | Generally salivation, teeth grinding, abdominal pain, severe diarrhoea, may be accompanied by nervous signs. Fatal in some cases. | Uncommon, symptomatic treatment of colic and diarrhoea, remove from access to suspect plants. |

Table 54.3 *Continued*

| Poison | Usual source(s) | Clinical signs | Management guidelines |
|--|---|--|--|
| Plants causing photosensitization (see p. 884) | (<i>Buxus sempervirens</i>), greater celandine (<i>Chelidonium major</i>), charlock (<i>Sinapis arvensis</i>). St John's wort (<i>Hypericum perforatum</i>) is a common plant in hedgerows and rough grazing and is the most frequently implicated in primary photosensitization. It contains the photodynamic hypericin which is retained when dried. Buckwheat (<i>Fagopyrum esculentum</i>) is also photodynamic. Several plants including the ragworts (<i>Senecio</i> sp.) and bog asphodel (<i>Narthecium ossifragum</i>) cause secondary photosensitization following liver damage. | Photosensitization, erythema, swelling, necrosis of skin in white areas only, pruritus, oedema, later sloughing and self-inflicted injury. | House animals out of direct sunlight, debride raw areas, protect against infection and blowfly strike. |
| Rhododendron | <i>Rhododendron ponticum</i> grows as a cultivated shrub but also extensively in the wild on acid soils where it can form large thickets. Poisoning usually occurs when hungry cattle break out into woodland or gardens or from hedge clippings dumped in fields. | Salivation, staggering gait, abdominal pain, collapse, death in a few days. Projectile vomiting, green froth around mouth. | Symptomatic treatment, purgatives, ensure adequate fencing of stock. Rumenotomy? |
| Selenium (see p. 305) | Toxic levels of selenium may accumulate in certain plants including certain forage plants and grasses growing on high selenium soils. Increased levels may occur accidentally in feeds; the diet should contain under 5 ppm. | Acute (rare) – blindness, depression, circling, head-pressing, colic, paralysis, death. Chronic – loss of condition, lameness, emaciation, hair loss from base of tail, hoof damage. | Test forage for selenium levels and withdraw suspect feed (>5 ppm is suspect). Levels in blood >2 ppm indicate excessive exposure. |
| Solanine-containing plants | Plants of the genus <i>Solanum</i> . Green tubers and leaves of the potato (<i>S. tuberosum</i>). The woody nightshade (<i>S. dulcamara</i>) is common in hedgerows; this plant together with the black nightshade (<i>S. nigrum</i>) are common in neglected pasture. All parts of the nightshades are toxic, the berries being the most dangerous. | Salivation, dyspnoea, diarrhoea, depression, prostration, coma. Can be fatal. | Symptomatic treatment, green potatoes should not be fed to livestock but boiling and feeding at less than 25% of diet reduces risk. |
| Tremorgenic mycotoxins | Certain fungi of the genera <i>Penicillium</i> and <i>Aspergillus</i> which grow at the base of the grass sward produce tremogens. Toxicity is most likely to occur in hot, dry summers with cattle grazing at the bottom of the grass plant. | 'Ryegrass staggers', usually not observed until animals are disturbed, muscular tremors, stumbling, swaying; when forced to run develop a high-stepping gait, staggering, sternal recumbency, will then recover if left undisturbed. | Recovery is usually uneventful when removed from suspect pasture and given alternative feed. |
| Urea | Inadequate mixing or diluting of dietary urea, accidental access to concentrated amounts, feeding to unadapted animals, or with high-fibre, low-energy rations. Overconsumption of urea-containing blocks or licks. | Begin within 1 hour, excessive salivation, frothing at mouth, bellowing, bloat, muscle fasciculations particularly of the head, colic, dyspnoea, death. | Drenching with vinegar (4–7 l daily) together with cold water (20–40 l). Ensure adequate mixing of urea, continuous access is preferred; tolerance will build up in cattle accustomed to urea feeding, but is short-lived on withdrawal. |
| Water dropwort (<i>Oenanthe crocata</i>) | Root tubers from the plant which grows commonly in ditches and marshes. Usually exposed tubers on pasture following ditching or drainage operations. | Often sudden death, salivation, dilated pupils, convulsions, death. | No treatment, awareness of potential danger to grazing animals when ditches are cleared. |

poisoning (p. 943), and it may clinically resemble nitrate toxicosis (p. 950) but without the cyanotic mucosae. The nicotinic effects may resemble hypomagnesaemia (pp. 253, 787).

Treatment and prevention

Atropine sulphate is the specific antidote to organophosphate or carbamate toxicosis. It acts by blocking the effects of acetylcholine at nerve endings and will thus only counteract the muscarinic effects. The recommended dose is 0.1 mg/kg bodyweight by slow intravenous injection followed by 0.4 mg/kg given subcutaneously. The effects are usually observed within minutes. Treatment may need to be repeated during the first 48 hours depending on clinical response. Cattle should be removed from the suspected source and washed with soap and water if exposed via the skin. Intestinal adsorbents such as activated charcoal given by drench or stomach tube are also useful. Prevention is dependent on recognition of the wide diversity of uses of organophosphates and carbamates in the environment and the possibility of accidental exposure or overdosage.

Lead poisoning (see also p. 906)

Poisoning by lead is one of the most common intoxications of cattle, which are more susceptible to this toxicant than other farm species.

Sources of toxicant

There are many potential sources of lead in the environment and accidental access by cattle to a lead-containing product is the usual predisposing cause which, combined with their natural inquisitiveness and a tendency to lick foreign objects, means that a toxic dose is soon ingested. Common sources of lead include old flaking paint, batteries, discarded engine sump oil, grease, putty, plumber's materials, linoleum and mine washings. Grass from verges of heavily used roads can also contain significant amounts of lead from leaded petrol. Lead poisoning is more frequently observed in calves than adults. Poisoning can result from a single ingestion of a toxic amount or from a continued ingestion of lead from the environment with accumulation in the body tissue.

Signs

The onset of disease and, to some extent, the clinical picture that ensues depends on the dose of lead ingested. Both neurological and gastrointestinal signs

are seen. Ingestion of large quantities, particularly by calves, tends to lead to an acute syndrome with the neurological signs predominating. Ingestion of lesser amounts results in a subacute pattern. In very acute cases sudden death may be the presenting sign. Acute cases are characterized by sudden onset of muscle fasciculations, particularly of the head and neck, frothing at the mouth, teeth grinding, jaw champing and abnormal movements of the head and eyelids. There is a staggering gait and apparent blindness with pupillary dilation. Colic may be observed. This may progress to collapse, tonic/clonic seizures, hyperaesthesia and death. In adults, abnormal patterns of behaviour, including pushing through fences, charging or mania can be seen.

Subacute cases are dull and anorexic and are apparently blind. There may be aimless wandering, there is muscular tremor and a staggering gait, tooth grinding, signs of colic and a ruminal stasis resulting in constipation followed by diarrhoea. The palpebral eye reflex is absent. Rarely, a more chronic form may be observed with poor growth and anaemia.

Necropsy

In very acute cases there may be no gross lesions but the lead-containing material, such as flaked paint, oil or grease, may be found in the reticulum and rumen. In less acute and subacute cases lesions of the gastrointestinal tract are frequently observed including abomasitis and enteritis. The liver and kidneys may be abnormally pale and show some degeneration. There are frequently epicardial and sometimes endocardial haemorrhages. The brain may be oedematous. Histological changes may be observed in the brain depending on the length of exposure. The hepatic and renal cells may also show degeneration.

Diagnosis

Often the history and circumstantial evidence (suspected lead-containing material in the environment) strongly support a tentative diagnosis of lead poisoning particularly when the neurological signs are observed in calves. This being the case treatment should be instituted immediately, a successful outcome of which is highly supportive of the diagnosis. A confirmatory diagnosis in the live animal rests on a measurement of blood lead levels. A heparinized blood sample should be submitted, and levels in excess of 0.4 ppm are considered diagnostic. From the dead animal, kidney, liver and stomach contents should be submitted. Measurement from the kidney is most reliable and levels in excess of 20 ppm are diagnostic.

Principal differential diagnoses

In the absence of compelling circumstantial evidence of poisoning, lead intoxication can closely resemble several other disorders of calves characterized by neurological signs. These include infections, e.g. listeriosis (p. 904), *Haemophilus somnus* infection, brain abscess, rabies, coccidiosis (p. 282), together with hypomagnesaemia, tetanus, cerebrocortical necrosis (pp. 261, 903), vitamin A deficiency, other poisoning (e.g. mercury) (p. 942) and in older animals nervous acetonaemia (p. 794) and bovine spongiform encephalopathy (BSE) (p. 909).

Treatment and prevention

Treatment is threefold: (i) supportive and symptomatic, (ii) oral salts to precipitate soluble lead and (iii) intravenous administration of lead-chelating agents, which can increase by up to 50 times the rate of lead excretion.

Convulsions and nervous signs can be controlled by the use of tranquillizers and sedatives including acepromazine and xylazine. Magnesium sulphate, egg whites and strong tea will precipitate any soluble lead remaining in the gut as insoluble salts of lead. Calcium disodium edetate should be given by slow intravenous injection at a dose of 110–220 mg/kg body weight. This dose should preferably be divided between two or three separate injections per day. Treatment should be given for two to three days, withheld for two days and then repeated, repeating this pattern again if necessary. Good nursing care and oral fluid replacement is required to combat dehydration. Clinical improvement may take two or three days to be apparent and blindness can persist for up to three weeks. Prevention of poisoning by lead is largely a matter of education of those responsible for the care of livestock. A knowledge of the common lead-containing commodities and the need to be vigilant about accidental access should be stressed.

Ragwort poisoning

Poisoning of cattle by the pyrrolizidine alkaloids found in certain genera of plants is a common problem in many parts of the world and can result in severe losses.

Sources of toxicant

The principal genus of plants containing pyrrolizidine alkaloids is *Senecio* of which there are in excess of 1200 species. The quantity and type of alkaloid varies between species, for example the widespread groundsel (*Senecio vulgaris*) is much less harmful than the most

important single species the common or tansy ragwort (*S. jacobaea*). In temperate regions the ragwort is widespread in wasteland and neglected pastures and poses a serious potential toxic threat to livestock. Plants of the genera *Crotalaria*, *Heliotropium* and *Amsinckia* also contain the toxic alkaloids.

Circumstances of poisoning

Common ragwort is not attractive to grazing animals and cattle will usually avoid eating the fresh vegetative plant. However, this is not always the case and should never be relied upon. The plant is relatively late in emerging through the sward in the spring and, particularly following widespread seeding from the previous year, small, young plants can become finely distributed within the grasses. This is then non-selectively grazed. In dry conditions and where grass growth is poor, cattle may also be attracted to ragwort. The unattractiveness of the plant is lost, but its toxicity largely retained, when it is dried in hay or ensiled and this represents the single most important cause of intoxication. Cattle will readily consume hay or silage containing ragwort.

Pathogenesis

The pyrrolizidine alkaloids are hepatotoxic, damaging the hepatocytes. The speed at which this cell damage occurs and the consequences thereof are dependent on the dose of alkaloid and the duration of consumption. The liver has a large functional reserve and thus can withstand the functional loss of many hepatocytes before gross dysfunction occurs. An animal would therefore only rarely ever ingest sufficient quantities of alkaloids over a sufficiently short period to result in acute poisoning. Much more commonly cattle will ingest smaller amounts of the toxicant over a period of weeks or even months resulting in a more gradual loss of hepatocyte function, it only being when the functional reserve of the organ has been exceeded that gross hepatic dysfunction and hence clinical disease results.

Signs

The clinical picture can vary: although the principal cause is a subacute to chronic intoxication, acute clinical syndromes may be observed, although more usually a subacute pattern is seen in cattle. Affected cattle will lose weight and usually develop a mild to moderate jaundice, and may show photosensitization. Diarrhoea, colic and straining characteristically occur. Subcutaneous oedema and ascites may be present due to hypoalbuminaemia. Affected cattle are usually dull and depressed. They may show signs of hepatic encephalopathy, resulting from the effects of raised

blood ammonia levels on the brain due to the inability of the damaged liver adequately to remove urea arriving via the portal circulation. Signs of encephalopathy include an unawareness of surroundings, staggering gait, aimless wandering, circling and apparent blindness. Head pressing and aggressive syndromes are rare in cattle. Death usually occurs a few days after the commencement of such clinical signs.

Necropsy

The carcass may be jaundiced and in poor condition, and ascites may be present. The liver is characteristically shrunken, fibrosed, slate-grey or mottled. The histological picture of the liver in pyrrolizidine alkaloid toxicosis is characteristic and highly suggestive of the condition but not pathognomonic. The lesions are a fine pericellular cirrhosis, bile duct proliferation and hepatocytomegaly.

Diagnosis

The history and circumstantial evidence are extremely important. It is vital to understand the chronic nature of the intoxication; in most cases animals will often have eaten the plants for several weeks or months prior to the development of clinical signs. Bearing this in mind, examination of hay, silage and pasture for the plants is vital, but their absence does not necessarily eliminate pyrrolizidine alkaloid toxicosis unless a history of an unchanged, uncontaminated diet can be positively established. Histological examination of the liver is the method of choice in establishing a diagnosis and, in the live animal, liver biopsy is the most useful diagnostic aid. Serum biochemistry will usually demonstrate an elevation of γ -glutamyl transferase (GGT), and in some cases an elevation in aspartate amino-transferase (AST). Chemical analysis for the alkaloids is not often of value.

Principal differential diagnoses

Particularly where hepatic encephalopathy is marked, ragwort poisoning can resemble rabies, BSE (p. 909), brain abscess/tumour (p. 902), encephalomyelitis (p. 901) or lead poisoning (pp. 906, 944). Where wasting, jaundice and diarrhoea are the dominant clinical signs, intestinal parasitism (p. 267), fascioliosis (p. 276), hepatitis and biliary obstruction should be considered.

Treatment and prevention

Once the clinical picture has developed there is no worthwhile treatment for pyrrolizidine alkaloid toxicosis, but clinically normal cattle in the same group should

be immediately switched to a non-contaminated food supply. Prevention relies upon control of the plant and an understanding of the syndrome. Hand pulling and burning of plants before seeding and the use of herbicide sprays is to be recommended on affected pastures. Sheep are less susceptible than cattle and can often graze affected pasture or eat hay if not too heavily contaminated. Hay or silage should never be prepared from ragwort-infested grassland.

Bracken poisoning

The bracken fern (*Pteridium*) is widely distributed in the UK, the USA and in many other temperate hilly and forested areas. It can relatively quickly become dominant in a grassland pasture. Where cattle have continued access to bracken-contaminated grazing, toxicosis can result.

Source of toxicant

Cattle are often reluctant to eat bracken and will usually only do so when grassland grazing is sparse. Cattle need to graze bracken as a significant constituent of the diet for several weeks or months before clinical disease may become apparent. The rhizomes, exposed after ploughing of bracken-infested pasture, are more attractive and dangerous as are newly sprouted young fronds. Some of the toxicity remains when bracken becomes dried in hay. Bracken contains a thiaminase but, unlike the situation in herbivorous non-ruminants, cattle are largely unaffected by it. Bracken also contains a variety of other toxic chemicals including a cyanogenetic glycoside (which is only usually present in harmless amounts), toxins that depress bone marrow and a carcinogen (ptaquiloside). These last two can cause disease in cattle.

Signs

Acute poisoning: Acute or subacute toxicosis is the result of bone marrow depression producing leucopenia and thrombocytopenia and occurs following consumption of comparatively large amounts of bracken. Clinical signs may develop for up to several weeks after the exposure to bracken has ended. Signs may be sudden in onset and include anorexia, depression and dysentery, and there may be pyrexia; various signs of capillary fragility and haemorrhage become obvious including petechiae on mucosae, bleeding from nose, vagina and conjunctiva. Trauma may produce haematoma. Heart and respiratory rates are increased. Progressive weakness ensues and death may

occur in one to five days. In calves there is often pyrexia, dysentery, frank haemorrhage and petechiation of visible mucosae. Death is often the result of heart failure. There may be laryngeal oedema and marked dyspnoea. Due to the leucopenia, a bacteraemia or other secondary infections are often complications.

Enzootic haematuria: Where cattle have consumed comparatively small quantities of bracken over prolonged periods, neoplastic changes can develop in the transitional cell epithelium of the bladder. Various tumour types may occur including haemangiomas, transitional cell carcinomas, adenocarcinomas and haemangiosarcomas. The resulting clinical picture is termed enzootic haematuria. The condition varies from a mild, persistent haematuria as the only clinical sign to severe cases in which there is pallor of the mucosae, dysuria and tenesmus. The urine in severe cases has visible blood clots in it (see p. 154).

Upper alimentary squamous cell carcinoma (see also p. 828): A third less common clinical syndrome resulting from prolonged exposure to bracken is upper alimentary squamous cell carcinoma, which may accompany changes or tumour formation in the bladder wall. The disease has strong regional incidence, e.g. in western Scotland and Wales, often in suckler cows. Four clinical syndromes are recognized depending on the site of tumour formation. Oropharyngeal tumours produce loss of condition, drooling of saliva, coughing or snoring, halitosis. The nasal discharge may contain ingesta, submandibular lymphadenopathy and diarrhoea. Oesophageal tumours produce diarrhoea, halitosis, coughing, drooling and palpable masses in the oesophagus. Ruminal tympany can result from tumours in the lower oesophagus; there is initially intermittent bloat with loss of condition, then diarrhoea and resistance to the passage of a stomach tube. Tumours in the dorsal rumen produce loss of condition, diarrhoea, distended abdomen and bloat. Oropharyngeal papillomas may often accompany tumours at any site.

Diagnosis

This is based on the clinical signs and an association with bracken feeding or of prolonged exposure to bracken. In acute or subacute cases, bone marrow depression results in thrombocytopenia and leucopenia, prolonged bleeding time and clot formation time.

Necropsy

In acute or subacute cases there are multiple internal haemorrhages of varying size and petechiation. The bone marrow is pale. Tumour changes are evident in the

bladder wall and/or carcinomas may be found in the upper alimentary tract.

Principal differential diagnoses

Acute disease can resemble leptospirosis, kale anaemia, or babesiosis. Enzootic haematuria should be differentiated from babesiosis (p. 748) and postparturient haemoglobinuria (p. 792). The syndromes caused by upper alimentary squamous cell carcinoma can resemble Johne's disease (p. 857), copper deficiency (p. 298) and mucosal disease (p. 853).

Treatment and prevention

In acute cases the clinical outcome is probably more influenced by the degree of bone marrow damage than by treatment. Broad-spectrum antibiotics should be administered to counteract bacteraemia and secondary infections. Blood transfusions can be considered. The use of bone marrow stimulants including DL-batyl alcohol has been described. There is no successful therapeutic management of urinary bladder or alimentary neoplasia. Despite its widespread abundance in certain areas the bracken fern should always be viewed as a potentially toxic plant to cattle. Access to bracken-infested pasture should be always limited, especially if grass growth is poor. In particular, cattle should never be allowed access to recently ploughed land with bracken present and where the rhizomes are exposed, especially if they have started to reshoot. Limited areas of bracken infestation can be fenced off, and burning, ploughing and reseeding or herbicide control are all measures that can reduce the level of bracken contamination.

Yew poisoning

Cattle that gain access to yew trees (genus *Taxus*) are frequently fatally poisoned.

Sources of toxicant

The various species of yew (*Taxus baccata*, English yew; *T. lineata*, Irish yew; *T. cuspidata*, Japanese yew) are common ornamental trees or hedgeing plants particularly of old established gardens. The leaves and woody twigs of the yew contain various toxic alkaloids collectively termed taxines. The taxines are also present in the seeds but not the fleshy red outer part of the fruit.

Circumstances of poisoning

Yew is well known as a toxic plant among the agricultural and rural community, and poisoning is thus usually

the result of neglect, ignorance or (rarely) malice. Cattle will often consume the fresh plant if they are allowed access and will also eat fresh hedge clippings or trimmed branches dumped into their field. The taxines are severe cardiac depressants.

Signs

If moderate amounts of yew have been ingested, sudden death is often the presenting sign. If seen alive, cattle may show dyspnoea, abdominal pain, muscle tremor, weakness and collapse. The pulse later becomes slower before finally disappearing with the heart stopping in diastolic arrest. Recovery is rare and is dependent on ingesting only relatively small amounts of the plant.

Necropsy

Frequently, there are no significant gross findings except the presence of yew leaves and twigs among the ruminal contents or sometimes still in the mouth. The characteristic leaves of the yew when separated by careful washing from the general ruminal contents are thus highly suggestive of poisoning.

Diagnosis

History or circumstantial evidence of access to yew, and presence of leaves and twigs in the rumen contents will usually establish a diagnosis.

Principal differential diagnoses

Yew poisoning should be distinguished from other causes of sudden death, for example lightning strike (p. 930), anthrax (p. 717), blackleg (p. 723), etc.

Treatment and prevention

There is no specific therapy. Symptomatic treatment can be offered to clinically affected animals but the likelihood of recovery or death is principally influenced by the amount of the plant already ingested. Rumenotomy is possible immediately after observing cattle consuming yew. Generally, yew is well known as a toxic plant but the necessity of preventing cattle from gaining access to the plant should be constantly stressed.

Copper poisoning (see p. 300)

Sources of toxicant

The normal problem is an extensive intake of copper, usually from the diet and particularly where there is an

absence of uptake inhibitory factors such as molybdenum, iron or sulphur. The acute form follows a single large dose of copper, but more commonly it is the result of mineral ingestion over a long period of time. The copper is retained and accumulates within the liver. It has also been seen with improper use of copper supplements. Some problems have arisen from industrial contamination, and from copper addition to the pasture. There are some areas in the world with copper-rich soil. While the problem of copper poisoning is common in sheep, it is much less seen in cattle. Problems have increased in North America, Britain and other countries in recent years.

Circumstances of poisoning

Cattle are less susceptible to copper toxicity than sheep and are able to ingest higher levels than the latter without any deleterious effect. Animals with intercurrent liver disease may be more susceptible. Chronic intoxication occurs when there is a build-up of the element within the liver until the maximum level which the organ can contain is exceeded. Then the copper is released into the blood and causes an acute intravascular haemolytic crisis. Problems of copper intoxication were reported to be increasing in the first years of the twenty-first century (Bidewell *et al.*, 2000). In their findings grossly increased copper intakes were not always found. However, points to consider include the duration of feeding a copper supplement and the type of supplement (it is claimed that the copper in many amino acid chelated minerals is many more times available than that in inorganic compounds). Jerseys have been said to be more susceptible, possibly because of genetic susceptibility or perhaps related to a lower bodyweight.

Signs

The problem can be either acute, which is rare, or chronic. The latter is more common but often also appears as a sudden presentation.

Acute: The animal shows pronounced depression with colic, rapid collapse and death. In some cases there is a green diarrhoea when the animal has had access to the excess copper within the diet.

Chronic: The average length of illness before death is one to three days, although individual animals may show signs for up to three weeks. There is an acute haemolytic crisis following a prolonged access to excess copper. The signs again often rapidly develop with anorexia, depression, rumen stasis, cold extremities, haemolytic jaundice, anaemia with pale mucous

membranes, cyanosis of the teats, haemoglobinuria, methaemoglobinaemia and death. Some animals have shown abortion, ataxia, photosensitization and other signs. Recumbency is common before death.

Necropsy

In acute cases there is a severe gastroenteritis with ulceration and erosion. The abomasum is particularly affected. The chronic signs are those of a haemolytic crisis. Jaundice is present but may be variable in degree; there is hepatomegaly. In sheep there is usually dark discolouration of the kidneys, but this is not so common in cattle. Histologically there is a necrotizing hepatopathy and nephropathy.

Diagnosis

The signs and post-mortem picture are helpful. Usually there will be a known source of copper which has been ingested, although this may not always be the case. The liver will contain more than 8000 µmol/kg dry matter (DM) (although often levels are between 10000 and 20000 µmol/kg DM). Plasma copper levels are usually very high (normally over 50 µmol/l). Blood biochemistry usually shows elevated liver enzymes such as aspartate aminotransferase, glutamate dehydrogenase and gamma glutamyl transferase, and this assists in diagnosis.

Principal differential diagnoses

Nitrate poisoning (see p. 950) may need to be eliminated. There are also many causes of haemolytic anaemia including babesiosis (p. 948), kale poisoning (p. 941) and post-parturient haemoglobinuria (p. 792). In most cases the history should be helpful. However, the use of blood copper examination should provide good evidence of the cause if due to copper toxicity.

Treatment and prevention

First remove the animals from the copper source, if known. While treatment is often of limited value, calcium versanate iv at a dose of 70 mg/kg bodyweight (see p. 945 for details) has been used in calves. Oral sodium thiosulphate at a dose of 1 g daily has resulted in some recoveries. Oral ammonium thiomolybdate at 100 to 400 mg daily can also be of use. In sheep, iv injection of ammonium tetrathiomolybdate at a dose of 2.7 mg/kg bodyweight on three to six occasions at intervals of two to three days has been successfully used. While not licensed, it might also be of benefit to cattle.

If cattle are suspected of having a copper deficiency, blood samples should be taken to estimate the copper

levels before any supplementation is given. The normal minimum dietary copper level for adult dairy cattle is 12 mg/kg dietary DM. This level often has to be raised, especially where there are inhibitory factors present such as molybdenum (see p. 298). However, in many countries there are restrictions on the amount of copper supplementation. Thus in Britain the Medicated Feedingstuffs Regulations allow dairy cattle to receive up to 35 mg/kg dietary DM (about 800 mg copper/head per day) without restriction. However, higher supplementation levels can be licensed up to a maximum of 2000 mg/head per day, but with certain restrictions.

Fluoride poisoning (fluorosis)

At normal levels the ingestion of fluorides causes no harm or is even beneficial to cattle. However, at higher levels a chronic (or rarely acute) intoxication results.

Sources of toxicant

Cattle normally gain access to excess fluoride from grazing contaminated pasture. Historically, this commonly arose from industrial effluent, for example from brick manufacture, aluminium smelters, steel works or phosphate production. More recently, other sources of excess fluoride have been recognized including geothermal spring water (when used either as a source of drinking water or for pasture irrigation) and high fluoride-bearing soils. Inorganic rock phosphate is often highly toxic and requires defluorination prior to use as a phosphorus supplement.

Circumstances of poisoning

Rarely will cattle consume sufficient fluoride to result in acute intoxication, but this may result following heavy pasture contamination. More commonly, the grazing of fluoride-contaminated pasture over months or years results in an insidious chronic disease.

Signs

In the acute disease there is anorexia, depression, restlessness, dyspnoea, excessive salivation and muscle tremor leading to convulsions, collapse and death.

Chronic fluorosis: The developing teeth of young cattle are sensitive to excessive fluoride and dental lesions are common in animals exposed before the full adult dentition has developed. The dental abnormalities observed are: increased attrition and liability to fracture, mottling of enamel with white areas, abnormal

pigmentation, and yellow or brown discolouration. Teeth may be poorly developed and mineralized.

Bones are also affected by excessive fluoride intake. Although the bones of young cattle are more susceptible, the bones of cattle of any age can be affected by fluoride-induced changes. These are principally periarticular calcification and the formation of exostoses resulting in an intermittent lameness and stiffness of gait, particularly of the hind legs. Palpable exostoses appear on the metacarpals and metatarsals, ribs and mandible and these are painful on pressure. In severe cases fractures of the third phalanx are not uncommon. Affected cattle are unthrifty and have a dull staring coat.

Necropsy

Dental lesions are found, as described above. Bones have a roughened surface and are chalky white, and new bone formation is evident.

Diagnosis

The history, clinical signs and post-mortem findings, together with circumstantial evidence of access to suspect sources of fluoride, are usually suggestive of fluorosis. Radiographic examination of lower limb bones may demonstrate the presence of exostoses. Chemical analysis of urine, blood and bone for fluorine content may be useful. The levels in bone rise with age and elevated levels are indicative of previous exposure to fluoride. Fluorides are chiefly excreted via the urine and do not accumulate in soft tissues.

Attempts should be made to identify the source of fluoride, and feed, water and pasture analysed for fluoride content. As a guide the diet should contain less than 50 ppm fluorine on a dry matter basis, and drinking water less than 8 mg/l.

Principal differential diagnoses

The dental and bone lesions are fairly characteristic of fluorosis but in their absence other causes of ill thrift including mineral deficiencies, parasitism and the common forms of lameness must be differentiated.

Treatment and prevention

There is no specific antidote and dental lesions are permanent. After removal from the source of excess fluoride the bones of affected cattle will gradually be remodelled, with normal bone deposition ensuing, but severely affected cattle will never completely recover. Mildly affected cattle should be removed from the source and given a good quality balanced diet. Where

ingestion of high or suspect levels of fluoride is unavoidable, aluminium sulphate or calcium carbonate added to the diet may be beneficial in reducing fluoride deposition in teeth and bone.

Nitrate/nitrite poisoning

Under certain circumstances various types of grazing and forage crops may accumulate toxic levels of nitrate within their foliage. In addition, the widespread use of inorganic nitrate fertilizers poses a potential threat of nitrate poisoning in grazing cattle.

Source of toxicant

The *Brassica* plants, green cereals (wheat, barley, rye and maize) as well as the *Sorghum* and Sudan grasses, docks, nightshades and sweet clover may accumulate excess levels of nitrate in their tissues. Nitrate accumulation may occur after excessive use of inorganic nitrate fertilizers or following heavy rain after a period of drought, which leaches accumulated nitrate into the water table. Water run-off from heavily fertilized fields or excess application of nitrogenous fertilizers are the commonest dangers in intensively managed pastures and can lead to problems on grassland pasture or even hay made shortly after exposure of the sward to high nitrate levels. Cattle thus become poisoned by consuming normal amounts of the fresh pasture containing the abnormal nitrate load.

Nitrate ions in the rumen are reduced by the ruminal microflora to nitrite ions, which are subsequently absorbed. The nitrite ion oxidizes the iron in haemoglobin (to its ferric state) producing methaemoglobin, which is unable to bind oxygen. A single intake of nitrate over a short period is more toxic than accumulating the same amount over several days or weeks. A degree of tolerance may also build up in stock receiving sublethal amounts over a prolonged period. High grain diets tend to be somewhat protective against the effects of excess nitrate.

Signs

The condition is usually acute, less commonly subacute. In the acute condition, signs are seen within a few hours of consuming high levels of nitrate. The clinical picture is due to methaemoglobinaemia and the associated anoxia. The visible mucosae become blue and cyanotic, the pulse is weak and rapid, there is drooling of saliva and tachypnoea, exercise is resented and, if forced, may result in severe dyspnoea with mouth breathing. If untreated the condition deteriorates, and there is weakness, ataxia, prostration, coma and death. The

rapidity of onset of the clinical signs is dependent on the dose consumed; death can occur in one hour or up to a day following acute intoxication.

Necropsy

High methaemoglobin levels impart a chocolate-brown discolouration to the blood, which is seen particularly in the fresh cadaver. This brown coloration is evident throughout the mucosae, viscera and possibly in the urine.

Diagnosis

The history may be suggestive if a link of known exposure to nitrates can be established. The clinical picture and particularly the post-mortem findings are also highly suggestive. Methaemoglobin can be detected in blood but is not stable and a fresh sample needs to be analysed within 4 hours. Alternatively, a sample of heparinized blood can be preserved, consulting the diagnostic laboratory for the preferred method. Nitrate levels in all sources of feed and water should be analysed but tolerance to nitrate may be apparent in some circumstances as described above. Levels in feed in excess of 1 per cent nitrate on a dry matter basis are highly suggestive of intoxication.

Principal differential diagnoses

Circulatory collapse or severe respiratory conditions can result in tissue anoxia and acute cyanosis, but in few other circumstances does methaemoglobinaemia with its characteristic chocolate-brown blood result. Intoxication with chlorates will also result in methaemoglobinaemia.

Treatment and prevention

The animal should be immediately removed from the suspected source of nitrate. The specific antidote is methylene blue, which restores the iron in haemoglobin to its ferrous state thus again allowing oxygenation of the blood and so reversing the tissue anoxia. Methylene blue should be given by intravenous injection at up to 4mg/kg body weight in a 2 per cent solution. It can be repeated if necessary. Defining the nitrate source and reducing exposure are the key elements in control. Ensiling will usually reduce the nitrate content of forage as will allowing the pasture to age and set seed, since nitrate is found mostly in stems rather than in grain.

Oak poisoning

Poisoning by the various oaks of the genus *Quercus* can be a serious seasonal problem in grazing cattle.

Sources of toxicant

Cattle may be poisoned at any time when they gain access to quantities of oak leaves or acorns, which contain the toxic tannins. Cattle can consume small quantities of acorns or oak leaves without ill effects.

Circumstances of poisoning

In temperate countries the autumn fall of acorns is the principal source. The acorn crop varies considerably from year to year and hence there is wide variation in prevalence. Storms and windy conditions that cause a heavy sudden drop of acorns are also predisposing factors. Cattle may also be poisoned from browsing on new leaves and buds or oak seedlings.

Signs

Although sudden death may be observed, poisoning is usually seen as a subacute condition. Affected cattle become depressed and anorexic. Early on in the disease constipation occurs, often with marked straining perhaps accompanied by groaning and abdominal pain; small, dry faecal pellets may be observed at this stage. Later on this gives way to a dark coloured or tarry diarrhoea often with blood; straining may be persistent and severe. As the condition progresses polyuria and subcutaneous oedema may be observed. Cattle then become progressively weaker and collapse with death supervening in four to seven days from the onset of clinical signs.

Pathogenesis

The tannins are nephrotoxic and damage the renal tubules but the precise mechanism of their action is unclear. There is a necrosis of the renal tubular cells and the consequent renal dysfunction leads initially to oliguria or anuria, later progressing in the subacute to chronic stages of intoxication to polyuria with the production of a very dilute urine.

Necropsy

Gross signs include those of oedema, particularly hydrothorax, ascites and ventral subcutaneous oedema, oedema fluid may contain blood, and there is often perirenal oedema together with swollen pale kidneys.

The contents of the rumen are frequently doughy in consistency and often contain large numbers of acorns and/or oak leaves, although this is not invariable in the more chronic cases. There may often be colitis, with tarry, bloodstained faecal contents. Histologically, the acute renal lesions include hyaline cast formation and a coagulative necrosis of the tubular epithelium; later mononuclear cell infiltration and fibrosis are observed.

Diagnosis

The history and circumstantial evidence of poisoning together with the clinical signs usually strongly suggest a diagnosis of oak poisoning. This is usually confirmed by finding large amounts of acorns and/or oak leaves in the rumen at post-mortem examination together with the characteristic gross and histological changes. In live animals there will be an elevation of serum urea and creatinine, and glucose and protein will appear in the urine.

Principal differential diagnoses

The main differential diagnoses include clostridial infections (Chapter 44) and other toxicoses.

Treatment and prevention

There is no specific antidote. Cattle may survive poisoning by oak but are frequently left with chronic renal damage, such that they will often perform poorly. The only treatment that is likely substantially to affect the outcome of clinical cases is expensive and specialized involving full-scale renal supportive therapy including measurements and adjustment of plasma electrolytes, oral and parenteral rehydration and the re-establishment of diuresis. Rumenotomy may be indicated. Anticipation of potential outbreaks by the recognition of the seasonal nature of the disease in inspection of pastures (particularly if the meteorological conditions would produce a sudden heavy acorn drop) followed by removing cattle from sources of contact is the key to successful prevention.

Public perceptions of the dairy and beef industries

Most members of the public who are asked about the dairy and beef industries think of cattle grazing in fields and cows living for some time whilst a series of calves are born and milk is produced. Milk products and beef are considered by the public in relation to their effects on human nutrition and health, their effects on the environment and their effects on animal welfare. If production is perceived to be bad in relation to any of these aspects, sales of the products could be severely affected. Bovine spongiform encephalopathy (BSE) resulted in a substantial but sometimes brief decline in beef consumption. Some people may limit their intakes of milk products because of a desire to reduce cholesterol intake whilst certain aspects of the dairy industry, such as methane production, may be criticized in relation to pollution; however, it is animal welfare rather than these topics which is the subject of this paper. Until recently, the welfare of the dairy cow was not often perceived to be poor and it has been only in calf rearing that dairy production systems have been regularly criticized. However, the dairy industry has been changing. Evidence of poor welfare in cows is accumulating and has had influence on public opinion in several countries. It is important to the dairy industry that welfare problems should be addressed before there is any widespread public condemnation of breeding and management practices. Similarly, beef cattle production is not often criticized on welfare grounds. However, a few critical newspaper articles or television programmes

which appear well founded can be very damaging to producers, processors and retailers.

Public concern about animal welfare manifests itself in actual product purchasing and in pressure applied to retailers and to legislators. Major supermarket and cooked food chains can be influenced rapidly by customer pressure and can cause changes to be brought about in the methods used by suppliers. Retailers may impose codes of practice on suppliers and the execution of these codes is checked because the retailers cannot afford public criticism of what they sell (Broom, 1999a). In several European countries, certain housing systems and farm practices have been changed by many farmers because of the standards required by the purchasing companies. For example, the use of crates for calves, stalls and tethers for sows, and castration of pigs slaughtered at 100kg or less has ceased on many farms.

The effect of public pressure on legislation is usually slower, but legislation makes for more equal constraints on producers. Legislation is becoming more and more international although it is clearly important that where there is legislation on wholly moral grounds, for example in order to prevent poor welfare in animals, there should be restrictions on imports from countries whose moral standards are lower and that such restrictions should be authorized by the World Trade Organization.

The concept of animal welfare

Animal welfare has to be defined in such a way that it can be scientifically assessed and the term can be used in legislation and in discussion amongst animal users and the public. Welfare is clearly a characteristic of an individual animal and is concerned with the effects of all aspects of its environment on the individual. The welfare of an animal is its state as regards its attempts to cope with its environment (Broom, 1986). This state includes the feelings of the individual, various physiological and behavioural responses and its health. The extent of the difficulty which the individual has in trying to cope with its environment, the extent of any failure to cope and the degree of happiness are all components

Box 55.1 Indicators of animal welfare (after Broom, 2000).

Physiological indicators of pleasure
 Behavioural indicators of pleasure
 Extent to which strongly preferred behaviours can be shown
 Variety of normal behaviours shown or suppressed
 Extent to which normal physiological processes and anatomical development are possible
 Extent of behavioural aversion shown
 Physiological attempts to cope
 Immunosuppression
 Disease prevalence
 Behavioural attempts to cope
 Behaviour pathology
 Self-narcotization
 Body damage prevalence
 Reduced ability to grow or breed
 Reduced life expectancy

Box 55.2 Possible causes of cattle welfare problems.

III treatment
 Neglect: calculated, accidental or due to lack of knowledge
 Inadequacies in design of housing/furniture
 Inadequate management system or poor husbandry on the farm
 Unnecessary or poorly executed mutilations of the animals
 Poor conditions and procedures:
 during transport
 at market
 at slaughterhouse

of welfare. Hence welfare varies from very poor to very good and can be scientifically assessed (Broom & Johnson, 1993; Broom, 1998a, 1999b).

Indicators of animal welfare are listed in Box 55.1. These include disease prevalence and reduced ability to grow and breed. As explained by Broom and Johnson (1993), the welfare of a diseased individual is poorer than that of an individual which is not diseased, and reduced ability to produce offspring given appropriate opportunities also indicates poor welfare. Individuals which are finding it difficult to cope with their environment, or which are failing to cope, may be more likely to become diseased, less likely to produce embryos, less likely to carry young to term and more likely to die early.

Welfare problem areas

Whilst cattle management has been changing, our knowledge of cattle physiology and behaviour has been improving. It is clear that cattle have complex regulatory processes, elaborate social structure and sophisticated learning ability (Kilgour & Dalton, 1984; Stricklin & Kautz-Scanavay, 1984; Fraser & Broom, 1990). These results have made many animal scientists reconsider the effects of conditions and procedures on farms, both in terms of their efficiency as regards production and with respect to the welfare of the animals.

The general range of welfare problem areas is the same for cattle as for other farm animals (Box 55.2). Ill treatment refers principally to physical abuse of animals. Neglect includes failing to give food and water, or to clean out, or to treat disease or to assist as necessary at calving. Accommodation for animals may, for example, give insufficient space, poor flooring or poor

food access and conditions indoors or outdoors may lead to risk of injury (Schlichting & Smidt, 1987).

Management methods and husbandry include all aspects of feeding, moving of animals, grouping, milking, serving, etc. Mutilations for the benefit of farming practice or of the animal require some special mention, both as regards the methods used and the consequences for the animals. Methods of handling and moving animals are of importance before and after transport, at markets and at lairage as well as on the farm. There are also special problems of transport vehicle construction and usage, market accommodation and procedures, and slaughter methods. Welfare problems that should be taken into account in cattle practice have been reviewed by Broom (1988).

III treatment and neglect

Human actions that can lead to poor cattle welfare include ill treatment, neglect and inadequate production systems. Ill treatment occurs most frequently when animals are being moved around the farm, when they are being loaded into or out of vehicles, or when they are at market or lairage. Those who do ill treat animals can be advised of likely economic effects of their actions as well as being told about the laws on the subject. Neglect includes failure to provide an adequate diet, failure to treat disease and the lack of normal husbandry procedures. The diet may be inadequate in nutrient composition or in quantity. Cattle are sometimes undernourished for a period, whilst food is scarce or expensive, with the expectation that compensatory growth will occur when more food is provided. If the undernourishment amounts to starvation and this is clear from the condition of the animal, then this is serious neglect. Lack of knowledge on the part of the farmer may result in the provision of a poor diet or in failure to treat disease. This is poor husbandry, a very important cause of welfare problems. Advice on good husbandry methods can be an important veterinary service. If animals are diseased and require treatment

there is a moral obligation upon the veterinarian to treat them. In the UK, the veterinary oath, which is sworn on admission to Membership of the Royal College of Veterinary Surgeons, includes the promise that 'my constant endeavour will be to ensure the welfare of animals committed to my care'. In certain circumstances, treatment without any prospect of payment may be necessary. In other circumstances it may be best to call in the State Veterinary Service, the police or the RSPCA, even if to do so might mean losing a client.

Housing and management (see also pp. 40–44, Chapter 56)

General points

Feeding of housed cattle may lead to difficulties for the animals because the acquisition of food in housing conditions is very different from that when grazing. Physical difficulties may occur, as described by Cermak (1987), but social factors are also very important. Cattle synchronize their feeding to a large extent (Benham, 1982; Potter & Broom, 1987), so where group feeding is possible enough feeding places for each animal are required (Metz, 1983; Wierenga, 1983). Those animals that cannot find a feeding place may not get sufficient food and it is likely that there are adverse effects on their welfare. The precise effects of the frustration that occurs when food is inaccessible because of competition

remain to be determined. Competitive feeding situations where there are no individual feeding places pose extra problems for cattle. The subordinate individual has to attempt to obtain food despite the attacks or threats of other individuals. Bouissou (1970) found that the greater the extent of the barrier between feeding places for cows, the fewer the attacks that occurred (Fig. 55.1). A trough that requires subordinate cows to come close to dominant individuals results in those subordinates walking greater distances and taking longer to obtain a meal (Albright, 1969; Fig. 55.2). Calves of low social rank obtain less of the favoured food if trough space is restricted (Broom, 1982). In order to minimize such welfare problems, which are often associated with poor weight gain, farmers should provide feeding spaces for all individuals, preferably with barriers between the individual places. Adaptation to food access from a single source is possible for cattle however, for a transponder-operated feeding stall can be quite successful (Albright, 1981), but some individuals in a herd may have difficulties in learning how to reach the feed in such systems.

Another general problem for housed cattle is having to stand on floors that are wet, slippery, uneven or hazardous because of sharp edges. Slippery slats can lead to difficulties in standing or lying (Andreae & Smidt, 1982; Fig. 55.3). These and other inadequacies of flooring can result in limb injuries, foot lameness, tail-tip necrosis and various diseases. Lameness is the greatest welfare problem of housed dairy cows and factors influencing its occurrence include floor quality

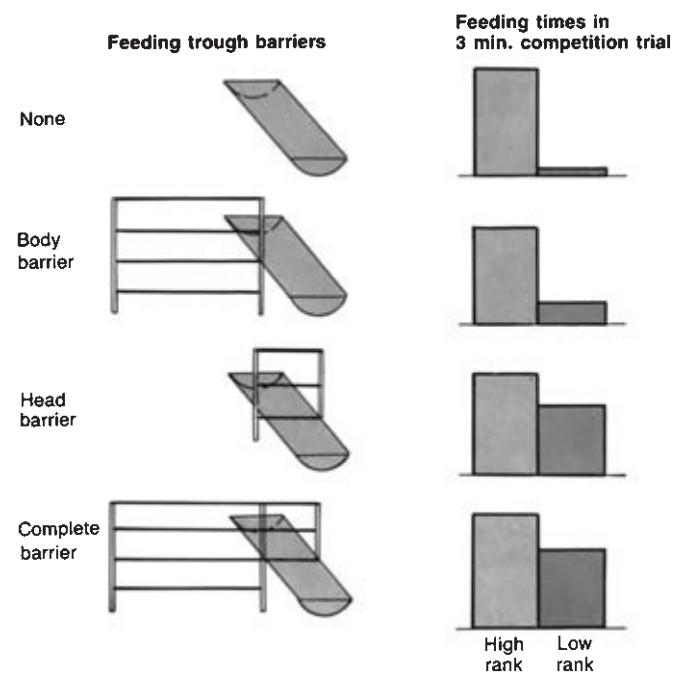

Fig. 55.1 Physical barriers affected feeding times by cows ranking high and low in a competitive order. With no barrier (a) the low ranking cows were scarcely able to feed. A body barrier (b) improved the situation slightly for the low ranking cows but a head barrier (c) and a complete barrier (d) had a much greater effect (redrawn after Craig, 1981; data from Bouissou, 1970).

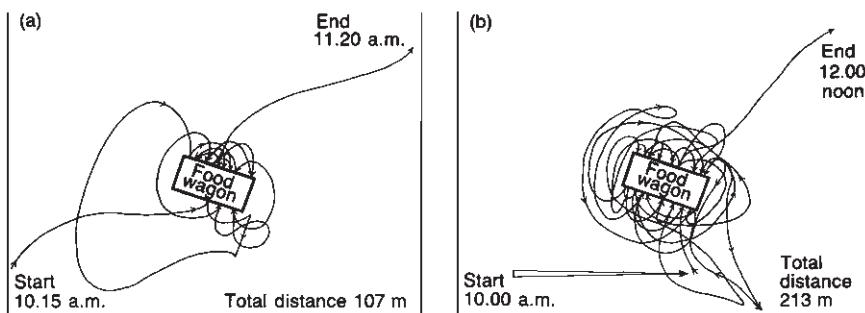

Fig. 55.2 The paths of two cows in a herd after food is provided in a food wagon are shown. Animal (a) was found to be high in a competitive order whereas animal (b), which was low in that order, walked further because of displacement at the food wagon and took longer to feed (after Broom, 1981; modified after Albright, 1969).

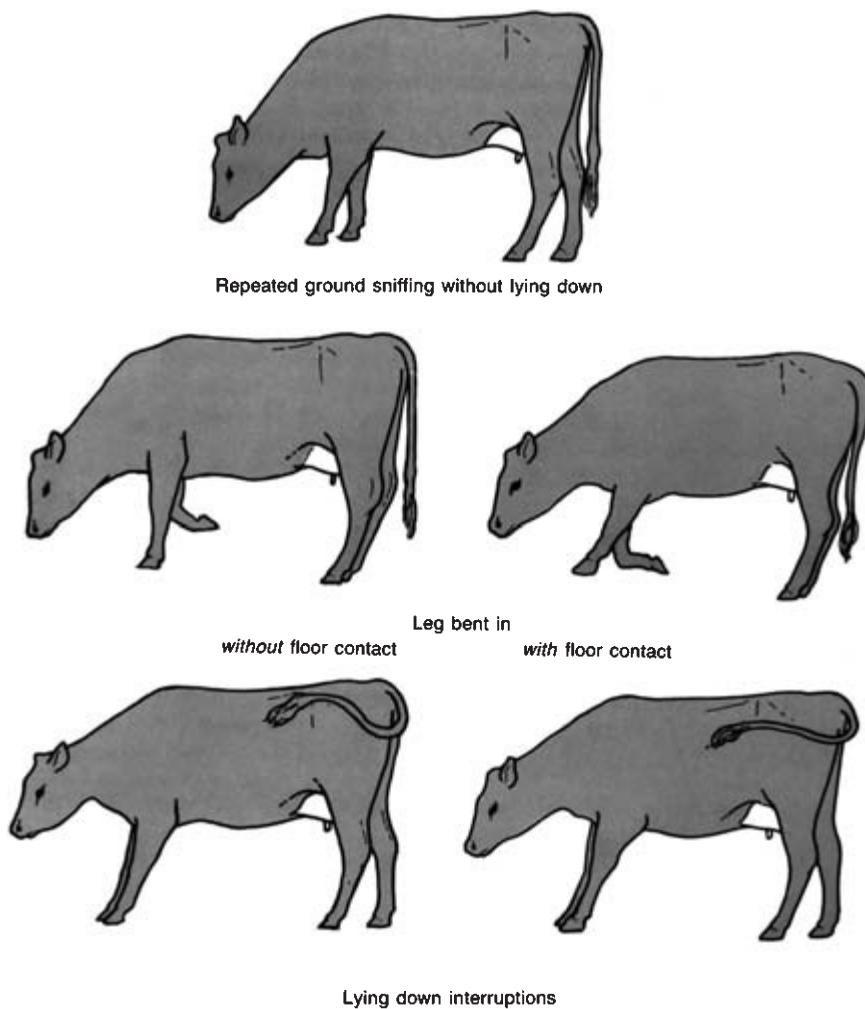

Fig. 55.3 Behavioural alterations in young cattle on a slatted floor (after Andreae & Smidt, 1982).

and poor drainage, which results in cows standing in slurry (Wierenga & Peterse, 1987).

Calf welfare

In the first few days after birth the major calf welfare problems are enteric and respiratory diseases. The calves of dairy cows may fail to obtain sufficient

colostrum for a variety of reasons (Edwards, 1982; Edwards & Broom, 1982; Broom, 1983). Management practices that maximize the chance that colostrum will be obtained and minimize contact with pathogens have important beneficial effects on calf welfare. If calves of dairy cows are normally left with their mother for the first 24 or 48 hours, the risk that the calf will not suckle early enough to obtain and absorb the immunoglobulin

from colostrum can be minimized by the stockworker placing one of the mother's teats in the mouth of the calf as early as possible after the calf stands. Group-calving situations where several cows calve during a short period can lead to a cow's colostrum being drunk by a calf other than her own or to calves being rejected by their own mothers. Such occurrences can be prevented by providing separate calving boxes, which should ideally allow the cows some visual contact with other cows. The provision of soft bedding for the calf is also desirable and is easier where special calving accommodation is available.

Dairy calves are deprived of their mother from an early age and many are individually housed so that they are confined in a small space and deprived of all or most social contacts.

The needs of calves

A need is a requirement, which is a consequence of the biology of the animal, to obtain a particular resource or respond to a particular environmental or bodily stimulus. The needs of calves are described in detail by Broom (1991, 1996) and examples are given here.

The calf needs to ingest colostrum very soon after birth and milk thereafter. It also needs to show sucking behaviour and if a calf is not obtaining milk from a real or artificial teat, it sucks other objects (Broom, 1982, 1991; Metz, 1984; Hammell *et al.*, 1988).

Calves need to rest and sleep in order to recuperate and avoid danger. They need to use several postures which include one in which they rest the head on the legs and another in which the legs are fully stretched out (de Wilt, 1985; Ketelaar-de Lauwere & Smits, 1989, 1991).

Exploration is important as a means of preparing for the avoidance of danger and is a behaviour shown by all calves (Kiley-Worthington & de la Plain, 1983; Fraser & Broom, 1990). Calves need to explore and it may be that higher levels of stereotypies (Dannemann *et al.*, 1985) and fearfulness (Webster & Saville, 1981) in poorly lit buildings are a consequence of inability to explore.

Exercise is needed for normal bone and muscle development and calves choose to walk at intervals if they can, show considerable activity when released from a small pen and have locomotor problems if confined in a small pen for a long period (Warnick *et al.*, 1977; Dellmeier *et al.*, 1985; Trunkfield *et al.*, 1991).

Normal calf anatomical, physiological and behavioural development occurs only if the calves have some fibre-containing material to eat (van Putten & Elshof, 1978; Webster, 1984; Webster *et al.*, 1985a) so it is clear that they need fibre in their diet after the first few weeks of life.

Grooming behaviour is important as a means of minimizing disease and parasitism and calves make considerable efforts to groom themselves thoroughly (Fraser & Broom, 1990). Calves need to be able to groom their whole bodies effectively.

A variety of nutrients are needed by calves. Sufficient iron is needed to allow normal activity and to minimize disease.

The needs of young calves are met most effectively by the presence and actions of their mothers. In the absence of their mothers, calves associate with other calves if possible and they show much social behaviour. The need to show full social interaction with other calves is evident from calf preferences and from the adverse effects on calves of social isolation (Broom & Leaver, 1978; Dantzer *et al.*, 1983; Friend *et al.*, 1985; Lidfors, 1994).

Comparisons of veal calf housing and management systems

The major housing systems which have been compared in studies of calf welfare are individual crates (Fig. 55.4), group housing on slats and group housing on straw. Where calves are housed individually, the size of the crate and whether or not the sides are solid have been varied. All aspects of diet are important in relation to welfare. For example, if inappropriate proteins or carbohydrates are fed, the calf may be unable to utilize them and if milk is acidified too much, calves may

Fig. 55.4 Veal calf in crate with slatted floor. The front of the crate has been removed.

find it very unpalatable. However, the two aspects of diet which have been of greatest concern in relation to calf welfare have been the amount of fibre and the amount of iron.

The incidence of disease in young calves is too high, for example, 25 per cent of veal calves had to be treated for respiratory disease in a study by van der Mei (1987). The use of antibiotics to prevent disease is also a problem. It is important for calf welfare and for farm economics that disease levels be lowered.

One aspect of management which causes problems is the practice of mixing calves from different sources. Webster (1984) found that calves purchased and brought into a unit were five times more likely to require treatment for disease. A second aspect is hygienic practice by farm staff and a third is early detection of disease. These variables seem to be more important than the housing system in exacerbating disease.

As a consequence of the evidence of poor welfare in veal calves, the European Union passed a directive in 1997 which required group housing of calves after 8 weeks of age, individual pens at least as wide as the height of the calf at the withers, no tethering of calves except for <1 h at feeding time, sufficient iron to ensure an average blood haemoglobin of 4.5 mmol/l and fibre in the diet increasing from 50 g/day at 8 weeks to 250 g/day at 20 weeks. Many EU calf producers have found group housing of calves to be more successful economically than the old crate system and white veal can still be produced from systems which comply with the new law.

Beef cattle welfare

The housing conditions for calves destined for beef production are sometimes similar to those kept for veal production so they have similar welfare problems. Older beef animals are kept in small individual pens or are tethered in some countries and they then show much stereotyped behaviour. Riese *et al.* (1977) reported that stereotyped behaviour included tongue rolling, weaving movements and self-licking. Wierenga (1987) reported that one-third of young, individually housed bulls spent several minutes in every hour showing tongue rolling. Physiological responses to confinement also occur. Ladewig (1984) reported that tethered bulls showed more frequent episodes of high blood cortisol levels than did bulls able to interact socially in groups. Such abnormal behaviour and physiology are probably exacerbated by both social deprivation and inability to perform behaviours because of spatial restriction. Tethered animals lack exercise and have different patterns of muscle fibres from those free to walk (Jury *et al.*, 1998) and more osteochondrosis (de

Vries *et al.*, 1986). Individual housing of beef animals is more frequent when they are bulls than when they are steers. In Germany almost all beef animals are bulls, but in the UK most were steers before the ban on growth promoters.

Fighting and mounting can lead to welfare problems when beef animals, especially bulls, are kept in groups. The most important way of minimizing such problems is to keep the animals in stable groups, since social mixing leads to much fighting with consequent injuries, bruising and extreme physiological responses (Kenny & Tarrant, 1982). In stable groups, mounting may lead to more injury than does fighting (Appleby & Wood-Gush, 1986). Animals that are frequently mounted become bruised and may suffer severe leg injuries. Mounting can be greatly reduced by the use of overhead bars, which physically prevent it, or an electrified grid, which deters animals that wish to mount. The brief initial experience of an electric shock has a relatively small adverse effect on welfare as compared with the serious effects on animals that are repeatedly mounted.

The stocking density of beef animals and the flooring provided also have considerable effects on welfare. High stocking densities lead to more aggression, injury and bruising. Beef animals increase rapidly in body-weight, but they have little exercise if they are housed in small pens and their leg growth may not be able to keep pace with that of the rest of the body. The final weights reached are much higher now than they used to be so the legs are scarcely adequate to support the body. The consequence is cartilage damage, clear indications of limb pain and obvious difficulties in standing and lying (Dämmrich, 1987). Graf (1984) found that these problems were absent if fattening bulls were reared on deep straw and that such conditions also led to fewer behavioural problems. Beef cattle have a strong preference for straw or other bedding.

All of these issues are reviewed in the EU Scientific Committee on Animal Health and Animal Welfare Report on the Welfare of Cattle Kept for Beef Production, 2001.

The welfare of dairy cows

The major welfare problems of dairy cows are lameness, mastitis and any conditions which lead to impaired reproduction, inability to show normal behaviour, emergency physiological responses or injury (Broom, 1999c).

Leg and foot problems (see Chapters 31, 32)

For a review of lameness, including the extent to which it is a welfare problem, see Greenough and Weaver (1996). Almost all animals which walk with a limp, or

reduce walking to a low level or avoid walking whenever possible suffer from some leg or foot pain. Their ability to carry out various preferred behaviours is generally impaired and there may be adverse consequences for various other aspects of their normal biological functioning. Lameness always means some degree of poor welfare and sometimes means that welfare is very poor indeed.

Measurements of the extent to which some degree of lameness occurs in dairy cows include 35–56 cases per 100 cows per annum in the USA, 59.5 cases per 100 cows per annum in the UK and more than 83 per cent of examined cows in The Netherlands. The actual figures depend upon the method of assessment and most of these cases were not treated by veterinary surgeons, but there is no doubt that lameness is often a severe welfare problem (Broom, 1999c).

Mastitis (see Chapter 23)

Mastitis in mammals is a very painful condition. The sensitivity to touch of affected tissues is clearly evident and there is obvious damaging of normal function. Mastitis prevalence should have declined greatly with improved methods of prevention and treatment, but it has not declined as much as it should have done. Webster (1993) reports 40 cases of mastitis per 100 cows per year as an average for the UK.

Reproductive problems (see Chapters 34, 35 and 36)

Reproductive problems in dairy cows have become very common in recent years with large numbers of cows being culled because of failure to get in calf. In a study of 50 dairy herds in England, Esslemont and Kossaibati (1997) found that farmers reported failure to conceive as the predominant reason for culling, with 44 per cent of first lactation, 42 per cent of second lactation and 36.5 per cent of cows in total being culled for this reason. However, mastitis, feet and leg problems, ketosis and other disease conditions can lead to reproductive problems and it is difficult to discover their initial cause from farmers' records. A report by Plaizier *et al.* (1998) concerning Canadian herds indicated that reproductive culling risk varied between 0 and 30 per cent, with a mean of 7.5 per cent.

Housing systems and welfare (see pp. 40–44, Chapter 56)

The incidence of lameness is much worse in housed cows than in cows at pasture. Cows at pasture may have stone damage to hooves if they do not have a suitable place to walk, but wet cubicle houses or poorly maintained straw yards can result in very high levels of lameness. Even the best cubicle housing systems seem to

have some lameness problems which are exacerbated by social factors (Bickert *et al.*, 1997). Since the best straw yards, with an abrasive area on which normal hoof wear occurs, have little lameness, these may be the best solution for housed cows. Mastitis incidence is affected by hygiene at milking and various other conditions of management. Poorly designed housing systems can result in a variety of welfare problems and these can be exacerbated by high stocking density. Most of these problems, such as those resulting from cubicles being too short for the length of the cows now occupying them or of poor design of cubicles which do not allow adequate movements in the cow, are well known so are mentioned briefly here. In general it seems that many dairy cow housing systems, and cubicles in particular, do not provide an environment to which cows can adapt easily. The best straw yards seem to be the most successful as they give the cows more opportunity to control their interactions with their environment.

Milk yield and welfare in dairy cows

The dairy cow of 1998 could produce 18000 l or more of milk per annum with a peak milk yield of 75 l per day. This compares with UK figures of 6000 l and 30 l per day 10 years ago (Webster, 1993) and a beef cattle average of 1000–2000 l and 10 l per day. The dairy animal is producing considerably more than its ancestor would have. This raises the questions of whether it is at or beyond its maximum production level and the extent of any welfare problems.

The peak daily energy output of the dairy cow per unit bodyweight is not very high in comparison with some other species such as seals or dogs, but the product of daily energy output and duration of lactation is very high indeed. Hence long term problems are the most likely to occur (Nielsen, 1998). This is what we see because, although some cows seem to be able to produce at high levels without welfare problems, the risk of poor welfare indicated by lameness, mastitis or fertility problems is greater as milk yield increases.

The steady increase in reproductive problems as milk yields have increased is well known. As Studer (1998) states, 'despite programmes developed by veterinarians to improve reproductive herd health, conception rates have in general declined from 55–66% 20 years ago to 45–50% recently (Spalding *et al.*, 1975; Foote, 1978; Ferguson, 1988; Butler & Smith, 1989). During the same periods, milk production has greatly increased.'

Studies showing that milk yield is positively correlated with the extent of fertility problems have come from a range of different countries (van Arendonk *et al.*, 1989; Oltenacu *et al.*, 1991; Nebel & McGilliard, 1993; Hoekstra *et al.*, 1994; Pösö & Mäntysaari, 1996; Pryce *et al.*, 1997, 1998). Studer (1998) explains that high

| | |
|--|-------------|
| Milk yield from 10569 lactation records: | |
| calving interval | 0.28 ± 0.06 |
| days to first service | 0.41 ± 0.06 |
| mastitis | 0.29 ± 0.05 |
| somatic cell count | 0.16 ± 0.04 |
| foot problems | 0.13 ± 0.06 |

producing cows which are thin and whose body condition score declines by 0.5–1.0 during lactation often experience anoestrus. A loss of condition score of about 1.0 during lactation was normal in the review presented by Broster and Broster (1998). Data on the relationships between milk yield and reproduction measures from two large scale studies are presented in Tables 55.1 and 55.2.

In some studies, effects of health problems on reproduction are evident, for example, Peeler *et al.* (1994) showed how cows which were lame in the period before service were less likely to be observed as being in oestrus. The lameness could be more likely in high producing cows. Direct links between level of milk production and extent of disease conditions are also evident from a range of studies, positive correlations being reported by Lyons *et al.* (1991), Uribe *et al.* (1995) and Pryce *et al.* (1997, 1998; see Tables 55.1, 55.2). In addition to mastitis and leg and foot problems, which are often measured in such studies, the occurrence of other clinical conditions can also be affected by production level. Modern, high producing cows with good body condition have a high incidence of milk fever, retained placenta, metritis, fatty liver and ketosis (Studer, 1998).

The high yields of modern dairy cows are a consequence of genetic selection and feeding. Cows are adapted to high fibre, low density diets. The ways in which they have been modified genetically do not change these basic characteristics much. Cows do not adapt easily to high grain diets or to manufactured diets with high protein and low fibre. Genetic selection has not taken adequate account of the adaptability and

welfare of cows. Current trends towards ever greater milk production and feed conversion efficiency should not be continued unless it can be ensured that welfare is good (Broom, 1994; Phillips, 1997). Bovine somatotropin (BST) (see p. 1073) results in high milk yields and higher levels of mastitis, lameness, reproductive disorders and other problems such as those at the injection site (Broom, 1993; Willeberg, 1993; Kronfeld, 1997; Willeberg, 1997; Broom, 1998a). Whether or not much of the effect of the genetically engineered hormone is a consequence of the milk yield, the poorer welfare caused by the BST is unacceptable.

The Report of the EU Scientific Committee on Animal Health and Animal Welfare (1999) on animal welfare aspects of the use of bovine somatotrophin concluded as follows:

'BST is used to increase milk yield, often in already high-producing cows. BST administration causes substantially and very significantly poorer welfare because of increased foot disorders, mastitis, reproductive disorders and other production related diseases. These are problems which would not occur if BST were not used and often results in unnecessary pain, suffering and distress. If milk yields were achieved by other means which resulted in the health disorders and other welfare problems described above, these means would not be acceptable. The injection of BST and its repetition every 14 days also causes localized swellings which are likely to result in discomfort and hence some poor welfare.'

The Committee also made the following recommendation:

'BST use causes a substantial increase in levels of foot problems and mastitis and leads to injection site reactions in dairy cows. These conditions, especially the first two, are painful and debilitating, leading to significantly poorer welfare in the treated animals. Therefore from the point of view of animal welfare, including health, the Scientific Committee on Animal Health and Animal Welfare is of the opinion that BST should not be used in dairy cows.'

Farm operations

Certain mutilations of cattle are performed on farms by staff with no veterinary qualification. In most cases, no anaesthetic is used. The most widespread of these operations are disbudding or dehorning, castration and various sorts of individual marking. Some of the procedures used must also cause pain to the animals, but there is little precise information about this. The use of caustic materials that remain in contact with living tissue for any length of time is likely to cause severe

pain and should be avoided. Any use of hot irons on living tissue must also cause pain and hot iron branding is a painful and unnecessary form of marking. Castration is often carried out by applying a rubber ring around the testicles until the tissue in them dies and it seems likely that this is also very painful for a long period. Even the ubiquitous ear notching and punching must be painful for a few days and it would be better if alternative marking methods such as freeze branding or tattooing could be used.

More extensive mutilations should only be carried out under anaesthetic by qualified veterinarians and should be permitted only if the animal will benefit. Any practices that necessitate the use of operations should be avoided. An example of a problem area is the breeding of cows such that their calf cannot be born normally. No animal should be made pregnant if there is a likelihood that caesarean section or a difficult birth will occur.

Handling, transport and slaughter of cattle

Every dairy farmer has to be able to move dairy cows in milk to and from the milking parlour. If the races and collecting yards that are used or the methods of moving the animals are inadequate and disturbing to some or all of the cows, there will be welfare problems. Such welfare problems will often be associated with reduced milk yield. Cows may be reluctant to enter a milking parlour because of the behaviour of the stockworker or because of design faults in the parlour that result in uncomfortable milking stalls or stray voltages. Such problems can lead to the use of excessive force by stockworkers in the collecting yard or to forcing animals towards the parlour entrance using gates or an 'electric dog'. The 'electric dog', which is a row of electrically live wires hanging downwards and moved towards the cow in the rear of the yard, has a marked

adverse effect on some cows so that their milk let-down may be prevented and they may become extremely unwilling to move towards the parlour.

The problems associated with the design of races for moving cows to the milking parlour are very similar to those of designing races used for other purposes, such as movement towards vehicles prior to transport. The most extensive study of how to design good races is that of Grandin (1983, 2000). She reported that cattle often balk if they encounter dark areas or areas of extreme lighting contrast. Races with sharp angular turns in them may also pose problems for cattle that are being driven and long straight races may result in animals being either reluctant to move or moving too fast. As a consequence of these observations, Grandin recommends that races should be evenly lit, have solid walls if animals unfamiliar with them have to use them and should be gently curved rather than having sharp corners or long straights (Fig. 55.5). Other studies also suggest that if animals are being loaded into vehicles, the ramp should be long and sloping not more than 1 in 7, should allow a good grip for the feet of the cattle and should have solid sides, and the interior of the vehicle should be well lit.

Vehicles are often not well designed as regards flooring, ventilation and ease of subdivision. Just as important as vehicle design, as regards the welfare of animals during transport, is the behaviour of the transport staff. Problems arise because of rough treatment during loading, over- or understocking of compartments on the vehicle, inconsiderate driving or leaving the animals in conditions that are too hot or too cold and windy for them. The other major transport problems are the effect of very long journeys, especially where there are no stops for food and water, and contact between transported animals or their products which results in disease transmission and poor animal welfare. This area has been reviewed in a Commission of the European Communities (CEC) Report (1984) (also see Broom *et al.*, 2002).

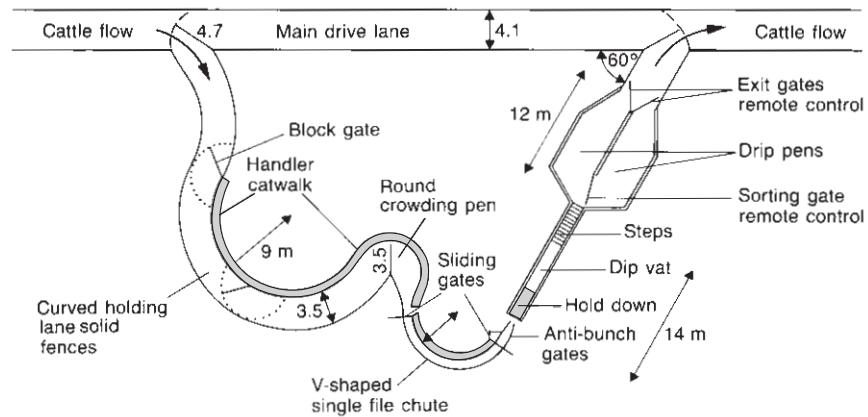

Fig. 55.5 Races for cattle should have no long straights or sharp corners so Grandin (1980) designed this race for movement to vehicles. (Measurements are in metres.)

When cattle arrive at an abattoir they are often injured or bruised during unloading because of too much haste on the part of animal handlers or inadequate ramps. Grandin (1979, 1980) reported that 66 per cent of bruises of the loin area occurred during loading or unloading of trucks. At lairage, animals are often mixed with individuals that are strange to them. This causes much fighting amongst bulls and considerable emotional disturbance in other cattle. Studies of bulls by Kenny and Tarrant (1982) show that mixing at lairage causes much fighting, high levels of bruising and other injury and a great increase in the incidence of dark firm dry (DFD) meat. Both bruising and DFD meat are of economic importance as well as indicating severe welfare problems prior to slaughter.

In an efficient slaughterhouse the period during which animals are moved from pens to the point of slaughter can be very brief and the stunning and slaughter procedure itself can result in no pain for the animal. Welfare is worse if the animals are kept in a confined race for a period of more than one or two minutes before stunning, if stunning is carried out inadequately or if there is inversion before slaughter or no stunning. Poor equipment or lack of care by slaughter staff can result in extreme pain and discomfort for the animals. Extreme pain and discomfort are also inevitable if animals are not stunned, for example in the Jewish shechita or the Muslim halal ritual slaughter procedures. There is a period during which evoked potentials in the brain can still be produced after the throat is cut that may last for from a few seconds to two minutes, during which the animal must be in great pain and distress. As the heart still beats after stunning and blood drains from the animal just as effectively whether or not the animal is stunned there is no logical reason why stunning should not be carried out before the throat is cut.

Introduction

Good health is the birthright of every animal. Considerable progress has been made towards achieving improved health in cattle but the disease pattern has changed radically in recent years. The most acute, specific, diagnosable and preventable or treatable diseases, using vaccines, sera and medicines for their control, have been largely controlled. In their place have emerged more chronic, insidious and complex diseases not infrequently caused by organisms that are the normal inhabitants of the animal body but which circumstances allow to become pathogenic. These disease conditions may be difficult to diagnose, have a large and confusing number of causal agents, create a massive morbidity and economic loss and require for their control great expertise in the exercise of husbandry, hygiene, housing and management skills rather than recourse to the use of medicines or biological products.

This chapter is concerned with those underlying principles of the management, hygiene and housing of cattle that are essential to assist in the prevention and control of disease.

The essentials of good health

The size of livestock farms

From the point of view of animal health, the smaller the livestock unit the better; nevertheless, the current trend, which appears likely to continue, has been towards increasing the size of units to achieve economies of scale – in manpower, buildings and services. However, in dealing with biological material, in this case cattle, there is clear evidence to show that if the farm becomes too large, efficiency generally decreases and health and productivity are adversely affected. Economic surveys have shown that very small farms as a group are generally less efficient but once the three-man unit has been reached, further improvements in performance are small or non-existent (Britton & Berkeley Hill, 1975). This knowledge often goes unheeded and overlarge livestock enterprises are a cause of great health and management problems and enormous economic loss. It is, however, pertinent to emphasize that it is the young immature animal which finds itself at greater risk from disease and mismanagement. Therefore, whilst there should be a limit on unit size at a reasonably low level for the young animal, it may be much higher for the adult. The main reason for this, apart from the extra vulnerability of the young animal to stress caused by bad management, is the varying immunity to infectious disease among the stock that is unavoidable on a large unit with a mixture of animals of different ages and possibly of various sources of origin. The adult presents a more stable picture in both respects, being rather more resistant to management changes or errors and very much more uniform in its disease resistance or susceptibility.

Depopulation

So far as possible the principle of periodic depopulation of a building or, if possible, even a site should be

followed. The benefits of eliminating the animal hosts to disease-causing agents are well understood and the virtue of being able to clean, disinfect and fumigate a building is also accepted. Nevertheless, in practice the whole concept of the 'all-in, all-out' policy is more complex than the preceding sentences would indicate. For example, it is in the young animal that it is particularly important to consider this and far less so in the older beast, which has achieved an immunity to many of the local diseases. Much also depends on whether the herd or flock is a 'closed' one with few or no incoming animals, or an 'open' one with a constant renewal of the animal population. If the latter is the case, then the depopulation principle is of much greater importance as there is little or no opportunity for natural immunity to develop, and there is a constantly running risk, and usually a near certainty, of introducing animals that are either clinically infected or carriers of disease. Basic design specifications for 'open' herds should be quite different from those of the closed herd.

Group size

One of the principal ways of putting the housing on a firm footing is to keep the animals in groups of *minimal* size. At first sight this sounds an old-fashioned and even reactionary concept that may eliminate all those advantages from automation that large units can give us, but this certainly need not be the case. If groups are small it is easier to match the animals in them for size, weight and age. Under these circumstances it is well established that fighting and bullying are kept to a minimum, if not completely prevented.

There is yet another very important advantage in keeping animals in small groups. It is obviously good practice for a farmer to keep his livestock somewhere near the level that has been shown to be the densest possible for optimal productivity yet still satisfying the welfare essentials. If livestock are kept in a house at a high density it is essential that they spread across the house uniformly, so they do in actual practice occupy and use the whole area. Regrettably, this is very rarely the case in practical experience and especially so when large numbers are housed together without any subdivision at all. If the animals crowd in certain parts of the building there may be grossly overstocked floor areas. This is bad enough in itself but it has further unfortunate side-effects. If they crowd excessively in a part of the house, this part may become polluted with dung and exhalations to an abnormal and harmful degree; the humidity becomes high, proper air movement is impeded and the animals may soon become ill. Sick animals feeling cold tend to huddle together even more, so the vicious circle is perpetuated and there is seem-

ingly no end to it unless some measures are taken to ensure a better distribution of the stock.

When animals are kept together in large numbers the effects of a fright caused by an unusual disturbance can be extremely serious. It is almost impossible to guard against all the extraneous sounds and sights that may adversely affect the stock. The best safeguard, therefore, is once again to have the animals in small groups so that the effect of a panic movement will be more limited and will never build up into highly dangerous proportions.

Isolation facilities

There is a critical need for farmers to give better consideration to the isolation of sick and incoming animals. There are numerous reasons why this should be done. First and foremost, isolation removes some of the dangers of contagion to the normal animals; it also makes it much more likely that the sick animal will recover without the unwelcome attentions of the other animals who will always tend to act as bullies. In nature, the sick animal usually separates itself from the rest of the herd, but it is often impossible for the housed animal to do this. Also, under the more intensive systems of management, more animals are likely to suffer from the aggression of their pen-mates and it is essential that such animals are removed to prevent them from suffering or being killed. It is also easier, with an isolated animal, to give it such therapy as it needs and to give it any special environmental conditions, such as extra warmth or adjustments to comfort requirements. For new entrants to the farm it will also enable such tests to be carried out to ensure the animals are free from infection before they can be safely introduced into the herd.

Many modern livestock units completely ignore the provision of facilities to isolate animals and much greater attention should be given to this need. It is also an essential part of helping the attendant to do a satisfying job.

Housing types and systems

(see pp. 40–44)

There are three essentially contrasting types of housing: 'climatic', giving only a cover and protection to the animals; 'controlled environment', which regulates the microclimate as completely as is required for the particular stock being housed; and the 'kennel', which is in a sense a half-way house between the other two forms and gives two environments in the one building allowing some free and appropriate choice for the animals. The methods of use of each of the types and their suitability

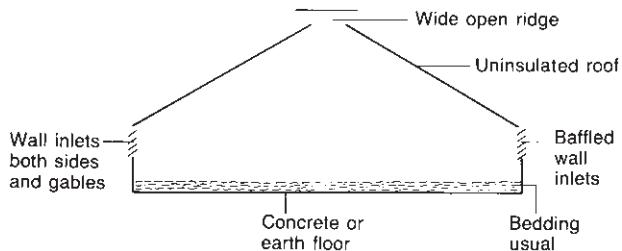

Fig. 56.1 Cross-section of 'climatic' livestock house with open ridge and baffled wall ventilators.

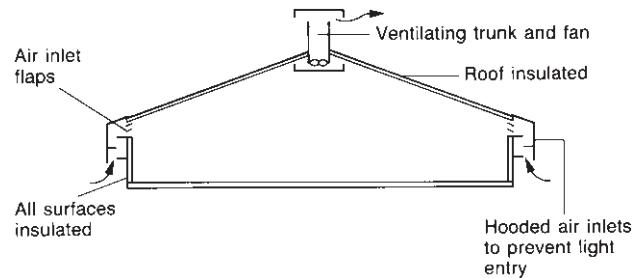

Fig. 56.3 Cross-section of a typical conventionally ventilated controlled environment house with roof fan extraction and hooded wall inlets.

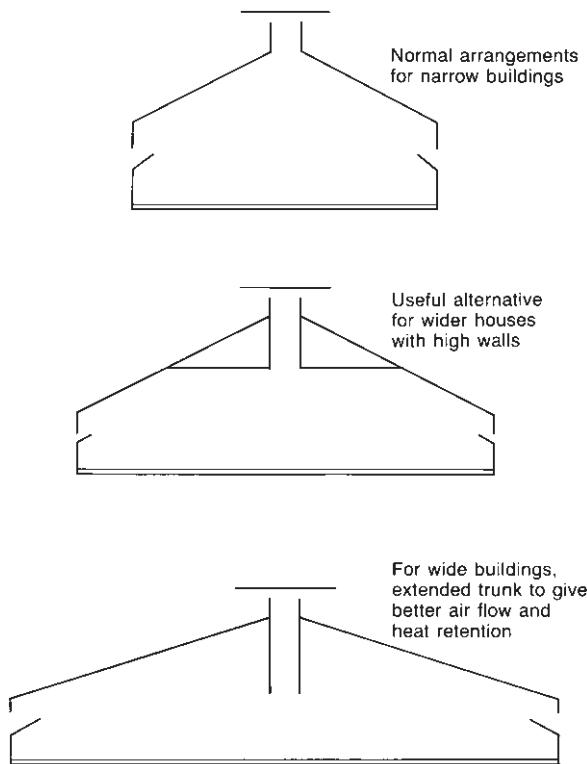

Fig. 56.2 Alternative arrangements suitable for natural ventilation of various widths of buildings and using outlet ('chimney') trunks.

for different countries, climatic regions and forms of livestock vary enormously and must be carefully defined.

Climatic housing (Figs 56.1 and 56.2)

The climatic house is ideal for the adult beast that has developed a large measure of adaptability to climatic stress. The house can be cheap because it is basically a cover alone but because of the lack of control of the climate the space given to the animals must be much greater, especially since there usually is no powered ventilation.

In general, stocking densities tend to be half or less those in the controlled environment house. A major problem is created by agriculturists when they attempt to apply the high stocking rates that are suitable for the controlled environment house to the climatic house, as the building is unable to cope with the demands of the stock and poor productivity and high disease incidence can result. Climatic housing is usually the correct choice for cattle over about six months of age. Such housing usually requires deep bedding for its success, particularly in cooler climatic areas.

Controlled environment house (Fig. 56.3)

The controlled environment house is in great contrast. It has a limited use for cattle, being sometimes used for young calves and to a lesser extent for cattle kept on any bare surfaces, solid or slotted, without bedding. It is most economically viable with livestock that are fed largely concentrate food rather than substantial quantities of roughage, since the former is too expensive to be utilized as a form of energy. The housing is expensive and because of the cost it is usually necessary to stock the buildings as densely as possible to make them viable economically, and this can place a great strain on health control. To cope with the special requirements, management needs to be of the highest standards and unless these criteria can be observed it is the wrong type of housing to have. The rewards can be great but the dangers are greater.

'Kennel' accommodation (Fig. 56.4)

This is an increasingly popular system of accommodation that is in a sense half-way between the climatic and controlled environment housing. It attempts to combine the virtues of both, but at low cost, and often succeeds. The essence of the system is that the animals are kept in pens or groups that are sufficiently small to allow them to be closely confined, at least while resting,

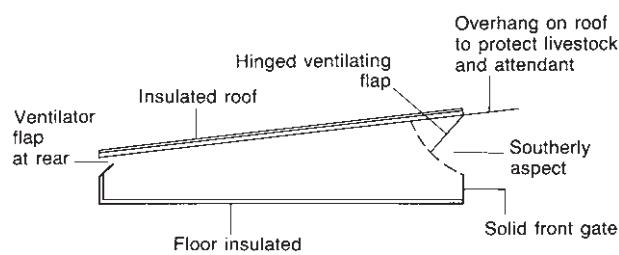

Fig. 56.4 Cross-section of a mono-pitch ('kennel') naturally ventilated stock building.

without too great a danger from respiratory or other disease. The close confinement makes it possible to keep the groups warm and draught-free by utilizing their own body heat and by good insulation of the kennel and a limited cubic air space. This part of the accommodation is a simple form of controlled environment house: the rest is the climatic house and can be justified as this is an area where the animals will be moving about freely and will not normally be inactive or lying down. It is likely to contain the dung and often the feeding and watering arrangements and so must be very adequately ventilated, usually by non-mechanical means. In harsh climatic areas it is covered; in milder regions there is no need for this and the 'yard' can, with benefit to health and productivity, be left uncovered.

It is instructive to examine the logic of the 'kennel' system.

- The cost of the housing can be as low as any system, especially with uncovered yarding, and such buildings are also the easiest type of building for the farmer himself to erect.
- Good health is promoted by separation of the animals into small groups. The separation of the kennels one from another should be as absolute as possible as this will limit the build-up and spread of respiratory disease. It will also be a great assistance to the health of the animals if the muck is not allowed to accumulate in the warmth or the closely confined resting area. It is often possible as well, by good design, to keep the dunging areas separate so that the muck from different pens does not come together until after it is out of reach of the animals.
- The cheapness of the housing is largely due to the fact that the environment is controlled only where it is absolutely necessary.

It is certainly a distinct virtue if the dung can be in an area where the air is moving more freely and the temperature and the humidity possibly much lower, at least in temperate climates. Feeding in an outside yard achieves this objective. Controlled environment housing is becoming more and more expensive and

Table 56.1 A guide to the minimal space allowance for cattle at different stages of growth in strawed yards.

| Age | Area/animal (m ²) |
|---------------------|-------------------------------|
| Up to 14 days | 0.9–1.4 |
| 14 days to 3 months | 1.4–1.8 |
| 3–6 months | 1.8–2.4 |
| 6–9 months | 2.4–2.7 |
| 9–18 months | 2.7–3.8 |
| Adults | |
| small | 5 |
| large | 7 |

there is no possible justification for this control to embrace the effluent from the animals, which is not only a considerable expense but is also likely to intensify the disease risk.

Whatever the system, the principal practical faults in livestock housing systems are as follows:

- Having too close a confinement of the animals.
- Placing too many animals in one common air space.
- Reducing both cubic area and floor space.
- Failing to remove muck from close proximity to the animals.
- Transferring muck through pens, aiding the transfer of disease.
- Failing to separate age groups.
- Neglecting clean feeding and water arrangements.
- Having poor or sometimes no drainage.
- Neglecting the comfort of the stock.
- Inefficient ventilation systems.

Table 56.1 shows the space allowances for cattle in strawed yards.

The environmental requirements of cattle

In most cool, temperate environments, ruminants maintain a stable body temperature by regulating evaporative loss, at little metabolic cost. Ruminants have a very marked ability to alter their zone of thermal neutrality in response to previous thermal history. Thus there are no absolute criteria for the thermal requirements of any class of ruminant livestock, except perhaps the newborn animal; they depend to a large extent on what the animal has grown accustomed to.

Some examples of the lower critical temperatures for cattle under conditions of varying air movements are shown in Table 56.2. This table illustrates a situation where the beasts are standing up, in a dry enclosure, under two variations in air movement (Webster, 1981).

Table 56.2 Lower critical temperature of ruminants housed in a building with very low air movement (0.2 m/s) and in a draught (2 m/s). Source: Webster (1981).

| Type of animal | Liveweight (kg) | Lower critical temperature (°C) | |
|-------------------------------|--------------------|------------------------------------|---------|
| | | Low air speed | Draught |
| Calf | | | |
| Newborn | 35 | +9 | +17 |
| 1 month old | 50 | 0 | +9 |
| Veal | 100 | -14 | -1 |
| Store cattle (maintenance) | 250 | -32 | -20 |
| Beef cow (maintenance) | 450 | -17 | -9 |
| Dairy cow | 500 | -26 | -13 |

In an unheated building at low air movement the only cattle likely to experience cold sufficient to elevate the heat production are newborn calves or young calves whose metabolic rate is low by virtue of starvation, sickness or emaciation. Such animals can undoubtedly be stressed by cold and may require special attention. Increasing air movement to 2.0 m/s, which is not uncommon in draughty buildings, increases the critical temperature in the newborn calf from +9 to +17°C. This emphasizes the necessity of ensuring that adequate ventilation for calf houses is achieved without allowing excess air movement (or 'draught') to impinge on the calves.

By one month of age the healthy calf with a good appetite and access to an adequate feed source has a critical temperature close to 0°C and is not likely to be stressed by cold while indoors. Well-grown veal calves, by virtue of their very high energy intake and heat production, are particularly tolerant to cold and by the same criteria sensitive to heat. The traditional belief that veal calves should be kept in a warm environment because they are not ruminants and are therefore somehow more sensitive to cold is unscientific and untrue.

No other class of cattle is likely to experience a systemic stress of cold when standing up in a dry enclosure unless air movement is exceptionally high. However, problems do arise in damp conditions. For the dairy cow, however, cold stress should not be considered as a systemic but as a local problem. Heat production in the high-yielding cow is again very high and so the critical temperature is low. Milk synthesis, however, depends on blood flow to the mammary gland, which is reduced by local cooling. The production of dairy cows has been shown to fall at temperatures below about 0°C, although it is obvious that direct chilling of the udder

depends as much on the thermal properties of the floor as on the temperature.

It is worth stressing that European cattle tend to be tolerant to cold but intolerant to heat. Their 'comfort zone' is between about 0 and 20°C. The critical temperature leading to a decline in milk yield at the higher level is approximately 21–25°C for most European cattle, including Friesians and Jerseys, but as high as 30–32°C with Brown Swiss (see Chapter 8).

The effect of high temperatures may be ameliorated in practice in a number of ways. The provision of shade makes a great difference, also of wallows and artificial showers. For example, great benefit has been found in tropical climates with cattle kept under a so-called desert-cooler consisting of a three-sided shelter open to the north, with an upper roof of aluminium, which reflects the heat rays, a ceiling underneath of three layers of old hay and an evaporative cooler under the roof at the south end of the shelter. There are a number of highly effective methods of reducing heat stress by the use of water atomizers. In some cases atomizing units are suspended under the roof of the buildings whilst more sophisticated arrangements utilize a series of mist propagators above the stock connected by a pipe-line carrying the water. Provided the humidity of the ambient air is not too high, significant cooling effects can be achieved at a modest running cost (see Chapter 8). True refrigeration plants are very occasionally used but are rarely economic. At high temperatures farm stock also attempt to reduce their heat production by reduced feed intake. This leads to less production and often also to metabolic and fertility problems. Under hot sunny conditions the temperate breeds, particularly, spend less time in grazing and, in fact, under these conditions most of the grazing will be done at night. There are very marked breed differences, as might be expected, the tropical breeds being least affected.

In loose housing systems with open fronted barns, protection from solar radiation and maximum provision of air movement represents the limit of environmental improvement. With closed buildings, such as the cow-house, mechanical air cooling may be used and, in parts of the world where climatic temperatures warrant it, has been found worthwhile. For a comprehensive consideration of the effects of the environment on cattle the reader is referred to Clark (1981).

Environmental factors affecting susceptibility to disease

Many of the organisms that cause ill-health in intensive livestock units are normally present in the animals and their surroundings and it is environmental stress that

acts as a trigger, inducing their multiplication to such an extent that clinically obvious disease breaks out. There are numerous examples, such as respiratory diseases, diarrhoea and mastitis. Whilst these diseases may always become clinically obvious in the long term, there may be a lengthy period beforehand when their effects are limited to poor growth or productivity and an inefficient conversion of feed by the animal. It is an essential feature of a farmer's recording system that records of productivity are kept which should allow the detection of results that are beginning to deteriorate, and this can well be a warning that urgent action is needed to stop a slide in results leading eventually to disease. Most of the conditions of this nature are insidious, chronic and difficult to diagnose by any of the popular methods that are so effective with the well-described diseases. Very limited use can be made of vaccinations or antisera, nor are antibiotics or drugs more than a short-term answer. The only effective way is to attend to the whole environment of the animal by such methods that are known to reduce the risk of disease.

It is extremely difficult to reproduce clinical disease by experimental infections even when huge doses of mixed organisms are used. Whether or not an animal becomes clinically affected depends on non-specific factors of climate, housing and husbandry, which together form the total environment that is considered in this chapter. Above all it should be made clear that the state of health of the animals can transcend all other factors in determining the economic viability of a livestock enterprise. Disease at its worst kills the animal, but even in sublethal infections seriously affects productivity.

The factors influencing the dispersal, survival and deposition of airborne pathogens in farm animals have been reviewed comprehensively by Donaldson (1978). Droplet nuclei are the primary mode of spread of a variety of contagious diseases and many pathogens have been shown to have been spread in this way via the animals' breath and also from secretions and excretions of the infected animals (see p. 242).

Referring specifically to virus particles, the ambient temperature has little effect on their survival in an animal house but a general trend is that high temperatures are more harmful to their survival than low ones (Sanger, 1969). In fact it has been suggested that the inactivation of viruses immediately after exhalation and aerosol formation is dependent on the relative humidity and any temperature effect occurs secondarily (Donaldson & Ferris, 1976). The effect of relative humidity on viruses in general is that viruses with a lipoprotein envelope survive best at a low relative humidity, whereas non-enveloped viruses are unstable in dry conditions but survive best at a high relative

humidity. Rhinoviruses appear to survive better at high humidities but infectious bovine rhinotracheitis (IBR) and parainfluenza 3 (PI₃) viruses at low humidities. In these last examples the differences in survival time reflect the association between seasonal patterns of relative humidity and disease incidence. There is the further possibility that at high relative humidity there is accelerated sedimentation of airborne pathogens in large aerosols. *Mycoplasma*, on the other hand, tends to be stable at very low and at high relative humidities but sensitive to mid range relative humidity.

So far as bacteria are concerned, a rise in temperature produces an increasing destruction of bacteria but airborne spores are highly resistant. *Escherichia coli* survives and multiplies best at about 15°C, as also does *Mycoplasma*. Bacteria tend to be resistant to low and high relative humidity but sensitive to mid range relative humidity; bacterial spores, however, are resistant almost totally to relative humidity effects.

It is important to be aware that in airborne infections the size of the infecting dose will determine whether or not disease will result. Also, its severity and the likelihood of infection making headway will depend on the animal's overall resistance; for example, chilling can markedly lower an animal's resistance to inhaled pathogens by depressing lung clearance mechanisms (Whittlestone, 1976).

Systems in which the air is recirculated are being favoured as a means of reducing heating costs, but in such systems some form of air cleansing, e.g. filtration, may be necessary to avoid a build-up of pathogens.

It is known from the work of Honey and McQuitty (1976) that animal buildings are often very dusty, but the factors affecting dust production are ill defined. Small changes in relative humidity have been found to have significant effects on settled dust; lower humidities result in more settled dust. There is, however, mounting concern about the deleterious effect of dust on livestock health, and good systems of ventilation should be able to remove it from the building in the same way and as efficiently as other environmental pollutants.

The disposal of large accumulations of animal excrement, bedding and litter is a further problem and can, in some instances, be the limiting factor in determining the size of unit. It is common practice to dilute the effluent from farm buildings into a slurry and then spray it over farmland as a fertilizer. The hazard from the dissemination of slurry-associated pathogens over a wide area in this way can be considerable, particularly in windy weather (Wray, 1975). A dairy herd of 50 cows causes a potential pollution load as large as that of a village of over 500 people, yet frequently the manure is carelessly disposed of without thought of its potential dangers to man or animal.

Intensification and immunity

There are some underlying truths in connection with disease and immunity that need to be explained as they have a close bearing on the incidence of disease and its relationship to the environment.

An animal at birth has a degree of passive immunity to local disease that is passed from the dam to the offspring, partly *in utero* and partly from the colostrum or first milk. Such immunity is, however, only practically effective to local infections to which the dam has been challenged. If the birth takes place in a 'foreign' environment, then the young may have little or no passive immunity to the infective organisms in their new local environment. In many cases the young are housed during the early stages of life in such a 'foreign' environment and it is therefore most important that the challenge of disease-causing organism is reduced to a minimum.

Perhaps the first and foremost methods for reducing this challenge are by the processes of depopulation, cleansing and disinfection. This can obviously be understood to be most important in the case of the younger animal, which has a poor or uncertain resistance to disease. Whilst it can never be said to be other than advantageous, it is most important on sites that have a large population of animals in an area where there are substantial numbers of animals since many diseases, especially viral ones, can pass a great distance by the airborne route. Whilst small infective particles can be carried directly by dust particles moved by the wind, other pathogens are carried indirectly by vectors, especially birds.

Disinfection

The disinfection of a building implies the elimination from the house of all micro-organisms that are capable of causing disease, thus converting the place from a potentially infective state into one that is largely free from infection. A disinfectant is the agent that is capable of achieving this and in livestock farming it is usually a chemical agent.

The processes of disinfection of a building can take place by the action of nature (natural disinfection) and by artificial means (artificial disinfection). Before discussing these processes in some detail, it should be emphasized at the outset that 'cleansing' is an essential preliminary to disinfection. Organic matter has the ability considerably to reduce the effectiveness of disinfectants, so without good cleansing the action of disinfectants is often readily diluted.

Natural disinfectant agents

Most pathogenic micro-organisms do not survive long outside the animal body, but unfortunately sufficient may always remain to cause renewed infection. Some vegetative bacteria and viruses can live several months if protected with organic matter and the spores of bacteria can live almost indefinitely in the soil or protected in cracks and crevices of the building. For example, *Clostridium tetani* and *Bacillus anthracis* can live for many years. Even coccidian oocysts may survive for years in infected quarters.

The factors contributing towards natural destruction of microbes are nevertheless important as they do reduce the numbers and this in itself is a worthwhile aid to the artificial processes. Sunlight, heat, cold, desiccation and agitation all contribute. Sunlight is the most potent and its powers of destruction are enormous; its efficiency is entirely due to the ultraviolet range of wavelengths. Unfortunately, these ultraviolet rays have little penetrating power and cannot pass through glass or translucent roofing sheets or through clouds of industrial haze; the value of sunlight in animal buildings is therefore wholly unreliable. Desiccation, from fresh air and wind, will also contribute to the destruction, particularly when the micro-organisms are exposed to this by prior cleansing of the building.

Another process is antibiosis; many bacteria and fungi produce substances that are antagonistic to other organisms. Penicillin and streptomycin are agents of this nature whose antibacterial action is well known. In the soil, in floors and buildings generally, pathogenic organisms will be acted upon by antibiotics produced by non-pathogenic organisms that are normal inhabitants of the soil. Warm moist conditions will assist the action of such saprophytic agents.

The action of heat

For many years heat has been used for disinfection, dry heat being used with the 'flame-gun' and moist heat in the form of the 'steam-jenny', but both tend to be inexact and uncontrolled methods of applying the agents.

Many bacterial spores can easily survive the transitory attention of the heat source and pathogenic organisms may readily be protected from the heat in cracks and crevices of the building.

Chemical disinfectants

Disinfection on the farm is generally carried out by using chemical agents. The lethal action of disinfectants is due in the main to their ability to react with the

protein and, in particular, the essential enzymes of micro-organisms. Therefore, any agents that will coagulate, precipitate or otherwise denature proteins will act as general disinfectants. Among these agents are phenols, alcohols, acids, alkalis, aldehydes, halogens, chloramines and quaternary ammonium compounds, as well as heat and certain radiations.

Selective action

Many disinfectants have a selective action on different types of microbes. For example, Gram-positive and Gram-negative bacteria differ in the structure of their membranes, the latter being of a more complex nature. Micro-organisms also respond to changes in pH and as every protein has its own characteristic isoelectric point, each responds individually and will be influenced by the acidity or alkalinity of the disinfectant; for example, fungi are extremely acid-resistant, whereas viruses tend to be more susceptible to acid disinfectants, such as the iodophors. Another factor affecting the behaviour of a disinfectant is the lipid content of the cells; in some the content is high, as in acid-fast organisms, and it will thus attract a lipophilic moiety in a disinfectant substance and dissolve it more readily, thereby increasing the germicidal activity. Some disinfectants, which are called broad spectrum, are almost equally active against most species of micro-organisms, while others show specificity and are only active against a restricted number of species.

Disinfection of viruses

For disinfection purposes viruses can be classified into two groups, lipophilic and hydrophilic. Lipophilic viruses have lipid envelopes, which make them sensitive to the majority of disinfectants. Most of the animal pathogenic viruses are in this group. Hydrophilic viruses are enveloped and are less sensitive to disinfectants in general. Some very important viruses are in this group and these have a tendency to become dangerously persistent on farms and in animal buildings; examples are the enteroviruses and reoviruses. Against this latter group quaternary ammonium compounds have a poor effect, but are very good if associated with formaldehyde, gluteraldehyde, chloramines and certain organic acids.

Disinfection of prions

The various infective prions, such as those causing bovine spongiform encephalopathy or scrapie, have a number of common characteristics. They are extremely resistant to heat and, whilst some loss of infectivity occurs at temperatures above 100°C, temperatures

greater than 120°C over long periods are needed to inactivate the finely divided material. Resistance to common sterilants and other chemical agents is very high, as is resistance to extremes of pH and to ultraviolet or ionizing irradiation. The only chemical treatment so far found to be effective against all transmissible spongiform encephalopathies is sodium hypochlorite at 20000 parts per million of available chlorine, for about one hour (see p. 909).

Dynamics of disinfection

Disinfection is not an instantaneous process; it takes place gradually. However, many more microbes are killed at the beginning of disinfection than at the end, although there is an initial lag period before activity commences. The lag phase is normally only a few seconds, but may be seriously prolonged if the environment is unfavourable, for example extreme cold, high humidity or excessive organic matter. An examination of the number of organisms surviving at different stages during disinfection shows that the number of bacteria killed in unit time bears a constant relationship to the number of surviving organisms. Thus, after the lag phase, destruction of the bacteria is very rapid at first but tends to slow up so that eventually destruction of all the organisms takes a considerably longer time. The usual time–survivor curve is of the sigmoid type.

The concentration of disinfectant and temperature of disinfection influence the rate of death and also alter the shape of the time–survivor curves. As the death rate is increased by using higher concentrations of disinfectant, the initial lag phase is eliminated or, in fact, is so quick that it goes undetected. The action of most disinfectants is increased, often quite markedly as the temperature rises.

The effect of organic matter

Almost invariably when disinfection is carried out on the farm, organic matter will be present. It can be said that organic matter always interferes with the action of the disinfectant and may do so in the following ways:

- (1) The organic matter may protect the cell by forming a coating on it and preventing the ready access of the disinfectant.
- (2) The disinfectant may form an insoluble compound with the organic matter to remove it from potential activity.
- (3) The disinfectant may react chemically with the organic matter giving rise to a non-germicidal reaction product.
- (4) Particulate and colloidal matter in suspension may absorb the antibacterial agent, so that it is substantially removed from solution.

- (5) Fats, etc. in serum and milk may deactivate the disinfectant.

Approval of disinfectants

There is no completely satisfactory method of assessing or standardizing disinfectants and an enormous number of different techniques have been used in the past. There is also no universally effective disinfectant, so that different disinfectants are required for different purposes.

In the UK, approvals for disinfectants are under five headings, as follows:

Group 1A are active against foot-and-mouth disease;
 Group 1B are active against swine vesicular disease;
 Group II are active against fowl pest;
 Group III are active against tuberculosis;
 Group IV are for general farm use, the test organism being *Salmonella cholerae suis*.

The official test lays down a rigid procedure for specified reduction of the organisms in the presence of organic matter. The most recent lists of approved disinfectants list over 300 of them for livestock use.

Disinfectants

Phenols, cresols and related compounds

The phenols, cresols and related compounds are an important group of disinfectants that were once the most popular of all such agents.

All phenols can act bactericidally or fungicidally but generally are neither sporicidal nor particularly virucidal. They have high dilution coefficients, i.e. small concentration changes give rise to large differences in their killing rates. They are always more active as acid solutions. Organic matters can severely interfere with their efficiency and even small quantities of faeces can reduce their effectiveness to 10 per cent. There are many proprietary 'coal tar disinfectants', phenolic in nature, and in view of their inevitable low solubility in water they are either solubilized or emulsified. The solubilized types, known as 'black fluids', are those in which the phenol fraction is dissolved in a soap base and the emulsified types, known as 'white fluids', are those in which the phenol is emulsified into a permanent suspension with the aid of gelatin or dextrin.

In more recent years a number of synthetic phenols have been marketed. These may be a chloroxylenol, *o*-phenylphenol or one of the other diphenyl derivatives. Such preparations, in contrast to the cresols or coal tar disinfectants, are non-toxic, non-irritant and have a more pleasant odour, arising chiefly from their purer contents.

Formaldehyde and glutaraldehyde

Formaldehyde is a widely used disinfectant in both the gaseous and the aqueous forms, being bactericidal, virucidal and fungicidal. In aqueous solutions, formalin, which is a solution of formaldehyde gas containing 40g of formaldehyde in 100ml of the solution, is widely used at 5 per cent strength as a general disinfectant, but it does need to be in contact with the surface for some time to be effective. Its action is greatly affected by temperature (i.e. it has a high temperature coefficient) and the warmer it is the better, blood heat being most satisfactory. It also acts more efficiently when the surface is wet. In agricultural use formalin is largely used as a gas or an aerosol spray.

A very active complex disinfectant, which is useful against the most persistent viruses, is one containing formaldehyde, glutaraldehyde and a quarternary ammonium compound. This is active at much lower temperatures than formaldehyde.

Quarternary ammonium compounds

These are cationic neutral detergents available as aqueous solutions, powders or pastes. They are effective against a wide range of bacteria and moulds and have a high surface activity. Generally, when dissolved in water, they have a high wetting power and the ions adhere to the surfaces, giving a long-lasting residual effect. They also have low toxicity and lack odour or taste. Combined with other disinfectants they can give a wide spectrum of activity.

Oxidizing disinfectants

Hydrogen peroxide and other oxidizing agents including peracetic acid and propionic acid are emerging as increasingly popular disinfectants. At quite low concentrations they are active against bacteria, their spores, viruses and fungi. Several new proprietary forms are marketed for use in livestock buildings.

The halogens

In agriculture, chlorine is widely used for disinfecting water and in the cleansing of dairy and other farm equipment. Chlorine-releasing compounds containing up to 90 per cent available chlorine are available and have an important use in the formulation of bactericidal detergent powders of the alkaline variety. Products of this type are suitable for use in the washing down of an animal house. The inorganic chloramines, being a concentration of chlorine and ammonia, are used in water and sewage treatment; organic chloramines, such as halazone, are excellent water sanitizers.

The normal use of chlorine in cleaning milking and other utensils is to use a detergent wash with a solution containing 250–300 ppm of available chlorine followed by a rinse with a weaker chlorine solution. Failure of the chlorine disinfectant is more likely due to the presence of organic matter, which does seriously interfere with its action, so that it is not normally used where much dirt is present. In favourable circumstances it is best used warm and will act quickly. Chloramines are much more active in the presence of organic matter and have found a secure place as general disinfectants.

Iodine and iodophors

Iodine is an effective germicide, although like chlorine its action is much depressed by organic matter. It is effective against vegetative organisms and spores. The most widely used iodine preparations are the iodophores in which iodine is mixed with surface-active agents, which act as carriers or solubilizers for the iodine. They lack any real odour and are not irritant.

Iodophors have been used at dilutions of around 25 ppm available iodine for utensils. They have built-in indicators that reveal quickly the approximate concentration of the use dilution; a yellow tinge or pale amber colour is imparted by an iodophor even when only a few parts per million of free iodine are present in the solution. High concentrations give deeper shades of amber or brown to the solution. The use dilution of 25 ppm is equivalent to available chlorine concentrations up to 200 ppm. Iodophors are an ideal germicide to use in water utensils.

Ammonia

A 10 per cent aqueous solution of ammonia is an effective agent for the destruction of coccidial oocysts. This is the only use for ammonia as a disinfectant.

Ectoparasites

It is of great importance to control ectoparasites in and around the farm buildings. They are a nuisance both to the attendants and the animals, may be the cause of direct irritation and disease and may indirectly spread disease; indeed any infectious agent can be carried by ectoparasitic vectors. These ectoparasites include flies (the ordinary housefly, the lesser housefly and the stable fly), mites, ticks, lice, fleas, bugs, beetles and cockroaches.

For the control of external parasites of animals a variety of compounds are available, such as gamma-benzene hexachloride (lindane), piperonyl-butoxide pyrethrum (pyrethrin) or *O,O*-dimethylthiophosphate of diethylmercaptosuccinate (malathion) and *O,O*-

dimethyl-*O*-2,3,5-trichlorphenyl phosphorothroate (fenchlorphos 12 per cent) (see Chapter 60).

Health and safety

There are certain dangers to people and mammals in the use and disposal of disinfectants and ectoparasiticides and the residues of their applications. For this reason alone it is advised that only officially approved products should be used and the health and safety regulations attached to them are followed rigidly. An awareness of the possible harm to those using the substances and their effect on polluting the environment has increased immensely lately so that the manufacturers have been forced to update the health and safety data regularly. There are particular dangers with some ectoparasiticides as well as certain disinfectants and it is vital that protective clothing is worn.

Rotation of hygiene products

There are no products that are ideal. All of the disinfectants and ectoparasiticides have their strengths and weaknesses. To minimize the adverse effects of this fact, it is recommended that a rotational programme is instituted so that regular programmed changes are made in the type of product used, thereby reducing the chance of certain pathogens escaping destruction.

Recommended procedure in disinfection and disinfestation of animal buildings and equipment

Basically, two procedures should be adopted. The first is used between batches of livestock within a building in the absence of overt disease, and the second after an outbreak of a contagious and infectious disease.

Procedure of disinfection with no disease present

- (1) All equipment and fittings that are removable should be demounted and taken out of the building. It is advisable for them to be soaked in a bath of disinfectant where the materials are able to stand up to this treatment. Alternatively, they may be power-sprayed or steam sterilized. They should be left outside exposed to the elements and away from animals and their products for as long as possible.
- (2) All litter should be removed (Fig. 56.5).
- (3) The roof and structural elements of the house should be dusted and cleaned, preferably with a vacuum cleaner.
- (4) The lower part of the walls and all the floors should be thoroughly cleaned, preferably using a

Fig. 56.5 Cleaning out the litter after removal of the animals.

Fig. 56.6 Washing down with a pressure hose using a detergent disinfectant.

- pressure washer, with a heavy duty, wide-spectrum detergent/disinfectant mixture (Fig. 56.6).
- (5) The surfaces must then have a disinfectant applied (Fig. 56.7) with a wide spectrum of activity, capable of killing all the pathogens that are likely to be present.
 - (6) In some cases, if there is a heavy insect infestation, it will be necessary to apply a special insecticide spray.
 - (7) As a final measure a disinfectant is often sprayed over all the surfaces to give a residual effect. Thermal 'fogging' machines are widely used.

Procedure after contagious and infectious disease

- (1) The building should be closed and isolated from all visitors.
- (2) The bedding, litter and all areas in intimate contact with the stock should be sprayed with a strong disinfectant.
- (3) The litter should subsequently be removed from the building and may be burnt or buried so there is no possible contact with livestock.
- (4) Portable equipment and fittings should be given the same treatment as previously suggested and

Fig. 56.7 Spraying with a disinfectant.

preferably in the house, later to be taken out and aerated.

- (5) The floors and lower part of the walls should be cleaned with detergent disinfectant.
- (6) The house should then be treated in the same way as suggested in the previous section.
- (7) It may sometimes be advisable to skim off the top few inches of the soil around a heavily infected area.
- (8) The approaches to the building should be treated with disinfectant and foot-dips provided (Fig. 56.8).

Ventilation

There are few topics in animal husbandry where there have been more totally erroneous statements made than on the reasons why housed livestock require ventilation or 'air-change'. For example, for many years it was accepted that the main deleterious effect of having too little ventilation was due to the build-up of harmful concentrations of the gaseous products of respiration, and in particular carbon dioxide, combined with a depletion in the oxygen content of the air. It is now known that this is far too simple and usually quite an incorrect hypothesis.

Underlying principles and calculations

In any badly underventilated building the stagnant air gradually becomes both warmer and more humid and there is a rising concentration of dust, other particulate

Fig. 56.8 Using protective clothing and dipping boots in disinfectant to reduce the risk of introducing infection.

matter, ammonia and other gases and any pathogenic microorganisms the livestock may be carrying. The end result is that the animals suffer from 'heat stagnation', involving a susceptibility to chilling. Along with this will go poor productivity and a likelihood of disease, particularly respiratory, which modern experience shows to be of the greatest danger in intensive forms of housing.

In addition, in a badly ventilated building, condensation on the surface is often likely and bedding and floors may become wet and the animals uncomfortable. This will tend to exacerbate the effect of disease conditions, respiratory or enteric in nature, or infections such as mastitis.

In recent years a new hazard to livestock and their attendants has been the risk of gaseous intoxication of livestock due to the gases arising from slurry pits or channels under the animals. The risk is very great and has caused the death of many animals and several stockworkers.

The object of ventilation, therefore, is to remove the stale air in a building and replace it with fresh air and remove any danger of toxic gases. But while too little ventilation is obviously serious, so also is too much. In cold weather much valuable animal heat will be wasted. Further, overventilation may be synonymous with draught. Draughts are themselves responsible for causing many deaths by direct chilling and they may also act indirectly by lowering the animals' resistance to disease-producing organisms.

In planning a ventilation system allowance has to be made for all the factors that can influence the ventilation required, i.e. type, age and number of livestock, their management, the construction and locality of the house and finally the weather conditions.

Natural ventilation (see p. 40)

If natural ventilation is to be effective, it must function well in all weathers. To try to avoid too great a dependence on external wind and weather, it is best to make use of the so-called 'stack effect' as its foundation. The warm stale air around the body of the animal, being lighter than cold fresh air, will rise to the top of the building. Outlet ventilation is therefore provided at a suitable point or points in the ceiling or roof. The greater the difference between inside and outside temperatures, and the greater the distance between inlets and outlets, the greater the stack effect. Therefore, if an area of outlet ventilation is provided to cope with difficult conditions (i.e. a small difference between inside and outside temperatures) it can easily be restricted when temperature differences are greater or appreciable winds help in the ventilation. As mentioned, in houses where no great control is necessary, such as climatic housing for cattle, a fixed open ridge with a pro-

tective cap may be sufficient. But in other controlled-climate accommodations far more control is needed and down-draughts, which can be common with the fixed open ridge, must be avoided. Experience has shown that for the latter, good results are obtained by the use of a limited area of controlled outlet ventilation and for this purpose a simple chimney type or insulated 'flue' is satisfactory. It is good practice to have one or a few outlets, but a much larger number of smaller air inlets, as the fresh air should come in slowly all round the building, diffusely and carefully baffled. The basis of a useful inlet system consists of hopper-type windows, fitted with gussets to prevent direct draughts, serving as principal inlets, and small baffled openings between the windows which alone are left open during cold or windy weather. Since cold air coming into the building falls naturally towards the floor, there is no necessity to site inlets at floor level, where the danger of chilling draught is considerable.

The totally covered yard

In practice the following major faults are commonly found in the construction of covered yards:

- Either there is no ridge outlet for stale air or it is inadequate.
- Eaves openings are either absent or, where present, uncontrollable and at the mercy of the weather, causing chilling draughts in cold weather.
- The extreme width of many yards (20m upwards) prevents natural ventilation functioning properly. This problem is often combined with multispan construction and low eaves and roofs, so that the flow is generally impaired.
- The gable ends are closed and sealed.
- There is no insulation of the roof. While insulation is not usually necessary it may be a desirable 'extra' under a few circumstances, particularly where younger stock are housed or where the roof is low and natural air flow is difficult.
- Poor drainage under or around the yard leads to excessive straw usage and contributes to the humidity of the atmosphere.
- Bad construction of the walls leads to excessive moisture penetration at all points.

Natural ventilation works most satisfactorily on open sites; it is always useful to have it controllable, but this is not usually done. An open ridge 300mm wide, with a flat continuous top at least 150mm above, is a simple answer to extraction in narrow yards, and a 600mm wide ridge in yards above 14m width.

An even more satisfactory arrangement is to have a series of chimney-type ventilators along the ridge, allowing $0.09\text{ m}^2/\text{animal}$. A useful size of chimney is

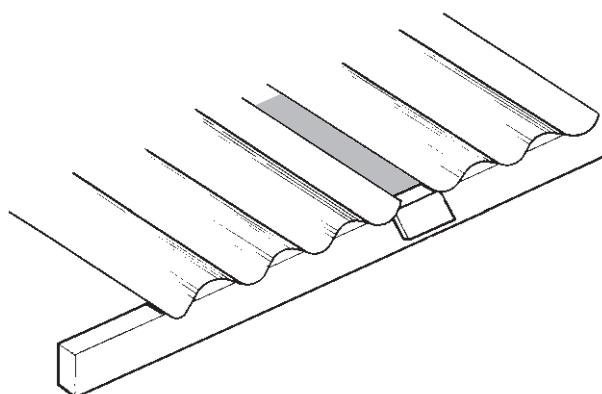

Fig. 56.9 The 'breathing' roof: ventilation achieved by leaving a gap between the roof sheets.

1 m²; this is sufficient for 11 animals. The throat can be controlled by a butterfly valve or hinged flap.

Alternative ways of achieving good 'top' ventilation are as follows:

- (1) Raised sheets, consisting of conventional steel sheets fitted with a batten or washers raising the overlapping, allowing air to pass between the sheets. A spacer batten of treated timber measuring 50 mm × 25 mm is suitable.
- (2) Upturned corrugated sheeting. Conventional galvanized corrugated steel sheeting is fixed upside down with a gap between each sheet, forming a Venturi flow between each sheet. Typically, a 25 mm gap may be used, which would give 3.75 per cent opening of the roof. (Fig 56.9).

Systems (1) and (2) are often described as 'breathing roofs'.

Mechanical ventilation

This has a place in some cattle yards as it has for other forms of intensively housed stock. With a system of chimney trunks, fans can be added as a complementary arrangement, since an extractor fan may be fitted at the base. If a 600 mm fan running at a maximum of 900 rev/min is fitted, 10 194 m³/hour will be extracted. A maximum allowance of 510 m³/hour per beast (or approximately 0.42 m³/hour per kg bodyweight) is found satisfactory, so that one fan will serve approximately 30 beef animals to slaughter.

Automatic or semi-automatic control can be achieved if a proportion (one-half to two-thirds) of the fans are put on a thermostatic control, with a thermostat that is easily seen and adjusted. Fans thus operated should have automatic antiback-draught flaps fitted to prevent down-draughts when they are switched off. All fans should be speed controlled. Alternatively, a system

of variable fan speed on a motorized thermostat or electronic control will give full automation on all fans.

Fan ventilation halves the number of roof outlets that need to be installed. The total capital cost of a fan-operated system will hardly be more than £30 per animal-place, an economical cost for automatic environmental control. Running costs may be a rather more daunting charge.

The main use of fan ventilation in cattle yards is in those cases where extremely high stocking rates are used, as with slatted floor units, or where the topography of the site or restriction of wind around the building makes natural flow all but impossible.

The inlet of fresh air is no less important, and it has been found satisfactory to provide inward-opening hopper flaps along both side walls, bottom-hung and 700–900 mm deep, with gussets and variable control through casement stays or remote control from the feeding passage. Alternatively, the hoppers may be controlled from the ends with horticultural glasshouse type fittings. It is preferable if the inlets are not closer than 600 mm to the eaves, to prevent incoming air 'bouncing' off exposed purlins and causing an irritating down-draught on the animals. The flaps should be made so that they can be removed or hinged down flat in the summer; they should extend along at least one-half and preferably two-thirds of the wall length.

With wide-span yards over 21 m, slatted boarding (100 mm boards and 12 mm gaps or 150 mm boards and 25 mm gaps) should be fitted at the gable ends and part of this area made as hinged doors that can be opened in the summer. This is normally not necessary, however, in narrow-span yards. In addition, there are a number of other excellent techniques for achieving good inlet ventilation for cattle and other yards.

'Spaced boarding' is excellent all around a yard – at the gable ends and along the walls above 'animal height' (Fig. 56.10). It gives an opening area of about 20 per cent of the total but is uncontrollable; an alternative is to have an adjustable system with fixed outer slats and inner sliding slats. There are also various other arrangements, such as the Ventair steel sheet with patented louvres (13 per cent open); slatted hardboard with slats 5 mm × 25 mm giving 30 per cent opening; Netlon polypropylene mesh (45 per cent open); Ventrex steel sheet with louvres (0.7 per cent open) and a common device of a space left between the outer sheet and the wall, giving a baffled protected inlet.

It is in no way suggested that the systems outlined are the only satisfactory methods of ventilating intensive cattle yards. For example, other mechanical means have been used, often with equal success. These do, however, often need more careful designing and management to prevent draughts and to give adequate control. The systems suggested are logical and generally understood

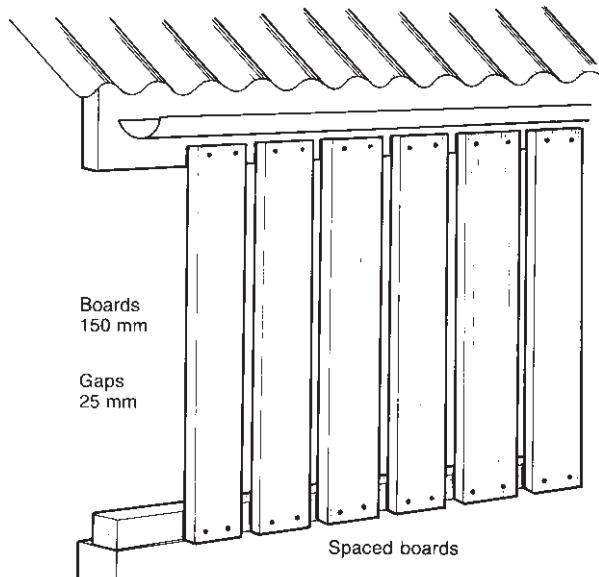

Fig. 56.10 Wall ventilation with spaced boarding.

and easily controlled by the stockworker. Mechanical assistance with the designs shown is complementary to natural flow and indeed may be used as an additional stage in the development and improvement of a design. Draughts are least likely where there is the fullest control of the system. Ventilation continues to function at a reduced rate in the event of power failure with the system advocated, since natural stack-effect ventilation takes over from the fans to tide the stock over this period.

If the trend towards high stocking rates continues it is inevitable that the farmer will turn increasingly to thermal insulation of the surfaces, especially the roof. Farmers who have used insulation of the roof have recorded considerable benefits in terms of liveweight gain and feed conversion efficiency, but above all because it helps also to solve environmental problems. A popular way of arranging the insulation is by using two skins of metal or fibre-cement sheeting for the roof separated by a vapour-sealed layer of mineral wool or glass wool. For the latter, a 50 mm thickness is minimal but 100 mm is very much better. A cheap treatment for an existing uninsulated building is to build a false ceiling of wire mesh supporting vapour-sealed insulation. It is an economical way of insulating the building, though somewhat temporary. It must be emphasized that individual attention does need to be given to each yard according to the site and locality. It is one of the advantages of fan ventilation that with mechanical ventilation this statement is much less true. The use of fans partially rules out the dependence on site and weather. It is generally better to have yards in exposed positions because it is easier to restrict the open area if too much

air comes in than to open up the ventilation space in a sheltered site. Sometimes the proximity of other buildings makes it impossible to increase the airflow at all.

Livestock yards are now often made very wide, of the order of 40–50 m. These are invariably the most difficult units to ventilate. From the point of view of ventilation it is desirable to limit the span to some 30 m. Indeed, if the trend towards the use of thermal insulation continues, views on what constitutes an adequate cubic area may change. In an uninsulated yard a large cubic area helps to buffer the outside weather extremes. But in an insulated construction, the roofing area must be reduced to a minimum to cut costs and more economical dimensions would be a height of 3.6 m to eaves with a maximum yard span of 21 m. These recommendations widely used and required for cattle buildings apply, with only minor modifications, to climatic yard accommodation generally, including that for pigs, sheep and turkeys.

Open-fronted yards and kennels

A fundamentally different approach to climatic housing is the ‘lean-to’ or open-fronted yard, often called the mono-pitch building. This is attractive in several respects and continues to gain in popularity as an alternative to the span roof yard. For a start it is usually cheaper. Also, by its very nature, it is impossible to make it very wide – a depth of 10 m being about the limit – so the enormous problems of ventilation created by wide spans are avoided and stock concentrations in one air space are limited. Best of all, such a system gives a cheap isolation of groups by carrying vertical partitions to the roof and if necessary supporting it every 3–6 m. With an open-fronted design animals have a choice of environment, as they can go towards the lower back part in colder conditions to keep warm, or come to the front for sunlight and more fresh air in warmer weather. Control of airflow can be by simple hinged flaps on the front and kennels can be incorporated if desired. It is most desirable that open-fronted yards in the northern hemisphere face in a southerly direction only; it is preferable not to face two rows together, since there is a risk of the passage-way between becoming a wind tunnel and in this situation one side at least will face north or east and so may get little sun and indeed may suffer from distinctly cooler conditions.

Dangers from gases in farm buildings

Problems associated with gases in and around the livestock farm have been highlighted recently, particularly in association with gas effusion from slurry channels under perforated floors, but it would be wrong to regard these as the only dangers. While there have been numerous fatalities of livestock recorded, and indeed of

man, due to gas intoxication, there is also mounting evidence that there may be concentrations of gases in many livestock buildings that may affect production adversely by reducing feed consumption, lowering growth rates and increasing the animals' susceptibility to invasion by pathogenic micro-organisms.

The most serious incidence of gas intoxication arises from areas of manure storage in slurry pits or channels under the stock, usually but not always associated with forms of perforated floors. The greatest risk arises when the manure is agitated for any reason, usually when it is removed. There is also an ever-present danger if a mechanical system of ventilation fails and this is the only method of moving air in the house. Several cases of poisoning have been reported when sluice-gates are opened at the end of slurry channels and the movement of the liquid manure has forced gas up at one end of the building.

High concentrations of gases, chiefly ammonia, may also arise from built-up litter in animal housing. The danger has undoubtedly been exacerbated within more recent years owing to the mistaken insistence of maintaining relatively high house temperatures in order to reduce food costs. The farmer has often attempted to achieve such temperatures by restricting ventilation and in the absence of good thermal insulation of the house surface, so that the result may often be generally harmful if not actually dangerous.

Introduction

Biosecurity means a multitude of things to different people. In its broadest interpretation in relation to human health it is defined as 'those cumulative steps taken to prevent transmission of pathogens and other harmful agents to individuals or populations of human beings' (Gillespie, 2000). Gillespie (2000) further states that the harmful effects of these agents may be direct (e.g. smallpox virus causing disease) or indirect, by disrupting the food supply (e.g. animal or plant pathogens), and that any substance that disrupts biological systems necessary for human health and well-being is a threat to biosecurity. In addition to pathogens, it is also suggested that naturally produced poisons, such as aflatoxin, toxic chemicals and pesticides, all have the potential to disrupt beneficial and necessary biological systems and can therefore also be considered to threaten biosecurity.

From the point of view of human health, the ultimate aim of biosecurity is therefore to safeguard the human food chain. While major epidemic diseases of cattle such as foot-and-mouth disease and rinderpest may threaten food supplies, they do not have direct public health implications. However, most foodborne illnesses are the result of inadvertent contamination of foods by pathogens, including viruses, bacteria, protozoa and perhaps also prions. These organisms may be zoonotic, causing disease in cattle and humans e.g. *Salmonella* spp., or foodborne pathogens that are non-pathogenic in cattle, e.g. *Escherichia coli* O157.

While the public health aspect of biosecurity is obviously extremely important, the prime role of the veterinary surgeon is to safeguard the health of food-producing animals, because disease will reduce productivity and/or be detrimental to animal welfare (Barrett, 2001a). It is this animal health aspect of biosecurity which will be dealt with in most detail in this chapter.

From the point of view of cattle health, biosecurity can be defined as 'the efforts put forth to prevent the introduction of pathogens or toxins that have the potential to damage the health of a herd of cattle or the safety and quality of a food product' (Sanderson *et al.*, 2000). An interrelated concept is that of biocontainment, which is the 'effort to contain the spread of disease or intoxication within a herd' (Sanderson *et al.*, 2000). For the purposes of this chapter, we will concentrate on the infectious disease components of both biosecurity and biocontainment, and use the term biosecurity in a generic sense to cover both concepts.

In the past, efforts to use biosecurity principles to control diseases of cattle in the UK have been largely confined to the statutory control and eradication, or attempted eradication, of notifiable diseases such as foot-and-mouth disease (FMD), bovine tuberculosis (TB) and brucellosis, or specific diseases such as bovine herpes virus-1 (BHV-1), the cause of infectious bovine rhinotracheitis (IBR) (p. 286), and leptospirosis (*L. borgpetersenii* serovar *hardjo* and *L. interrogans* serovar *hardjo*) (p. 735) within non-statutory cattle health schemes. This has resulted in an attitude amongst many cattle producers that infectious disease control is either something that government should take charge of, and pay for, on their behalf, or is something that is only relevant to a small number of herds who may benefit from having an 'elite' health status. The majority of commercial herd owners have considered that endemic infectious diseases are always going to be present within their herds. This has resulted in many of them tolerating the infections and acting in a reactive way to treat disease when it occurs while living with the associated depression in productivity, rather than taking a proactive disease control and/or eradication stance.

This is in contrast to the attitude in the UK pig and poultry industries where there are pyramidal structures, designed amongst other things to help control infectious disease. Pig and poultry producers, whether they are breeding companies or commercial units, would not entertain the idea of introducing new stock without taking specific precautions to protect both the newcomers and the indigenous herd or flock from infectious diseases. Although the cattle industry is structured very differently from the pig industry, cattle producers could learn a lot from the biosecurity principles that have been developed for pigs over many years (Moore, 1992). Even so, the outbreak of classical swine fever in Eastern England in 2000 (Sharp *et al.*, 2001) and the spread of new diseases such as post weaning multisystemic wasting syndrome with the movement of pigs between farms (Done *et al.*, 2001) has shown that disease transmission between pig units remains a problem.

Even before the devastating outbreak of FMD in the UK in 2001, the challenge to enhance biosecurity on cattle units was already very real. Biosecurity had become an increasingly topical issue in relation to cattle production, prompted by suggestions that TB control measures would be enhanced if biosecurity were improved (Anon, 1999a,b, 2001a; Collins, 2000; Phillips *et al.*, 2000; Barrett *et al.*, 2001), reducing both cattle-to-cattle (Menzies & Neill, 2000) and badger-to-cattle transmission of *Mycobacterium bovis* (see p. 857). More generally, much needed to be done at a herd level to improve herd health and productivity by implementing well-designed 'biosecurity plans' that were proactive in preventing the spread of numerous infectious diseases endemic within the UK.

The 2001 outbreak of FMD, which affected France, The Netherlands and the Republic of Ireland as well as the UK, emphasized the need to safeguard the national herd from exotic diseases, particularly in these times of a single European Market. The last frontier for disease control must be the farm boundary; cattle farmers have to take responsibility for disease control in their own herds, and, with advice from their veterinary surgeons, decide what precautions they need to take to reduce the risk of disease transmission.

Benefits of improved biosecurity

Improving biosecurity on cattle units, both to control infectious diseases already present and to prevent the introduction of new infections, has a number of potential benefits at the farm level (Box 57.1). If improved biosecurity measures are widely adopted such that increased numbers of cattle herds become free of

Box 57.1 The benefits of improved biosecurity to an individual farmer.

- Increases in production, productivity and profit
- Improved animal welfare
- More efficient utilization of resources
- Reduced use of medication, such as antibiotics and anthelmintics, with an associated reduction in the risk of resistant pathogens emerging
- Enhanced value of the individual herd, with livestock, and livestock products, of known health status commanding premium prices

Box 57.2 The benefits of improved biosecurity to the wider farming community.

- Maximizing export markets by the prevention of disease-orientated barriers being put in place by importing countries
- Possible limitation of imports by creating disease-orientated barriers to the importation of livestock, and livestock products, from countries of lower health status

selected infectious diseases, there will be potential benefits related to international trade (Box 57.2).

Farm biosecurity is also an important first step in safeguarding the human food chain with benefits to the community at large. It is an important part of any hazard analysis and critical control point (HACCP) plan to safeguard human health. Food retailers are taking much more interest in this area as a means of combating potential risks to human health (Noordhuizen & Wentink, 2001), for example the possible link between *Mycobacterium avium* subsp. *paratuberculosis* (Johnne's disease) (p. 862) in cattle and Crohn's disease in humans (Hermon-Taylor, 2000). The general population is now much more sensitive to disease epidemics and food scares, e.g. salmonella in eggs and bovine spongiform encephalopathy (BSE) (p. 909), and farmers may in future need to show that they have adequate biosecurity measures in place to minimize such risks in order to sell to certain retailers.

Routes of infection

There are many ways in which an infectious agent can enter a herd of cattle. These are summarized in Box 57.3. The greatest risk for most diseases is by contact with infected cattle, either by the introduction of infected cattle into a herd or by contact with neighbouring herds via cograzing or across boundaries. Attendance at shows and the return of unsold cattle from sales also risks the introduction of disease. These infected animals may be either asymptomatic 'carriers' of a specific disease such as bovine herpes virus-1 (BHV-1), bovine virus diarrhoea

Box 57.3 Common routes by which infectious agents can enter a herd of cattle.

Introduction of infected cattle or direct cattle-to-cattle contacts
 Feed or water, contaminated with pathogens such as *Salmonella* spp. or the prion responsible for BSE
 Visitors, including those regularly working with cattle on other premises, such as relief milkers, foot trimmers, AI technicians and veterinary surgeons
 Mechanical vectors such as vehicles and farm implements
 Wildlife, including badgers, rabbits, rodents, deer and birds
 Other species of livestock such as sheep
 Airborne transmission, notably FMD

rhoëa virus (BVDV) (p. 853), *Neospora caninum* (p. 584), *Streptococcus agalactiae* (p. 333) or cattle incubating a particular disease such as *Salmonella typhimurium* DT 104 (p. 850). In the case of cattle incubating disease, it may be possible to prevent the introduction of a pathogen by imposing quarantine measures of a duration that exceeds the expected incubation period. However, some pathogens may not cause infected animals to exhibit overt clinical signs, e.g. *Leptospira hardjo* (*L. borgpetersenii* serovar *hardjo* and *L. interrogans* serovar *hardjo*). Others may have excessively long incubation periods, making simple quarantine impractical without the use of accompanying diagnostic testing, e.g. *Mycobacterium avium* subsp. *paratuberculosis* (Johne's disease). In the case of 'carrier' animals that do not exhibit clinical signs, detection is reliant on diagnostic testing, either of the individual animals or of the herd from which they have been obtained. The reliability of diagnostic tests and the design and implementation of testing regimens have been discussed in detail by Caldow *et al.*, (2001). With or without adequate isolation and quarantine measures, appropriate diagnostic tests will need to be undertaken to ensure, as far as is realistically possible, freedom from disease in introduced animals or at least to define their health status and prior exposure to certain pathogens.

To prevent direct or indirect contact between herds of neighbouring cattle, there should be a 3 m gap between boundary fences and hedges. This should minimize the risk of short-distance airborne disease transmission such as is possible for BHV-1, the cause of IBR. Long-distance airborne transmission, as is classically seen with FMD, is almost impossible for an individual farmer to guard against.

Infectious diseases that can be introduced into cattle herds

The numerous infectious diseases that can be introduced into cattle herds can be divided into three cate-

Box 57.4 Diseases endemic in the UK and elsewhere, which may be controlled in part by enhanced biosecurity measures.

Bovine virus diarrhoea (BVD)
 Infectious bovine rhinotracheitis (IBR)
 Leptospirosis^a
 Salmonellosis^a
 Johne's disease^b
 Mastitis, e.g. *Streptococcus agalactia*
 Digital dermatitis
 Parasitic diseases^a
 Ringworm^a
 Udder skin infections
 Venereal *Campylobacter* spp. infection
 Neospora infection (causing abortion)

^a Zoonotic diseases transmissible to humans.

^b There is some evidence that links this disease with Crohn's disease in humans and its importance may therefore increase further in the future.

Box 57.5 Diseases notifiable in the UK.

These are the diseases subject to national control policies and/or international trade rules and include:

Anthrax^a
 Aujeszky's disease^{b,c}
 Bluetongue^a
 Bovine spongiform encephalopathy (BSE)^b
 Brucellosis^{b,c,d}
 Contagious bovine pleuropneumonia (CBPP)^a
 Enzootic bovine leukosis (EBL)^a
 Foot-and-mouth disease (FMD)^a
 Lumpy skin disease
 Rabies
 Rift Valley fever
 Rinderpest
 Tuberculosis (TB)^b
 Vesicular stomatitis
 Warble fly^a

^a Those diseases considered by the authors to pose the greatest threat of re-emergence or introduction into the UK.

^b Diseases known to be present in the UK in early 2002 (Northern Ireland only).

^c Occurred in the UK in 2003.

gories: diseases endemic in the UK and elsewhere, examples of which are shown in Box 57.4, notifiable diseases both present in the UK and exotic (Box 57.5) and other diseases not considered present in the UK (Box 57.6).

General principles of biosecurity

Biosecurity is not a new concept; the introduction of 'cattle plague' (rinderpest) (p. 707) into the UK in 1865 resulted in the Cattle Disease Prevention Act of 1866.

Box 57.6 Other important diseases not widely present in the UK that may be introduced.

If cattle are purchased from another country, there are diseases that are currently not present or at minimum levels in the UK but which are also currently not subject to national control measures or importation rules. For example:

Trichomoniasis

Some species of *Leptospira*

Type 2 BVD virus*

*Recently found in Great Britain.

This Act enforced the use of what we would now consider biosecurity measures to eradicate rinderpest from the British Isles after an estimated 400 000 cattle had died of the disease; the last cases were seen in 1877 (Dunlop & Williams, 1996). The basic principles for the prevention and control of many infectious diseases in cattle have therefore been well recognized for over 125 years.

Duncan (1990) set out the principles of infectious disease control in cattle in the early 1990s. At a meeting of the British Cattle Veterinary Association (BCVA) in 1994, three papers related to this subject were presented (Duncan, 1994; Taylor, 1994a,b), followed by a further paper in 1996 (Pritchard, 1996). Duncan (1990) set out a seven-point plan, subsequently modified slightly as follows:

- (1) Maintain a closed herd, with no introduction of animals and no contact with outside cattle.
- (2) If introduction of cattle is unavoidable, operate an isolation and testing policy for introduced stock, including other species such as sheep.
- (3) Ensure feed and water are free from contamination.
- (4) Control visitors and vehicles, and operate a policy to reduce the risk of transmission of pathogens from visitors and vehicles.
- (5) Control direct and indirect contact between wildlife and cattle, particularly rodents and birds.
- (6) Define and monitor the health status of the herd.
- (7) Establish and operate an agreed disease control programme or biosecurity plan.

The ‘closed’ herd

Maintenance of a closed herd is the main plank of a biosecurity programme. No animals must be purchased, borrowed or hired. New genetic material must only be introduced to the herd by artificial insemination (AI) or embryo transfer (ET), but even these introductions

can present some risk (see Chapters 39 and 40). When using ET, embryos must be transferred into home-bred recipients; pregnant recipients or animals for use as recipients must not be purchased. No animals must be loaned or hired out. No animals must be returned to the herd from shows or sales. There must be no contact with other cattle when grazing.

Introduction of purchased stock

It will not be appropriate for many herds to be closed, due to management constraints such as cograzing or a production system based on the rearing of purchased stock. It is therefore essential to minimize the risk of introducing infectious diseases into the herd when buying new stock. The introduced animals may bring with them an infectious organism not previously present on the unit, leading to disease in the indigenous population, e.g. Johne’s disease. They may also introduce a different strain of a pathogen, e.g. anthelmintic-resistant gastrointestinal nematodes, or virulent BHV-1, or may themselves succumb to a disease endemic in the indigenous population. Even where there is no desire to achieve or maintain a high health status herd, the risk of introducing more virulent strains of a pathogen, or drug-resistant pathogens, is a very real threat whenever cattle move between herds.

The safest source for new stock is a herd certified free of specific diseases, usually by a cattle health scheme. If such stock are not available, the next safest route is to buy from farms of known health status. In order of increasing risk:

- (1) A health scheme herd being monitored for specified diseases.
- (2) A single source herd of known disease status.
- (3) Multiple source herds of known disease status.

The highest risk is to purchase from multiple sources of unknown disease status or herds in which the disease is known to have occurred. Animals from livestock markets or dealers where cattle from multiple sources are mixed together should be considered a very high biosecurity risk.

Unless from certified disease-free herds, incoming animals should be isolated and tested before they enter the herd, preferably on the farm of origin before purchase. Use of the farmer’s own transport minimizes the risk of contact with sources of infection in transit, particularly if the haulier cannot guarantee not to mix stock in the lorry. The incoming animals should ideally be isolated on arrival and tested according to a specific pre-agreed protocol before entering the herd.

Some suggested control measures for diseases that may be introduced to a UK herd with the introduction of cattle are outlined in Table 57.1.

Risk of disease in the herd affecting an incoming animal

While many farmers will realize that introduced cattle may transmit disease to their herd, few consider the risk to the incoming animals from pathogens within the indigenous population. This can be a particular problem with breeding bulls, as breeding capacity can be severely depressed by many generalized illnesses as well as by specific infections of the reproductive tract. In addition, pregnant females may abort if infected with many pathogens during gestation. For this reason, the disease status of all incoming animals should be established with regard to pathogens endemic in the herd and, whilst in isolation, they should be treated and/or vaccinated as necessary.

In the specific case of an introduced bull, it is worth remembering that there is a time lag of approximately two months from the start of spermatogenesis to the ejaculation of the sperm. This means that an insult to the testes may not result in deterioration in semen quality for many weeks and, conversely, it can take months for semen quality to recover following a disease episode. Many diseases may also reduce conception rates in cows and heifers if they become infected around the time of conception. Therefore new bulls should be introduced to a herd only after an appropriate isolation and testing regimen has been undertaken. However, this may prove extremely difficult to achieve when bulls are purchased through commercial sales, as the timing of bull sales is often very close to the time they are required for breeding, especially in seasonally-calving suckler herds.

Principles of biosecurity planning

An effective biosecurity programme needs to be decision-focused and flexible enough to adapt to the unique situation of the individual enterprise. This requires an understanding of biosecurity principles and the goals of disease prevention, as well as specific information relating to the biology and epidemiology of the particular pathogens of interest.

When considering the construction of a biosecurity plan, it is important to establish which infections are worth concentrating on, to ascertain the current disease status of the herd and then to assess the risks associated

with the use of certain management practices in relation to the target infections. The next step is to assess the benefits of risk reduction within the specific biosecurity plan. In an ideal world, this would involve a quantitative risk analysis for each target infection. However, this is usually not practical on an individual herd basis, as many of the required data are often unavailable and gathering these data and undertaking the required modelling would not be cost-effective. This is not the case at a national level and it is now the norm when policy decisions are made on international livestock trade to employ quantitative risk assessment (Wooldridge, 1996; Murray, 2002). Nevertheless, a qualitative risk assessment, using what limited information is available for an individual herd, may be very helpful when beginning to construct a biosecurity plan. The basis for risk assessment is not to eliminate all risk, but to divide risks into various levels to assist informed decision-making (Wells, 2000). Focusing on the major hazards and major areas of risk will allow the cost-benefits of a biosecurity plan to be maximized.

Producing a biosecurity plan

A farmer needs help and advice from his veterinary surgeon if he is to make rational decisions to protect the health of his herd. This advice is best given in the form of a written biosecurity plan for the farm. This could be a stand-alone document or a component of a general Herd Health Plan such as the BCVA Herd Health Plan (Anon, 2001b).

The safest policy will always be to ascertain the disease status of the indigenous herd and then produce a considered biosecurity plan based on a qualitative (or if possible quantitative) risk assessment, looking at all likely hazards for disease transmission. Particular care needs to be taken when animals are to be introduced into a herd or where members of the herd are known to have had contact with outside animals, such as at a show. The action to be taken when new stock are to be introduced to the herd must be decided in advance. This should include details of where animals are to be obtained from, the provision and management of isolation facilities, the testing, treatment and vaccination strategy and what is to happen if an animal fails to meet the predetermined health criterion.

The written plan must have some flexibility built into it and it must be agreed by both the farmer and his veterinary surgeon. It must be reviewed regularly and both parties must work together to maintain interest and motivation.

A possible future aid to biosecurity planning in Great Britain may come from the British Cattle Movement

Table 57.1 Examples of infectious conditions likely to be introduced to UK herds with added animals, with brief suggestions of measures to prevent disease introduction. (Modified and extended from Pritchard, 1996.)

| Disease/infection | Preventive measure | | | Vaccines available in UK | Comments |
|---------------------------------|----------------------|------------------------|------------------|--------------------------|--|
| | Clinical examination | Prophylactic treatment | Laboratory tests | | |
| BVDV | (+) | ~ | + | Yes | It is essential to test for BVD virus (up to 1.8% of cattle may be virus positive); serology also useful. Calve pregnant females in isolation and test calves at birth for virus if dam seropositive; or isolate calves and test when over 4 months of age for virus and antibody. Bulk milk tests available. |
| IBR (BHV-1) | (+) | ~ | + | Yes | Significance of adding seropositive (potentially infectious) animals depends on virus strain, vaccination type if used, existing herd status and possible implications for sale of cattle, semen and embryos. Bulk milk tests available. |
| Leptospirosis | (+) | + | + | Yes | Test animals using ELISA, 25 mg/kg dihydrostreptomycin given twice within 14 days of entry reduces risk of excretion. Bulk milk tests available. Zoonotic. |
| Salmonellosis | (+) | (+) | + | Yes | Repeated culture of faecal samples should help to detect carriers. Positive SAT titre for <i>S. dublin/S. typhimurium</i> on serum may indicate recent exposure. Zoonotic. |
| Johne's disease | (+) | ~ | (+) | Yes | Individual animal screening to detect subclinical infection is hampered by a lack of suitable tests. Tests such as adsorbed ELISA may be useful on a group basis. Request certification of clinical freedom in the herd of origin for a substantial period of time, e.g. 5 years. If diarrhoea develops in isolation examine faeces repeatedly for acid fast organisms and undertake culture. Consider rejecting animals with intermittent/persistent diarrhoea regardless of test result. (Zoonotic?) |
| <i>Streptococcus agalactiae</i> | (+) | + | + | No | Should be readily preventable by using CMT, culturing positive quarters and/or treating. Bulk milk screening may be of use. |
| Digital dermatitis | + | (+) | ~ | No | Good clinical examination. If in doubt treat with topical antibiotic spray/footbath. |
| Ectoparasites | + | + | (+) | No | Use appropriate treatment. |

| | | | | | |
|--|-----|-----|---------------|-----|---|
| Gastrointestinal parasites | ~ | + | (+) | No | Use carefully selected, appropriate anthelmintics. |
| Lungworm | ~ | + | (+) | Yes | Use carefully selected, appropriate anthelmintics. Vaccine will not totally prevent infection. |
| Liver fluke | ~ | + | (+) | No | Use carefully selected, appropriate treatment. |
| Ringworm | + | (+) | (+) | Yes | Can cause quite serious problems in naïve herds, particularly amongst adult animals. Zoonotic. |
| Miscellaneous udder/skin conditions | + | (+) | (+) | No | Troublesome and best avoided. Some are zoonotic. |
| Venereal campylobacteriosis | ~ | + | (+) | No | Treatment probably more cost-effective than laboratory tests, although not 100% effective especially in older bulls. |
| Trichomoniasis | ~ | ~ | (+) | No | Probably absent from UK, but check imported bulls and remain vigilant. |
| Tuberculosis | (+) | ~ | (+) Skin test | No | Increasing incidence in UK making the introduction of infected cattle into a herd more likely than in the past. Consider isolation and private testing. |
| Brucellosis | ~ | ~ | + | No | Present in Northern Ireland but absent from Great Britain except for a small outbreak in 2003. |
| <i>Neospora caninum</i> | ~ | ? | (+) | No | Problematic, epidemiology complex and not fully understood. Consider not retaining calves from seropositive cows and not introducing seropositive cows or youngstock into a herd. Antibody titres wax and wane, likely to be highest around time of calving. Control dogs on farms. |
| Other exotic diseases, e.g. | | | | | |
| Foot-and-mouth disease | + | ~ | + | No | Major threat if national biosecurity is breached. |
| Contagious bovine pleuropneumonia (CBPP) | (+) | ~ | + | No | Threat if national biosecurity is breached. |
| Enzootic bovine leukosis (EBL) | (+) | ~ | + | No | Threat if national biosecurity is breached. |
| Warble fly | (+) | + | + | No | Threat if national biosecurity is breached. |

CMT, California mastitis test; ELISA, enzyme linked immunosorbent assay; SAT, serum agglutination test.

+, Indicated; (+), possible benefit; ~ not indicated.

Note: All animals entering a herd should have a period in isolation; this is assumed in the table.

Service (BCMS). Introduced in 1998, it gave British farmers, for the first time, information on the origin and movement of all cattle they may be considering purchasing. This allows some assessment of disease risk to be made based on the animal's movement history. This can be enhanced by declarations of health status by farmers, supported where applicable by veterinary certificates and copies of laboratory test results. In future, there may be an opportunity to include health information on cattle passports, including vaccination history and the health status of all herds in which the animal has previously resided.

Herd biosecurity: where is the final frontier?

For many years, efforts to use biosecurity principles to control diseases of cattle in the UK were largely confined to control and eradication of statutory diseases. Cattle imported into the UK were required to be kept in official quarantine premises before being allowed to move to the destination farm. The general attitude therefore was that the frontier was the UK border.

When the single European Market came into force in January 1993 the quarantine requirement was dropped and it became much easier to import cattle, not only from other EU member states but also elsewhere. It was only then that farmers started to realize that 'The farm gate is the frontier' (Taylor, 1994b). That principle still holds today, 'The primary frontier for disease control must be the farm boundary' (Gibson & Andrews, 2000).

Responsibility for biosecurity at farm level is the joint responsibility of the farmer and his veterinary surgeon. However, prior to the outbreak of FMD in the UK in 2001, only a small number of herds were members of voluntary non-statutory cattle health schemes such as the Premium Cattle Health Scheme and Herdcare. Standards for such schemes are set by the Cattle Health Certification Standards (CHeCS), which is a self-regulatory body established in 1999 by the UK cattle industry. The CHeCS technical document (Anon, 2000) includes rules on biosecurity, which are mandatory for members in the accreditation and screening and eradication programmes and are recommended as good practice for all cattle herds. Other high status herds include commercial bull studs, which operate under EU Directives and UK Regulations (Barrett, 2001b).

The 2001 FMD outbreak in the UK brought home to the whole cattle industry the absolute necessity of good biosecurity to control the spread of the disease. In this outbreak, there was very limited airborne spread of the virus. The initial spread was due to movement of

animals, but even when animal movements were banned in the early days of the outbreak, the disease continued to spread due to movement of people and vehicles (Gibbons *et al.*, 2001). Increasingly stringent rules were introduced in the worst affected areas and it was only when these rules were rigidly enforced that the spread of the disease was stopped.

Elimination of the FMD virus from the UK and the EU does not, however, reduce the need for good biosecurity. On the contrary, it emphasizes the need for continued vigilance so that the impact of any future outbreaks of disease, whether at farm, local or national level, is kept to a minimum.

Conclusions

In an ideal world all herds would be maintained as closed units of known and preferably high health status, with the introduction of genetic material only by the use of AI and ET following strict quality control standards to minimize the disease risk. However, we do not live in that world. We live in a world of widespread, frequent, long distance transport of animals and animal products, often with little regard for biosecurity. Nevertheless, there is a lot that can be done, even on commercial units, to manage and reduce the risk of infectious disease.

The principles of biosecurity are applicable at some level to all cattle units and each and every one stands to gain by the implementation of a specific tailor-made biosecurity plan. However, it is important for veterinary surgeons to evaluate the risks of various hazards on each cattle enterprise and use this to design and implement an appropriate biosecurity risk management plan specific to the individual farm.

Introduction

What does the word ‘immune’ mean? The derivation of the word stems from ‘exempt from burden’. In reality the word was coined to explain what we now term immunological memory. Populations, both human and domestic stock, suffered and continue to suffer from epidemic disease; the old observation was that individuals recovering from a clinical syndrome were ‘exempt’ at the appearance of the next epidemic.

This ability of the vertebrate immune system to ‘remember’ a previous exposure to a foreign or non-self material is at the very heart of preventive medicine. The response is normally termed an *adaptive immune response*. This is in contrast to the *innate immune response* which covers the mechanisms pre-existing within an individual. The division between these two main areas of the immune system is not absolute; there is much interaction and interdependence between effector mechanisms in both camps. What do we mean by effector mechanisms? The term usefully describes the sharp end of the immune response: the antibody that actually causes the destruction of a bacteria, the cell that actually destroys another, but potentially malignant, cell.

There are three other broad concepts to consider at an early stage. First, the immune response can itself be harmful. The millions of individuals suffering from allergy will know this fact only too well. The second main concept is one of specificity/recognition. The immune system is exquisitely specific and has the ability to recognize millions of different combinations

of molecules that make up the myriad of different types of ‘non-self’ material that individuals are exposed to constantly. These are termed *antigens*, each site on the antigen that retains the ability to be recognized by the immune system being termed an *epitope*. Note the use of the word ‘non-self’; this is a useful term as ‘self’ means the immune system has lost the ability to recognize that particular antigen within an individual and therefore the latter remains free of potentially harmful effector mechanisms. Unfortunately this protection can break down leading to an increasing plethora of autoimmune disease. The third main concept is the division of both the acquired and innate immune response into *cellular* (e.g. lymphocyte, etc.) and *humoral* (e.g. antibody, etc.) components.

A study of immunology as it relates to bovine medicine is artificially skewed towards two of the four main areas that cause sickness/death: injury and infection. The other two main areas are degenerative disease and cancer but these are problems of the older individual; subsequently defence mechanisms against these latter two are not as important within a population, such as cattle, with a fast turnover of generations.

The majority of the mechanisms, both cellular and humoral, that make up the ruminant immune system are common to all mammals. The highly developed mammalian immune system is the culmination of evolutionary pressures with effector mechanisms that are traceable in the lower animal kingdom. However, there are aspects of this mammalian immune system that are specifically enhanced and specialized within ruminants (such as the passive transfer of lactogenic antibody). These differences will be discussed within the relevant sections. An important conceptual point to get across early on is one of balance between two conflicting points of view. On one side is the animal trying to preserve its integrity against a variety of potential pathogens by utilizing the effector mechanisms themselves comprising the innate and adaptive immune response. On the other side are the organisms that are trying to survive in the face of these mechanisms, relying on a fast turnover of generations and natural selection. This balance is at the heart of almost all host-pathogen interrelationships. With cattle and intensive

husbandry we are tilting this balance in favour of the organism and allowing them to replicate and cause diseases such as mastitis, enzootic pneumonia, etc. Intensive husbandry is here to stay for production reasons and we will have to turn to artificial means to restore the balance. This scenario will involve research to ascertain which 'batch' of effector mechanisms is applicable to a particular pathogen, and then how can we artificially boost this immunity.

Innate immunity

These immune mechanisms pre-exist in an individual and are not improved by repeated infection. Like acquired immunity they can be divided up into humoral and cellular components.

Humoral

Complement

The word 'complement' is a collective term for 15 or so plasma proteins (enzymes) which can be activated sequentially into functional units that then have three major effects:

- (1) Production of peptides which are active in inflammatory processes.
- (2) Production of C₃b which, by its ability to 'opsonize' micro-organisms or other particulate matter, is a powerful incentive for phagocytosis.
- (3) Attachment to cell membranes to create lysis and destruction of the target.

After immunoglobulins, albumin and transferrin, C₃ is the most abundant of bovine serum proteins (in excess of 1 mg/ml).

How is complement activated? The combination of immunoglobulin with antigen will often cause activation, but enzymes such as trypsin and bacterial components such as endotoxin will all activate complement. The normal route of activation by such agents is termed the *classical pathway* and as far as the antibody-antigen reaction is concerned it relies on the availability of the Fc portion of the antibody molecule. In the cow it used to be thought that of the two major subclasses of IgG (IgG₁ and IgG₂) only IgG₁ could fix complement by this route. Recent research using a homologous bovine IgG₂/complement system, has clearly shown that both subclasses can fix complement. Another pathway of complement activation is via the *alternative route*. This is a more primitive pathway and does not require the Fc portion of the antibody and can indeed be activated by antibodies such as IgA which is not effective by the classical route. Certain isolates of *E. coli* and virus-infected cells can all set the alternative

pathway going, an important point in assessing complement as a defence mechanism.

Lysozyme and other serum proteins

Lysozyme, a protein with a molecular weight of approximately 14000, is highly active against bacteria and is found in many biological fluids and is sometimes called the 'natural antibiotic'. It is not often realized that Fleming discovered both penicillin and lysozyme!

Neutrophils can be stimulated to produce lactoferrin. This protein works by competing with bacteria for the available iron molecules. Milk contains approximately 6 mg/ml.

Acute phase proteins appear within hours of tissue damage or infection. The best known one is C reactive protein which binds to phosphorylcholine on the surface of certain bacteria thus promoting phagocytosis by complement fixation.

Interferon (IFN)

These glycoproteins are a family of cell-regulating proteins produced by many cell types in response to stimuli. Although viruses are well known as interferon (IFN) inducers, others include endotoxin, bacteria and a variety of other antigenic stimuli. Interferons are classified as follows:

- (1) IFN- α is produced by leucocytes.
- (2) IFN- β is produced by fibroblasts.
- (3) IFN- γ is produced by T lymphocytes.

Interferon offers a rapid protection to viral infection. It induces an antiviral state in cells by firstly triggering a receptor (IFN- $\alpha\beta$ share a receptor, IFN- γ remains separate). This stimulates the cell itself to produce proteins to block the transcription of viruses, so protecting them from infection.

Interferon can be produced within hours of stimulation and the antiviral state can last several days. Interferon also has a number of other effects both on the immune system (such as stimulation of cytotoxicity and increased expression of major histocompatibility complex (MHC) products), as well as other functions such as cell division.

All three types of bovine IFN have now been genetically engineered and are being investigated for their potential as therapeutic agents. There may well be a role in diseases such as enzootic calf pneumonia.

Cellular

Phagocytic cells

These include neutrophils, macrophages and other cells of the reticuloendothelial system. Free-living bacteria

are fairly easy to kill without antibody or complement, but bacterial pathogens such as streptococci with large capsules can alter the surface tension between the phagocyte and the bacteria so preventing phagocytosis. It is for this reason that specific antibody and/or complement is needed to 'coat' or 'opsonize' the bacteria, altering the surface tension and allowing phagocytosis to proceed. Bovine neutrophils and macrophages/monocytes have C₃ and Fc membrane receptors. Cattle have unusually high numbers of monocytes in circulation.

The phagocytic cells have several agents such as acid hydrolases, peroxidase and cationic proteins which can kill micro-organisms after phagocytosis. The cationic proteins come into play first when the pH goes up and in fact these mechanisms are now thought to be at least or even more important than the traditional peroxidase-dependent pathways involving H₂O₂.

Several pathogens such as *Brucella abortus*, *Salmonella* spp., *Listeria* spp. and *Mycobacterium* spp. can live intracellularly and thus pose a problem for the immune system. The solution is by activation of the macrophage, usually by specific protein messengers released especially by T lymphocytes, called cytokines. Activated macrophages are basically a lot 'meaner', more efficient and, for example, contain more lysosomes; they are quite capable of dealing with these more awkward pathogens.

We must also consider another vital, indeed pivotal, role for macrophages. This is one we term *antigen presentation*. These antigen presenting cells (APCs) are found throughout lymphoid tissue, the archetypal one being the Langerhans' cell in the skin. Other specialized APCs are found in the gut, respiratory tract and mammary gland. These cells basically phagocytose the antigen, process it and then deliver it as a neat package to lymphocytes of the immune system. They combine this 'antigen presentation' with MHC products on their membrane and by the release of a soluble mediator such as interleukin-1 (IL-1).

Natural killer (NK) cells

It is only in the last five years or so that natural killer or NK cells have come into their own. They are basically lymphocytes with a separate lineage from T and B lymphocytes. The genealogy of NK cells remains unclear: they share membrane determinants with both monocytes and lymphocytes. They have Fc receptors and are quite large cells, often with noticeable granules. Two fascinating things about NK cells are that: (i) they pre-exist within individuals and do not require antigenic stimulation; (ii) they can kill innumerable targets from virus-infected cells to tumour cells without the need for antibody. Therefore, they could operate a type

of 'policing' role within the body, ready to destroy spontaneous tumour cells when they arise or help clear up virus infections. Cattle have NK cells, although the term almost certainly covers a heterogeneous population. Natural killer cells can easily be recruited (stimulated by cytokines such as IFN and IL-2). Interestingly in cattle, NK activity is quite low in stock reared outside in extensive systems but is often very high in intensive systems. Whether this is caused by the greater prevalence of microbial infection in such individuals is not clear.

Natural killer activity can also be down-regulated by agents such as prostaglandins. Do NK cells have any *in vivo* relevance? They certainly will kill virus-infected cells such as IBR-infected fibroblasts and tumour cells, but the real clinical relevance requires further research.

Acquired immunity

Humoral

Acquired humoral immunity is mediated through immunoglobulin, or antibodies as they are commonly known. These are a group of glycoproteins that have combinations of incredible variety and specificity. The basic units are two identical polypeptide chains, termed light chains, linked to two further identical polypeptide chains, heavy chain, by several disulphide bonds (Fig. 58.1).

The Fc portion of the molecule is responsible for linking to the Fc receptor on leucocytes, while the other end, Fab, carries the actual antigen-combining site itself. This latter site is also called the hypervariable region simply because it is variation in amino acid sequence in this region that produces the incredible diversity of antibodies.

An explanation of the plethora of titles that accompany a description of immunoglobulins is given in Table 58.1.

IgM

IgM has five of the basic units forming a pentamer structure and represents an early stage in the evolution of antibodies. All vertebrates (with the exception of cyclostomes such as the lamprey) have an IgM closely resembling that of mammalian IgM except for the number of units polymerized into the complete molecule. The level of IgM in normal cattle is in the range of 2–3 mg/ml from the age of 4 months. Levels of IgM in calves is complicated by the amount absorbed in colostrum. The actual amount in bovine colostrum is about 6 mg/ml which drops to approximately 0.1 mg/ml in milk. Interestingly the bovine fetus is quite capable

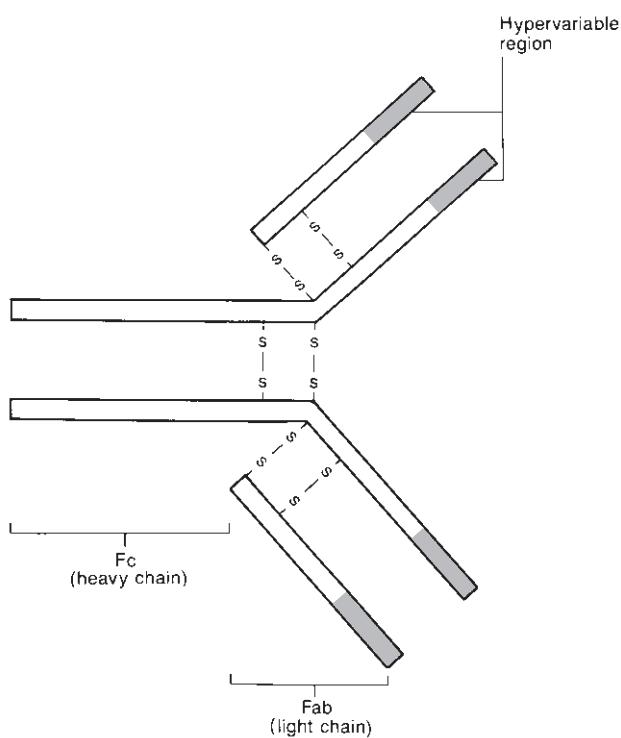

Fig. 58.1 Descriptions used for immunoglobulins.

Table 58.1 Descriptions used for immunoglobulins.

| | |
|----------|--|
| Class | Five major classes are distinguished in mammals: IgM, IgG, IgA, IgE and IgD. These are distinguished in structure and major variations within the heavy chains. |
| Subclass | Several of the individual classes are further split into subclasses, e.g. IgG ₁ and IgG ₂ . These are very similar in structure, but vary in the amino acid sequence of the heavy chain. |
| Allotype | This is a term used to refer to genetic variation within a given animal species involving alleles at a given locus; the variants normally occur within heavy chains. Allotypes in domestic animals could well be linked to disease resistance/production efficiency. |
| Idiotype | This term describes the product of a single clone of B cells, a unique antibody with a unique antigen combining site. Monoclonal antibodies consist of a single idiotype. |

of producing IgM from about the third or fourth month of gestation.

It is, of course, well established that in a primary immune response the major antibody produced early on is IgM. What is not so well recognized is that certain antigens can bypass many of the normal T cell interac-

tions and stimulate B cells directly. Such antigens, including bacterial lipopolysaccharides, normally stimulate only IgM production. The efficacy of specific IgM should not be underestimated. Not only is IgM highly efficient at aggregating antigen, it can bind with the secretory component (see below under IgA) and act as a protective antibody at mucosal surfaces. In diseases, such as *Escherichia coli* enteritis in calves, IgM has been shown to be a major protective mechanism.

In cattle suffering from infection with trypanosomes, IgM levels can rise in serum to over 20 mg/ml, although the majority of this overproduction is not particularly useful against the trypanosomes. On the other hand, in bovine leukaemia IgM levels can fall quite dramatically.

IgG

IgG predominates over other immunoglobulin classes in serum and contributes in excess of 85 per cent of all circulating immunoglobulins. Its structure is based on the usual immunoglobulin model, and it has a molecular weight of approximately 180 000.

IgG occurs in two subclasses: IgG₁ and IgG₂. Adult serum contains approximately 11 mg/ml of IgG₁ and 9 mg/ml IgG₂. In colostrum the figure is well in excess of 50 mg/ml IgG₁ and 3 mg/ml IgG₂; this reflects the incredible selective concentration of IgG₁ in colostrum (more details are given in the section Maternal immunity, p. 1002). Twenty-four hours after successful suckling the calf has approximately 20 mg/ml IgG₁ and 1 mg/ml IgG₂, underlining the obvious and often reiterated importance of successful colostral transfer.

As mentioned above, both subclasses can fix bovine complement; IgG₁ somewhat more so than IgG₂. As for their reaction with leucocytes exhibiting Fc receptors, a somewhat paradoxical situation exists. In experiments involving freshly purified monocytes or neutrophils, IgG₂ was always much more efficient at mediating phagocytosis or antibody-dependent cell-mediated cytotoxicity (ADCC). Yet IgG₁ is the predominant subclass that the calf receives from the dam.

In the cow and calf IgG₁ has a highly significant presence at the mucosal surfaces. While IgA is the predominant immunoglobulin in nasal secretions in the adult, IgG₁ is the predominant immunoglobulin in the calf up to at least the 6th week of life. In the lower respiratory tract, for instance the bronchoalveolar secretions, IgG₁ becomes the dominant immunoglobulin in all ages. Even infections at mucosal surfaces will produce high levels of circulating and specific IgG₁ equal to those achieved by intramuscular injection. When one considers that the main site of the IgG₁ synthesis is in the respiratory tract mucosa, it underlines the important potential of this immunoglobulin subclass in local defence mechanisms.

IgA

IgA is recognized as a major immunoglobulin associated with mucosal surfaces. It is basically a dimer (consisting of two of the basic units) joined by another molecule called the J chain (molecular weight of approximately 15 000). This structure is combined with a secretory component (molecular weight of approximately 60 000) to form secretory IgA or SIgA for short.

Individuals with mucosal surfaces have to have a selective system that can decide which antigen to ignore and which to respond to. It is not in the animal's interest to respond to dietary antigens, although of course this can occur, leading to disease. Conversely the mucosal immune system must be able to respond quickly and effectively against a pathogen. One of the most important mechanisms in this decision-making process is distinctive epithelial cells called 'M cells' that overlie Peyer's patches and other mucosal lymphoid aggregates. These cells have a tubulovesicular system with pits in the lumen surface and cytoplasmic processes on the opposite surface enfolding lymphocytes and other mononuclear cells. These cells can actively 'sample' the micro-environment within the lumen and pass information on to the proactive cells of the lymphoid system.

The stimulation and subsequent expansion of the plasma cells that are responding to a particular antigen take place within the local lymphoid tissue itself. These IgA-producing cells migrate to the submucosa where they assemble and secrete the complete dimer and J chain. The epithelial cells on the microvilli have a receptor for IgA on their internal side that is probably the secretory component itself. The whole molecule, now the complete SIgA, is transported across the cell in endocytic vesicles and discharged into the mucus itself. This process can also take place in the liver where hepatocytes can make secretory component; therefore bile has high levels of SIgA.

What is the function of the secretory component? It can be found free within normal gut contents or saliva, with large amounts in the newborn calf when very little IgA is being produced. It seems to increase the resistance of the complete SIgA to proteolytic enzymes, although there is little evidence for any direct antipathogenic role. One of its major roles may be to help anchor the SIgA on the mucous layer on top of the epithelium, creating a high concentration of antibody activity at this crucial site.

The IgA part of the SIgA is not particularly effective at 'traditional' roles of antibody such as opsonization, aggregation and complement fixation. Its major, and highly successful role, is simply to block adherence. Micro-organisms *must* attach before penetration of mucosal barriers, e.g. the filamentous K antigen of *E.*

coli. So by a simple steric hindrance such microbes are unable to attach and are excreted.

This local stimulation does underline the necessity to consider vaccination via a local mucosal route when dealing with diseases where a major defence mechanism involves secretory immunoglobulin. Many of the currently successful vaccines are given via the mucosal route and even more are under active research.

Another property of IgA lies in the dimer itself rather than the complete SIgA, or as one famous immunologist put it 'IgA can be more important beyond its laudable but essentially unglamorous role in intestinal sanitation'. Thus, if a dietary or microbial antigen penetrates the mucosal barrier, a high-affinity IgA attaches to it. There is no complement fixation or inflammatory process, so the whole complex is carried off in the blood to the liver where the IgA dimer reacts with the secretory component on hepatocytes with subsequent release into bile.

IgE

This immunoglobulin was first described for humans in the mid 1960s, and is sometimes called the reaginic antibody. It is, of course, associated with immediate hypersensitivity reactions. The structure of IgE is based on the usual immunoglobulin model but has a higher molecular weight than IgG (196 000 as compared with 180 000). This is due to an additional structure in the heavy chain, which is thought to help in the high affinity this immunoglobulin has for Fc receptors on mast cells. IgE normally exists in very low concentrations in serum (e.g. 20–400 ng/ml in dogs). Reliable and specific reagents are not yet available for the cow but by sensitive *in vivo* tests like the passive cutaneous anaphylaxis (PCA) test, potent IgE-like activity can be demonstrated in cattle.

The antigens that can elicit a specific IgE response are called allergens. The allergens are processed in the normal way and plasma cells in lymph nodes local to the area through which the allergen gained access, produce the specific anti-allergen IgE. Mast cell precursors also migrate to the lymph node and they take up the IgE via their Fc receptors. The mast cells now coated with the IgE migrate back to areas underlying the skin and/or mucosal surfaces. When the allergen again gains access it reacts with the IgE and this causes the mast cell to release the contents of its granules, a whole range of pharmacologically active substances. These latter include 5-hydroxytryptamine, histamine, prostaglandins and cytokines such as eosinophil chemotactic factor. The outcome is smooth muscle contraction, increased permeability of capillaries and, through the chemotactic agents, migration of leucocytes. In fact the latter function is a component of the mechanisms

that 'dampen down' the reaction: eosinophils contain many factors such as phospholipase D and histaminase that will inactivate the products of the mast cells.

Although such IgE reactions are considered a real clinical nuisance both by humans and their animals, there must have been an evolutionary advantage to develop and then retain this hypersensitivity reaction. One clue for this is a possible mechanism against parasites, especially intestinal nematodes. Although there is a lot of experimental evidence in rodents, using parasites such as *Nippostrongylus brasiliensis*, there is some evidence for nematodes of ruminants such as *Haemonchus* spp. The antiparasite mechanism works by antigens secreted by the nematode (often those associated with their mouth parts) being recognized as allergens by the host. This results in suitably and specifically sensitized mast cells migrating back to the gut. When the worm feeds again the freshly released allergens activate the mast cells. The resultant smooth muscle contractions, and increase in permeability allowing through other factors such as IgG, and the possible direct action of the mast cell mediators themselves, cause a mass expulsion of the worms. Prostaglandin might be one of the important effector mechanisms. A lot of research needs to be done to extend our knowledge of this intriguing immunoglobulin before it could be confidently stated that it is a main mediator of intestinal immunity.

IgD

A brief and quite basic chapter such as this cannot go into details of this immunoglobulin which, although presumed to occur in the cow, has yet to be convincingly demonstrated. IgD is linked to B lymphocytes and appears on the surface of B cells after the initial expression of IgM. The IgD will co-express with IgM and subsequently other immunoglobulin classes. The IgD is lost when the B cells respond to antigen by differentiating into immunoglobulin-producing plasma cells or memory B cells. The exact role of IgD remains unclear.

Cell-mediated immunity

This is an often used 'catch-all' phrase that by strict definition could cover most of the immune system. Early on in fetal development the ubiquitous haemopoietic stem cells produce two distinct progenitors: a common myeloid and a common lymphoid. It is the eventual offspring of the latter cell population that are often considered to constitute cell-mediated immunity.

The lymphoid progenitors produce several different populations of lymphocytes. The rapid development of

monoclonal antibodies has meant a highly specific and accurate assessment of these lymphocyte subpopulations. These are in today's parlance called CD (or cluster determinant) markers, each CD classification describing an identifiable membrane molecule which helps identify subpopulation. The major groups of lymphocytes to consider are:

- (1) T lymphocytes, especially the major subsets coded for by the CD4 (T helper) and CD8 (T cytotoxic) markers.
- (2) B lymphocytes; lymphocytes involved in delayed-type hypersensitivity.
- (3) An increasingly well-researched group of lymphocytes lacking the classical T and B cell markers. The average human adult has about 10^{12} lymphoid cells, representing approximately 20 per cent of all leucocytes.

T lymphocytes

The thymus is central to immunological function. The T-cell precursors migrate there from the bone marrow via the blood. The thymus extends a complicated but highly effective 'education' of these immature T cells, after acting through a cascade of thymic-derived hormones such as thymosin and thymopoietin. The precursor T lymphocytes undergo about eight to ten cell divisions before they leave the thymus. A lot of the cells die within the thymus (maybe up to 90 per cent) and it would be a neat solution to claim that this is how the host rids itself of all potential self-reactive lymphocytes. Unfortunately there is much conflicting evidence as to how exactly the thymus does its job.

What is certain is that when the lymphocytes eventually leave the thymus they can be classified as CD4+ve or CD8+ve cells, two populations that are mutually exclusive in peripheral blood. The lymphocytes have an amazing ability to migrate from blood to secondary lymphoid tissue (within lymph nodes, spleen, gut, skin, respiratory tract, etc.) and often back again to blood. This thorough 'mixing and movement' of lymphocytes is essential for them firstly to respond to antigen when it first appears, and then to be able to contact other cells with a view to initiating and finally curtailing an immune response. T lymphocytes tend to mass into their own areas within secondary lymphoid tissues, quite distinct from B lymphocytes.

CD4 T cells are often called 'helper T cells', which does underlie their important role. The antigen-presenting cells or APCs are responsible for the initial processing and presentation of antigen to the CD4 cells. The latter then further present the antigen to other lymphocytes such as the CD8 population and B lymphocytes. The whole business of presentation is not only

dependent on cytokines such as IL-1 and IL-2 but it is also MHC-restricted at the class II level. Crucial to the immune reaction is the T-cell receptor (TCR). The identification of the TCR remained a mystery until a few years ago when the TCR was shown to consist of two chains which clearly belong to the immunoglobulin supergene family. This structure is closely linked to another CD marker: CD3. The human immunodeficiency virus (HIV) preferentially binds to CD4 cells and it is the gradual destruction of this population that is an important factor in the marked immunosuppression that is such a feature of HIV infection.

The CD8 population is also MHC restricted but at the MHC class I level. This is useful as a major function of CD8 cells is cytotoxicity. Like other T cells, CD8 cells are highly specific for antigen, and for cytotoxicity to occur the CD8 cell needs to recognize antigen and MHC. As most body cells express MHC class I then any cell expressing say a virus antigen could be attacked and destroyed by the appropriate CD8 effector cell. In cattle diseases such as *Theileria parva* or IBR infection, these CD8 effector cells, or cytotoxic T lymphocytes (CTL), have been shown to be important.

A single CTL can kill several individual target cells and there is evidence that in virus infection, for example, recognition and then destruction of the target cell can occur before fully infectious virus is assembled inside the cell. The molecular basis behind the actual destruction itself remains poorly understood. Certainly it is vital to have the all-important recognition and close contact. The killing probably involves the release of more than one soluble 'mediators'.

B lymphocytes

B cells develop initially in the fetal liver but production then shifts to the bone marrow. The pre-B cell has IgM heavy chains within the cytoplasm. On a commitment to B cell lineage the B cell acquires surface IgM, the initial antigen receptor. A second phase of development allows the B cells to express immunoglobulins of a different class or subclass (plus IgD). On meeting its pre-ordained antigen the B cell retains only the immunoglobulin it is programmed actually to produce and then enters the terminal stage of immunoglobulin-secreting plasma cells. A proportion of the antigen-specific cells remain as an enlarged population of memory cells.

Although B and plasma cells produce the immunoglobulins, they are under the tight control of the CD4 helper T cells for the majority of antibodies; a proportion of T-independent antigens can avoid this control but at a cost of only IgM production and no immunological memory.

Maternal immunity (see p. 211)

This is an important area for cattle. In the harsh economics of farm animal practice, death in the neonate is a major problem, and the passive protection provided by the mother is vital. Ruminants have five tissue layers between maternal and fetal circulation, so there is little or no transfer of immunoglobulin during pregnancy.

In bovine colostrum the level of IgG is up to a massive 75 mg/ml with 4 mg/ml IgA and 6 mg/ml IgM. Why does the neonate actually need all this antibody? The newly born calf has a somewhat limited capacity to mount a fully effective immune response. It can produce IgM and some IgG₁ at birth; from 36 hours old it will start producing a lot of IgG₁ at a rate of approximately 1 g/day (depending on antigenic challenge). From one to two weeks SIgA starts production and it is several weeks before IgG₂ production starts in earnest.

The neonate is thus basically immunocompetent but has not 'tuned' its immune system to deal with the environment, and it is in this period of tuning and massive primary antibody responses that the neonate needs passive protection. How does this concentration of immunoglobulin in the bovine colostrum occur? The major constituent of the immunoglobulins in colostrum is IgG₁ which is selectively transferred from serum. For example, a sheep can produce up to 2500 g of colostrum in the first 48 hours after parturition of which 90 g will be IgG₁. When one considers that the concentration of IgG₁ in her own serum is probably less than 0.015 g/ml, it is a major transfer. This transfer of IgG₁ occurs via receptors on the heavy chain which binds to the acinar epithelial cells. This receptor interaction is under hormonal control and only occurs during late pregnancy. There is no such selective concentration for the much smaller amounts of IgG₂, IgM and IgA.

The specificity of the immunoglobulins is also of obvious importance, not only reflecting the microenvironment of the dam herself, but also as a result of deliberate immunization policy. The neonatal calf has a greatly increased intestinal permeability due to specialized epithelial cells capable of pinocytosis. These cells are activated by the presence of macromolecules and eventually slough off after releasing their contents into the circulation. This spontaneous closure starts in the calf at 12 hours postparturition with a mean complete closure time of approximately 30 hours. Degradation of this colostrum in the neonatal calf is minimal because it contains a trypsin inhibitor, and pancreatic activity itself is low. Abomasal pH is between 6 and 7 due to the delayed development of parietal cells, but by 36 hours postparturition the pH has dropped to between pH 3.0 and 4.0, and pepsin is then active. A final point con-

cerning immunoglobulin in colostrum/milk is that in some diseases in cattle, such as rotavirus in calves, the passive protection is better obtained by the *ingested* immunoglobulin rather than systemic immunoglobulin being re-excreted into the gut. Therefore, it would make more sense to feed diluted colostrum from vaccinated dams during the first week of life rather than relying totally on the protection acquired passively during the first 24 hours of life.

As well as the immunoglobulins in colostrum there is a high concentration of other effector proteins such as lactoferrin. In addition, there are leucocytes, with the macrophage and other mononuclear cells predominant in the resting mammary gland and at parturition. During lactation, however, the predominant leucocyte is the neutrophil, possibly reflecting the constant, although usually non-clinical, bacterial presence. The importance of leucocytes in mammary secretions is as yet unclear for the neonate, but of obvious use for the mammary gland itself; the area of local and effective immunity in the working mammary gland will continue to be a goal for researchers.

Homeostasis and stress (see Chapter 67)

In any book involving diseases of cattle, environmental stress must be a major consideration. Every living organism in an effort to cope with its environment attempts to reach *homeostasis* which can be defined as the steady state achieved by the optimum action of physiological regulation. Stress can be achieved by changes in the animal's environment such as restraint, handling, housing, weather, etc. Although there are many definitions of stress, one of the most useful is 'the cumulative response of an animal resulting from interaction with its environment via receptors'.

This is therefore an adaptive response and is primarily directed at coping with changes in the environment

and, perhaps most importantly it is to a large extent an *automatic* response. The response is switched on in three main areas:

- (1) A voluntary motor response, which operates via the lower brain centre → spinal cord → peripheral nerves and results in fight/flight, etc.
- (2) The adrenal medulla. This works via the autonomic nervous system and adrenal medulla releasing catecholamines, inducing the alarm reaction.
- (3) The hypothalamus, which is probably the most important for cattle.

This latter mechanism involves the neuroendocrine system, with the hypothalamic stimulating adenohypophysis, which in turn stimulates (via ACTH) the adrenal cortex, which releases cortisol. The latter hormone has an alarmingly high number of effects such as vasoconstriction in skin and intestine, vasodilatation in muscles, raising blood glucose, raising pain threshold, reducing secretions, etc. The integrity of lysosomal membranes is enhanced by cortisol, so although phagocytosis of bacteria and other particulate matter still occurs, it is more difficult for the enzymes to be released from the lysosomes into the phagosomes. Clinically this can manifest itself as muscle weakness, trembling, impaired immune response, poor wound healing, weight loss, etc. Cortisol normally inhibits the production of adrenocorticotrophic hormone (ACTH) in a feedback mechanism; however, this latter mechanism can be overridden by highly stressful conditions.

Summing up this section: the body attempts to respond to stress by a variety of means to restore homeostasis. These responses evolved to occur in an open environment where the individual can move, seek shelter, etc. But in a crowded calf pen there is no escape, the stress conditions remain with the inevitable consequences.

There are many vaccines available for use in cattle in the UK and worldwide. This chapter is an attempt to summarize some of those available.

Definitions

Vaccination is the introduction of a vaccine into the body to produce immunity to a specific disease. The vaccine may be administered by subcutaneous, intra-dermal or intramuscular injection, by mouth, by inhalation (intranasal) or by scarification.

Vaccine

A vaccine is a suspension of attenuated or killed micro-organisms administered for the prevention or treatment

of infectious disease. In cattle practice a vaccine should produce herd resistance to minimize the economic effects of infectious diseases. They are usually administered to healthy animals. There are various types of vaccine.

Modified live vaccines (MLV): These produce high levels of immunity from a single inoculation. Their virulence is reduced by attenuation, which is achieved by either serially passaging the organism through tissue cultures or by genetic manipulation when those genes associated with virulence are removed. These types of vaccine induce immunity by causing a mild infection in animals, often showing mild disease signs and occasionally causing unwanted side-effects.

Inactivated vaccines: These are killed vaccines; the infectious agent is inactivated but retains its antigenic properties, although these are often weaker than live preparations. As a result, two inoculations are needed initially to provide adequate immunity. The antigenicity is often enhanced by using various adjuvants. These adjuvants may cause a local reaction at the site of the injection.

Genetically modified vaccines: These are vaccines where specific genes have been removed or added to the DNA of the infectious agent. Apart from the attenuation of vaccines these techniques have enabled the development of marker vaccines. These are useful in distinguishing between vaccine protected and infected animals.

Autogenous vaccine: This is a vaccine prepared from cultures of material derived from a lesion of the animal to be vaccinated.

Toxoid: This is a toxin that has been treated by heat or chemical agents to destroy its deleterious properties without destroying its abilities to stimulate the formation of antibody.

Serovaccine: This is a combination of an antiserum with a vaccine to produce passive and active immunity.

Anthrax (see p. 717)

Many types of vaccines are available internationally. No commercial vaccine is currently available in the UK. The disease is notifiable and DEFRA should be contacted if emergency supplies of this vaccine are needed. The vaccine that was available was a live vaccine prepared from a suspension of living spores of an encapsulated strain of *Bacillus anthracis*. The vaccine was stable for long periods.

Vaccines have been produced by overcoming virulence using saponins or saturated saline to delay absorption (Carbozo vaccines). In the UK the Stern vaccine contained an avirulent strain.

Dosage and administration

A dose usually of 1 ml is given by subcutaneous injection. This confers an immunity in seven to ten days that lasts for nine months. Annual booster doses are recommended except in areas of increased risk when they should be given at six-monthly intervals.

Contraindications

The use of antibiotics should be avoided from shortly before to 14 days after vaccination to avoid any interference in the production of immunity. Animals in the last stages of pregnancy should not be vaccinated unless there is a serious risk of infection.

There may be a slight reaction at the site of injection and animals may have a mild pyrexia for one to two days and milk yield may be depressed. These side effects will subside.

Empty or part-filled vials must be destroyed by incineration.

Other vaccines

Another vaccine incapable of producing disease is a cell-free filtrate of a culture of a non-encapsulated spore-forming strain of *B. anthracis*. This requires two injections to produce immunity but it is long lasting.

Clostridial disease (see pp. 719, 725, 733)

The clostridial organisms are common and responsible for many serious diseases in cattle (see Table 59.1). Vaccines against these diseases are available individually, for example blackleg and tetanus, but they are often combined as polyvalent vaccines. In general, the vaccines are prepared from formalin-killed cells adsorbed on to aluminium hydroxide producing a

Table 59.1 *Clostridium* spp. and disease syndromes in cattle.

| Causative organism | Disease |
|-------------------------------------|-------------------------------------|
| <i>Cl. chauvoei</i> | Blackleg Postparturient gangrene |
| <i>Cl. septicum</i> | Braxy |
| <i>Cl. novyi</i> type B | Black disease |
| <i>Cl. haemolyticum</i> type D | Bacillary haemoglobinuria |
| <i>Cl. tetani</i> | Tetanus |
| <i>Cl. botulinum</i> | Botulism |
| <i>Cl. perfringens</i> (welchii) | Enterotoxaemia |
| Mixed species of <i>Clostridium</i> | Gas gangrene |

toxoid. Vaccines for *Cl. chauvoei* are often a mixture of formalin-killed cells and a purified toxoid.

Dosage and administration

Usually 2 ml is give by subcutaneous injection. The initial course is two inoculations separated by four to six weeks followed by an annual booster unless there is great risk, when it should be every six months.

Specific vaccines

Blackleg (see p. 723): If this disease is identified at pasture then cattle should be removed from the pasture until the vaccination course is complete. Some veterinarians give a concurrent dose of long-acting procaine penicillin at the same time as the initial vaccination to avoid further disease outbreaks during the period of developing immunity.

Tetanus (see p. 733): Immunity usually lasts for three years following an initial course of vaccination and one annual booster. For especially valuable animals, there is a tetanus vaccine that carries a minimum risk of hypersensitivity; whilst primarily designed for horses it can be used in cattle. It is prepared from purified tetanus toxin converted to toxoid by treatment with formalin and then adsorbed onto aluminium phosphate. A polyvalent vaccine that is commonly available contains the following organisms: *Cl. chauvoei*, *Cl. septicum*, *Cl. novyi*, *Cl. haemolyticum* and *Cl. tetani*. It seems eminently sensible to use a polyvalent vaccine such as this instead of an individual vaccine since all these diseases occur commonly.

Botulism (see p. 721): Vaccination is practised in enzootic areas with either a combined *Cl. botulinum* types C–O or a type-specific toxoid vaccine.

Salmonellosis (see also Chapter 15)

Many species of *Salmonella* can cause disease in cattle, e.g. *S. dublin*, *S. typhimurium*, *S. newport* and *S. arizona*. The two commonest species in the UK are *S. typhimurium* and *S. dublin* and these can be endemic in a herd. The so-called exotic *Salmonella* species are not usually endemic.

Live vaccine

A live *Salmonella dublin* vaccine prepared from an avirulent strain (HWS 51) used to be available in the UK. It was a freeze-dried vaccine, which was reconstituted immediately before use. This vaccine was very effective both in calves and in adults. It was especially useful in controlling the disease in the face of an outbreak.

Inactivated vaccine

An inactivated vaccine containing *S. dublin* and *S. typhimurium* is licensed in the UK and can be used in the face of a disease outbreak. When the disease has been confirmed, all at-risk stock not showing overt clinical salmonellosis can be vaccinated. Calves are given a 2 ml dose subcutaneously and can be vaccinated from 21 days old. A second dose must be given after 14–21 days. Adult cattle require a 5 ml dose; again this is repeated after 21 days.

Pregnant cows should be vaccinated six and three weeks before calving. All cows that have not calved within eight weeks of the second inoculation should be vaccinated again three to four weeks before calving. This will then confer passive immunity to the calves via the colostrum.

Risks

A small number of animals may not show an adequate response to vaccination. Ideally, healthy animals should be vaccinated. Adequate immune levels will not be reached until two weeks after the second injection. Avoid stress when vaccinating pregnant cows or abortion or metabolic disease may occur.

Serovaccines

Commercial serovaccines have been available containing mixed antisera to *S. dublin* and *S. typhimurium* together with polyvalent strains of *E. coli* and *P. multocida*. These are designed to give passive immunity to calves for prophylaxis and treatment of enteric and pneumonic infections caused by *E. coli*, *S. dublin*, *S. typhimurium* and *Pasteurella multocida*.

Dosage and administration

For prophylaxis in calves, up to 20 ml is given subcutaneously and repeated at 10–14-day intervals during the period of risk. For therapy up to 40 ml is given subcutaneously and repeated at 24 hours if required. In the author's experience these products are not always cost-effective.

Neonatal calf diarrhoea

Neonatal calf diarrhoea is a multifactorial disease complex involving managemental and infective factors. Several bacteria, viruses and protozoa are associated with the disease, for example enterotoxigenic *E. coli* (ETEC) (see p. 201), *Salmonella* spp. (see p. 215), rotavirus (see p. 191), coronavirus (see p. 199) and cryptosporidia (see pp. 204, 282). Pathogenic infections with *E. coli* are most common in the first four days of life, whereas rotaviruses are most pathogenic from 7–14 days and coronavirus causes disease from 7–21 days. Vaccines are available (Table 59.2) and are very successful in practice; they contain inactivated strains of bovine rotavirus with coronavirus and *E. coli* K99 antigens. It is important that the *E. coli* component contains both K99 pilus antigen and K99 capsular antigen. The K99 antigen enables *E. coli* to adhere to the villi of the calf's small intestine where rapid bacterial multiplication causes the production of toxins that are responsible for the diarrhoea.

Dosage and administration

The pregnant cow is vaccinated between 12 and 4 weeks of the expected calving date. Calf protection is dependent upon the calf receiving adequate (3 litres) colostrum within the first six hours of life. They must then continue to receive colostrum or milk from vaccinated cows for the first two to three weeks. This is no problem in the suckler herd. In the dairy herd, milk from the first six to eight milkings should be collected, pooled and stored in a cool place. The calves should then be fed, according to size, 2.5–3.5 litres/day of this milk for the first two weeks of life. In a seasonal calving dairy herd with a close calving pattern it is common practice to vaccinate one cow in four and use her colostrum and milk for the calves. However, the best results are achieved if all the cows in the herd are vaccinated; in this way infection and the level of excretion of infected organism are kept to a minimum.

Oral vaccines have been used and are available in some countries (for example the USA). They are combined MLV of rotavirus and coronavirus and must be given as soon as possible after birth. The suggestion that colostral antibody may interfere with these oral

Table 59.2 Neonatal calf diarrhoea vaccines available in the UK, 2003.

| Vaccine | Manufacturer | Type of vaccine | Dosage and administration | Vaccination programme | Duration of immunity |
|----------------|-----------------|--|---------------------------|---|---|
| Lactovac | Intervet | Inactivated strains bovine rotavirus (str 1005/78 and Holland), bovine coronavirus (str 800) <i>E. coli</i> K99 and F41 | 5 ml sc | 2 doses 4–5 weeks apart to pregnant cows and heifers, 2nd dose 2–3 weeks before calving | Single annual booster given 2–6 weeks before calving |
| Rotavec K99 | Schering-Plough | Inactivated strains bovine rotavirus, <i>E. coli</i> K99 | 1 ml sc in neck | Single injection 12–4 weeks before calving | Single annual booster |
| Rotavec Corona | Schering-Plough | Inactivated strains bovine rotavirus (str UK – Compton) serotype G6P5 bovine coronavirus (str Mebus) <i>E. coli</i> F5 (K99) | 2 ml im in neck | Single injection 12–3 weeks before calving | Single annual booster |
| Trivacton 6 | Merial | Inactivated strains bovine rotavirus, bovine coronavirus <i>E. coli</i> – enterotoxigenic (ETEC) strains K99, F17 (= Y), F41 – septicaemic strain 31A | 5 ml sc | 2 doses to pregnant cows and heifers, 1st dose 4–8 weeks precalving, 2nd dose 2–4 weeks later – at least 2 weeks before calving | No data but suggested annual single dose booster given 2 weeks before calving |

All these vaccines depend upon the calf receiving passive immunization from the cow via the colostrum – adequate colostrum must be fed for at least 10–14 days.

im, intramuscular; sc, subcutaneous.

vaccines has cast doubt on their effectiveness. The *in utero* vaccination of the fetus has been achieved experimentally with some success, but this is not a practical method at present.

Serovaccines containing mixed antisera to *E. coli*, *Salmonella dublin* and *Salmonella typhimurium* used to be available and details of their use can be found under salmonellosis in the first edition of Bovine Medicine.

Respiratory disease

Bovine respiratory disease complex (see Chapter 17)

Bovine respiratory disease complex (BRD) is a multi-factorial disease which can be summarized as follows. The disease complex is triggered by various stresses such as transport, housing, the weather, general cattle handling or by immunosuppression by bovine virus diarrhoea virus (BVDV). These stresses lead to infection by primary pathogens which cause lung damage and disease. These primary pathogens are bovine respiratory syncytial virus (BRSV), parainfluenza-3 virus (PI3), infectious bovine rhinotracheitis virus (IBR) or *Mycoplasma bovis*.

Following these primary pathogens, damaged lungs are invaded by secondary bacterial pathogens of which the principal organism is *Mannheimia haemolytica* (formerly *Pasteurella haemolytica*) which causes severe lung damage, pneumonia and even death. Further bacterial involvement follows, usually *Pasteurella multocida* and *Arcanobacterium (Actinomyces) pyogenes*, resulting in chronic lung pathology.

BRD can be controlled by the strategic use of vaccines. There are many and those that are available in the UK are summarized in Table 59.3. Often the use of one or two vaccines is sufficient to control the disease.

PI3 and IBR

There are individual live vaccines available against PI3 and IBR. These are freeze-dried preparations which are administered intranasally. The calf is held with its head inclined and the 2 ml reconstituted dose is instilled into one nostril. A short time is allowed for the vaccine to flow into the upper respiratory tract where it stimulates the development of local immunity (IgG) in the upper respiratory mucosa. These vaccines are temperature specific and will not replicate at the high temperatures of the inner tissues. The live PI3 vaccine can be used in the face of an outbreak as a therapeutic agent.

Table 59.3 Vaccines against BRD complex available in the UK, 2002.

| Name of vaccine | Company | Type of vaccine | Method of administration | Vaccination programme | Comment | Duration of immunity |
|--------------------------------|----------|---|--------------------------|---|--|--|
| Bayovac IBR-Marker Vivum | Bayer | Live IBR marker (gE negative) | in im | Calves from 2 weeks of age 2 doses 3–5 weeks apart (1 × in, 1 × im) Calves from 3 months of age 2 doses 3–5 weeks apart (2 × im) | Intranasal dosage if specific local protection needed in acute infections For use in herds with uncertain infection status and new reactors | Booster every 6 months |
| Bayovac IBR-Marker Inactivatum | Bayer | Inactivated IBR marker (gE negative) | sc | Cattle from 3 months of age 2 doses 3–5 weeks apart | For use in non-infected herds | Booster every 6 months |
| Bovilis IBR | Intervet | Live avirulent strain of IBR virus | in (preferred) or im | From 4 weeks of age, 2nd dose at 12 weeks or single dose from 12 weeks | Full protection in 2 days (in), 7 days (im) | Annual booster |
| Bovilis IBR and PI3 | Intervet | Live avirulent strains of IBR and PI3 | in | From 4 weeks 2nd dose at 12 weeks or single dose from 12 weeks, special situation for early protection from 1 week | | Annual booster |
| Bovilis IBR-Marker | Intervet | Live IBR marker (gE negative) | in or im | From 2 weeks with second dose at or after 3 months, or single dose given if over 3–4 months old | | Booster every 6 months |
| Bovipast RSP | Intervet | Inactivated strain BRSV PI3 <i>Mannheimia haemolytica</i> serotype AI | sc | From 2 weeks of age 2 doses separated by 4 weeks | | BRSV – 5 months <i>M. haemolytica</i> 6 weeks |
| Immuresp | Pfizer | Live PI3 virus strain RLB 103 | in | From 3 weeks with second dose at 10 weeks or single dose after 12 weeks, special situation from 1 week | | |
| Immuresp RP | Pfizer | Live PI3 virus strain RLB 103 live IBR virus strain RLB 106 | in | From 3 weeks with second dose at 10 weeks or single dose after 12 weeks | | Animals may remain seropositive to IBR |
| Pastobov | Merial | Inactivated adjuvanted <i>Mannheimia haemolytica</i> type AI | im or sc | From 4 weeks with second dose 3–4 weeks later | | Booster dose before each risk period at least annually |
| Rispoval RS | Pfizer | Modified live bovine respiratory syncytial virus | im | From 7 days of age, repeat doses at intervals of 3 weeks and then at 16 weeks or over 16 weeks with second dose after 3 weeks | | |

Table 59.3 *Continued*

| Name of vaccine | Company | Type of vaccine | Method of administration | Vaccination programme | Comment | Duration of immunity |
|------------------------|------------|---|--------------------------|---|----------------------------|----------------------|
| Rispoval Pasteurella | Pfizer | Inactivated adjuvanted <i>Mannheimia haemolytica</i> biotype A serotype 1 | im | Single dose from 12 weeks of age | Full protection in 7 days | 4 Months |
| Rispoval 4 | Pfizer | Live strains of BRSV and PI3 virus inactivated adjuvanted IBR and BVD virus | im | From 3 weeks of age with 2nd dose 3 weeks later and 3rd dose at 12 weeks or from 12 weeks 2 doses 3–4 weeks apart | Full protection in 2 weeks | |
| Tecvax Pasteurella 1/6 | Vetoquinol | Inactivated <i>Mannheimia haemolytica</i> serotypes A1 and A6 | im | From 4 weeks, 2 doses separated by 3 weeks, vaccination of pregnant or lactating animals is not recommended | | 6 Months |
| Torvac | Vericore | inactivated adjuvanted BRSV | sc | Calves under 9 weeks 3 doses at 3 week intervals Calves over 9 weeks 2 doses 3 weeks apart | | |
| Tracherine | Pfizer | Live IBR virus strain RLB106 | in | From 3 weeks with 2nd dose at 10–12 weeks or single dose after 12 weeks | | Annual booster |
| Grovax | Intervet | Polyvalent serovaccine containing serotypes of <i>E. coli</i> , <i>Salmonella dublin</i> , <i>Salmonella typhimurium</i> , <i>Pasteurella multocida</i> (Roberts) type 1, 2, 3 and 4) | sc | Calves from 1–2 days old or on arrival also weaner calves Pregnant cows, dosages repeated at 10–14 days or 14 days before calving, provides active and passive immunity, increase dose to debilitated or infected calves | | |

in, intranasal; im, intramuscular; sc, subcutaneous.

Bovine respiratory syncytial virus (BRSV) and *Mannheimia haemolytica*

There are both live and attenuated vaccines available against BRSV.

Mannheimia haemolytica types A1 and A6 are the principal secondary invaders of damaged lung and also the most frequently isolated organisms from cases of

transit or shipping fever. *M. haemolytica* is a common commensal of the pharynx of normal calves. Stress and viral infection lead to the invasion of the lung by this organism. Multiplication of the organism causes the release of leucotoxin which lyses responding leucocytes with the corresponding release of toxic cytoplasmic proteins which cause further lung damage. There are vaccines available against *M. haemolytica*. They are

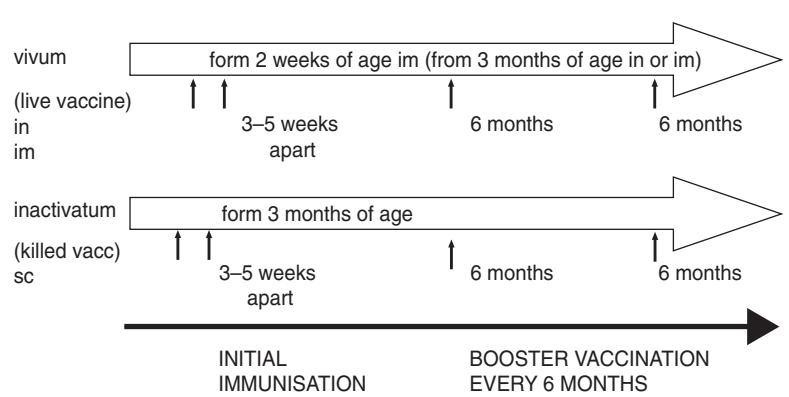

Fig. 59.1 The vaccination schedule with IBR marker vaccines.

inactivated, can be used at various ages and produce immunity of varying duration. They are all effective. Combined and multifactorial vaccines are also produced. The live vaccines for PI3 and IBR are combined. These are very useful and can be used in conjunction with the live BRSV vaccine to give a more complete cover. From Table 59.3 it can be seen that there are several multifactorial vaccines available. From the author's experience these are all very effective and a vaccination programme can be produced to cover most on-farm situations. It is important to be sure that full protection is in place before the period of stress or risk; for example, before the housing of spring born suckler calves and their dams in the autumn in the UK.

Infectious bovine rhinotracheitis (see p. 289)

Infectious bovine rhinotracheitis (IBR) is caused by bovine herpesvirus 1 (BHV-1) and is responsible for enormous economic loss in worldwide cattle production. BHV-1 is responsible for various clinical syndromes:

- Infectious bovine rhinotracheitis (IBR)
- Infectious pustular vulvovaginitis (IPV)
- Infectious balanoposthitis (IBP)
- Abortion
- Conjunctivitis and keratoconjunctivitis
- Meningo-encephalitis (now classified BHV-5)
- Enteritis
- Dermatitis

Vaccines against IBR have been available for some years and are listed in Table 59.3. Whilst they are useful for the protection of all ages of cattle, they will not protect cattle incubating the disease and animals may remain seropositive after vaccination. The latter point is important when the animal's disease status needs to be considered in the future, for example with the export of animals or in cattle health schemes.

The recent development of IBR-Marker vaccine is a real step forward in the control and eradication IBR.

The vaccine is based on a glycoprotein E (gE) deleted herpesvirus 1 strain. A killed virus as well as a modified live virus marker vaccine have been developed; this enables differentiation between immunized and BHV-1 infected cattle. The vaccine is based on the principle that animals do not form antibodies to the deleted glycoprotein whilst animals infected with the field strain do produce antibodies to gE. By using a gE antibody ELISA test, animals can be distinguished by testing serum or milk. This marker vaccine and the serological diagnostic kit can be used to eradicate IBR both on farms and nationally.

There are four steps to establishing an IBR-free herd:

- (1) *Determine the status quo* – all animals are tested using gE-ELISA to ascertain the serological status of the herd.
- (2) *Immunization* – all animals are vaccinated with the marker vaccine and so given protection against clinical signs (Fig. 59.1). Where there is an acute risk of infection the live vaccine should be used.
- (3) *Stabilization* – natural wastage steadily reduces the number of 'field virus' infected animals in the herd. The natural herd replacements are 'field virus' free.
- (4) *IBR freedom* – once the last serological positive animals leave the herd, the herd is IBR negative but protected by the vaccine.

***Haemophilus somnus* infection**

(see pp. 240, 737, 907)

Haemophilus somnus is considered by many to be the aetiological agent of *Haemophilus* septicaemia in cattle. The disease is recognized in the USA and also in the UK and Europe. A vaccine is available in America. It is a killed bacterin containing whole bacteria adhered on to an aluminium hydroxide adjuvant. It is administered by subcutaneous injection and two doses are given at a two to three week interval. Immunity is not long-lasting.

Various vaccination programmes have been tried in feedlot conditions and their efficacy is difficult to evaluate. Some success is claimed for protection in the face of an outbreak. No claims are made on the efficacy of the vaccine in the reproductive form of the disease.

Contagious bovine pleuropneumonia

(see p. 868)

Contagious bovine pleuropneumonia (CBPP) is a highly infectious disease causing septicaemia with localization in the lungs and pleura. It is common in many countries of the world. Control by vaccination is possible and several vaccines are available. They are all live vaccines and are considered by some people to be responsible for some spread of the disease. The vaccines (p. 873) available include the following:

- Pleural exudate from natural cases. This is not a satisfactory vaccine since it can cause severe reaction and spreads natural disease.
- Vaccines produced from culturing the organism *Mycoplasma mycoides* var. *mycoides*.
- Vaccines produced by attenuating the organism in avian egg cultures.

Administration

Vaccination in the tail is the route of administration using a high pressure syringe. Severe reactions can occur in the tail, both generalized and localized. Intranasal vaccination is now being developed with some satisfactory results. Antimycoplasmal drugs should not be used during vaccination as they will possibly reduce the immune response. However, if the side-effects are very severe then treatment may be essential. The immunity to the vaccine varies from six to ten months for some of the cultured broth vaccines to three to four years for the avian egg attenuated vaccines. All vaccines against CBPP are light susceptible and should therefore be stored in the dark.

Parasitic bronchitis

(see p. 272)

There is a very successful oral vaccine available. It is a live vaccine consisting of an aqueous suspension of third-stage infective larvae of *Dictyocaulus viviparus* partially inactivated by exposure to ionizing radiation. Each dose contains at least 1000 irradiated larvae (see p. 274).

Administration

Each dose comes in a bottle that should be shaken well and the contents then given orally. Calves should be at

least eight weeks old when dosed and a second dose is given four weeks after the first. Calves should not be exposed to any potential source of lungworm infection for at least two weeks after the second dose. During the following grazing season exposure to lungworm infection reinforces this initial immunity. Vaccinated stock should not be grazed with unvaccinated animals or follow behind unvaccinated stock in a grazing system since any increase in pasture lungworm burden may cause a vaccine breakdown. Only healthy calves should be vaccinated. Careful consideration should be given to calves suffering from any respiratory disease before dosing. It is advisable not to use any other live vaccine for a period of two weeks either side of vaccination.

The use of anthelmintics should be avoided for at least two weeks after the second dose, particularly the use of sustained-release boluses. Similarly, the use of any avermectin must be avoided for eight weeks before and ten days after the dosing regimen is complete. The routine use of other anthelmintics and parasiticides must also be avoided for seven days before and at least ten days after treatment. This is due to the residual effects of modern anthelmintics.

Following vaccination it is not uncommon for there to be transient periods of coughing; this occurs after some seven to ten days. Indeed on rare occasions vaccination can initiate an outbreak of calf pneumonia by activating latent infection (see p. 239).

It has been suggested that where ivermectin is used to control lungworm and gastrointestinal worms in a control programme then cattle may enter the second grazing year with no immunity to lungworm. In this case vaccination against lungworm may be carried out before the second grazing season. This is a suggestion only as, at present, no trial work on this has been carried out.

Bovine virus diarrhoea

(see pp. 579, 853)

Bovine virus diarrhoea virus (BVDV) is widespread throughout the UK. At the present time there are two vaccines available (see Table 59.4), both containing inactivated strains of BVD virus, and one combined vaccine where inactivated BVDV is combined with IBR, PI3 and BRSV (see Respiratory disease on p. 1007).

BVDV is endemic in the UK and in many if not most countries of the world. The arrival of the inactivated BVDV vaccines has allowed the development of control programmes. The BVDV status can be established by the ELISA testing of bulk milk or blood samples and the results of these tests can direct the control/vaccination strategy. Table 59.5 shows the interpretation of bulk

Table 59.4 Bovine virus diarrhoea vaccines available in the UK, 2003.

| Vaccine | Company | Type of vaccine | Route of administration | Vaccination programme | Duration of immunity |
|-------------|----------|---|-------------------------|--|--|
| Bovidex | Vericore | Inactivated non-cytopathic strain of BVDV | sc | Two doses 3 weeks apart, to protect the fetus the vaccination programme should start in the 3 months prior to service and be completed 1 week before service | 14 Months – booster vaccination recommended annually |
| Bovilis BVD | intervet | Inactivated cytopathogenic BVD virus strain C86 | im | From 8 months of age 2 doses 4 weeks apart; fetal protection if primary inoculation is at least 4 weeks before gestation | Annual |
| Rispol 4 | Pfizer | See Table 59.3 | | | |

im, intramuscular; sc, subcutaneous.

Table 59.5 Interpretation of bulk milk BVDV serology and appropriate action. (After Pritchard, 1998.)

| Category | OD ratio | Approximate % seropositive | Interpretation | Action |
|--------------|-----------|----------------------------|--|--|
| Negative | <0.10 | <5 | Naive | Maintain high level of herd biosecurity; test all new arrivals in herd; monitor herd every 3 months; vaccinate if biosecurity poor |
| Low positive | 0.10–0.35 | <25 | Basically naive; few older animals immune | As above; test pooled samples from 1st and 2nd calved cows; if naive, vaccinate them |
| Mid positive | 0.35–0.70 | 25–65 | Some naive animals (probably youngest half of herd); some immune animals (probably older cows) | |
| Positive | >0.70 | >65 | Likelihood of PI animals increases with increase in OD ratio | Check for active Infection by checking each age group; bulling heifers using paired serology of 6 animals; 1st, 2nd, 3rd calvers using pooled milk samples; vaccinate whole herd if active infection found |

OD, optical density.

milk serology and possible action to be taken. Serology in BVD-positive herds (suckler or dairy) interpretation and action are given in Table 59.6.

In all circumstances if herd biosecurity is poor consider vaccinating the whole herd. After several years of vaccination the older cows, some of which would be persistently infected, will have left the herd and the temptation would be to stop vaccinating. If this happens the herd soon becomes naive and unprotected. Under these conditions there must be complete confidence in the biosecurity of the herd or regular booster vaccination must continue. In Europe and the USA live vaccines, which have originated from strains of cytopathic BVDV, are in use and there is evidence that these vaccines can precipitate mucosal disease.

Johne's disease (see p. 857)

Vaccines are available for the control of the disease. Two vaccines are commonly available: the Vallee vaccine, which contains live *Mycobacterium paratuberculosis* organisms in a paraffin oil/pumice stone vehicle, and the Sigurdsson killed vaccine. In the UK the only vaccine available contains live non-pathogenic strains of *Mycobacterium avium* subsp. *paratuberculosis*. This vaccine is only available from the Veterinary Laboratories Agency in Weybridge. The vaccine causes interference in the interpretation of the tuberculin test. It causes a positive reaction to tuberculin, particularly to the avian component. It obviously also causes a positive reaction to the Johne's intradermal test where it is used.

Table 59.6 Results of cohort serology in BVD positive herds. (After Pritchard, 1998.)

| 9–18 m Heifers | 1st Lactation cows | 2nd Lactation cows | Interpretation and action |
|----------------------|----------------------|----------------------|--|
| All negative | All negative | Some or all positive | Active infection unlikely unless 1st lactation cows are recently calved; PI animals probably died or culled from herd; monitor 1st lactation cows – maintain biosecurity |
| All negative | Some or all positive | Most or all positive | Active infection (acute infection/PI animals in milking herd but no PI heifers): (1) vaccinate heifers (2) test milking herd for PI animals |
| Some or all positive | Most or all positive | Most positive | Active infection in herd, as above; PI animals present in heifers: (1) screen heifers for PI animals (2) test milking herd for PI animals (3) vaccinate herd |

PI, persistently infected.

The vaccine is given to calves under one month of age. It is given by subcutaneous injection, usually in the dewlap. The dewlap is used as an injection site because the vaccine usually produces a localized reaction; indeed such a reaction should be looked for two weeks after inoculation as it indicates that the vaccine has 'taken'. Johne's disease vaccine has a very short shelf life of 14 days.

Rinderpest (see Chapter 43d; pp. 707–10)

Vaccination against this disease is common practice in areas where it is endemic. There are several good vaccines available and in theory complete eradication is possible with a vaccination programme.

Tissue culture vaccine

Attenuated vaccines manufactured from cell culture have largely replaced other attenuated vaccines. They are safe and effective and produce a long-lasting immunity suitable for all cattle.

Goat-adapted vaccine

This is an attenuated vaccine that produces life-long immunity. It is useful for Zebu-type cattle. It is a fairly virulent vaccine, which produces severe generalized reactions in susceptible stock. The signs seen are severe gastroenteritis with high temperatures and loss of milk.

Rabbit-adapted vaccine

This vaccine produces a good immunity that lasts for two years. It can be attenuated to a point where it will

not cause severe side reactions, but then is not effective in Zebu-type cattle.

Chicken embryo vaccine

A cheap, stable and safe vaccine that is unfortunately difficult to manufacture and produces variable degrees of immunity.

Measles vaccine

Measles, rinderpest and distemper are antigenically related and human measles vaccine will produce good immunity to rinderpest in all ages of cattle. It is especially useful in very young calves, which can be vaccinated at an earlier age than with normal vaccines. Measles vaccine is not affected by the calf's colostral immunity.

Brucellosis (see p. 580)

Abortion and infertility in cattle caused by *Brucella abortus* can be very successfully controlled by vaccination. There are two vaccines available, strain 19 (S19) and strain 45/20 (45/20). Once eradication is in progress the use of either is limited or prohibited as it interferes with the interpretation of blood and milk antibody tests.

Strain 19 vaccine

S19 is a live vaccine and is presented in freeze-dried form, which is reconstituted with diluent immediately prior to use.

Dosage and administration

The dosage is 5 ml given subcutaneously. It can be given to any age of stock from two months of age onwards. The ideal time is in calves from two to six months of age; at this time it confers a good immunity for approximately seven years.

Inoculation of adult cattle is very successful in controlling severe outbreaks of abortion. In an infected herd the incidence of abortion will begin to subside 40–60 days after vaccination and most herds will be free of infection within two years.

Bulls should not be vaccinated with S19; it does not seem to protect them from infection and has been known to be responsible for the development of an orchitis with *Brucella abortus* S19 present in the semen.

Side-effects

Vaccination reactions: Localized swellings at the site of injection can occur, especially in adult cattle. These reactions are sterile, do not rupture and persist for many months as fibrous nodules. Generalized systemic reactions can also occur with high temperatures and loss of milk in lactating cows. Heavily pregnant cows have been known to abort and should not be vaccinated. Idiopathic gonitis (see p. 458) may be caused by vaccination.

Serological reactions: Following vaccination the serological titres can remain very high for a long period of time and therefore they can interfere with the interpretation of serological testing in an eradication programme. The complement fixation test becomes negative sooner than the serum agglutination test and can be used to identify a post vaccinal reaction from an uninfected cow.

Zoonotic risk: The vaccine is live and accidental injection into cattle handlers and veterinary surgeons can cause severe illness (undulant fever) and so great care must be taken when handling the vaccine.

Strain 45/20 vaccine

Strain 45/20 is a killed vaccine.

Dosage and administration

Two inoculations are given by subcutaneous injection to animals over six months of age. There are often large localized reactions at the site of injection. Although said to be non-agglutinogenic there is usually a rise in serum titres, but these are such that they

never reach conclusive levels. Brucellosis has been eradicated from many countries by a programme of initial vaccination followed some years later by serological screening.

Louping-ill (see p. 770)

A vaccine is available for use in cattle in tick-infested areas where louping-ill is a problem. It is an inactivated tissue culture vaccine prepared from the arbovirus and is a thick oily emulsion.

Dosage and administration

A dose of 2 ml is given subcutaneously. Because of the thickness of the vaccine, prewarming can facilitate its use. This prewarming must not exceed 37°C for 30 minutes because the vaccine is heat labile. Initially, two inoculations are given, not less than three weeks and not more than six months apart, with annual boosters. The initial course should be completed at least two weeks before exposure and in pregnant cows before the last month of pregnancy.

Accidental injection of the vaccine into the operator can cause severe localized reactions and immediate medical attention should be sought. The oily vehicle can sometimes cause localized vaccination reactions in animals, which may persist for some time.

Papillomatosis (warts) (see p. 883)

Autogenous vaccines can be prepared for the treatment of warts in individual animals. In the author's opinion their efficacy is doubtful as warts have a tendency to regress spontaneously. Individual vaccines can be prepared by removing 5 g of the lesion from the animal, grinding it up and extracting the virus using glycerine. After sterilization the autogenous vaccine is administered to the affected animal in two doses, one month apart.

Erysipelas (see p. 455)

Erysipelas is a rare disease of cattle but has been associated with clinical arthritis of calves and isolated on post mortem from adults. In an outbreak of disease, vaccination is possible using the available porcine vaccines. The vaccine is killed and produced from cultures of *Erysipelothrix insidiosa* inactivated with formalin and adsorbed on the aluminium hydroxide gel.

Table 59.7 Vaccines against leptospirosis available in the UK.

| Vaccine | Company | Type of vaccine | Route of administration | Vaccination programme | Duration of immunity |
|-------------|-----------------|--|-------------------------|--|--|
| Leptavoid-H | Schering-Plough | Formol killed <i>L. interrogans</i> serovar <i>hardjo</i> | sc neck, chest wall | For vaccination against <i>Leptospira interrogans</i> serovar <i>hardjo</i> , <i>prajitno</i> and <i>Leptospira borgpetersenii</i> serovar <i>hardjo bovis</i> ; two doses 4–6 weeks apart completed before period of risk; calves from 5 months old | Annual; give booster before period of risk, maternal immunity interferes before 5 months so if very young calves are vaccinated the complete course must be repeated at 5 months |
| Spirovac | Pfizer | Inactivated <i>L. borgpetersenii</i> serovar <i>hardjo</i> | sc neck | For vaccination against leptospirosis caused by <i>Leptospira borgpetersenii</i> serovar <i>hardjo bovis</i> ; 2 doses 4–6 weeks apart before period of risk, calves from 4 weeks old | Annual; give booster before period of risk |

sc, subcutaneous.

Dosage

A dose of 2 ml is given by subcutaneous injection. Two doses are given, separated by two to six weeks. If pregnant cows are vaccinated, with a second dose being given three weeks before the expected calving date, then there is good passive immunity in the calves via the colostrum.

Leptospirosis (see p. 735)

Leptospira serotypes are found in all farm animals; they are distributed worldwide and are an important zoonosis. In cattle the important species are *Leptospira interrogans* serovar *hardjo* (*hardjo prajitno*) and *Leptospira borgpetersenii* serovar *hardjo* (*hardjo bovis*) of which *L. borgpetersenii* serovar *hardjo* is the predominant strain. It is only recently, using genetic typing techniques, that the strains previously classified as *hardjo prajitno* and *hardjo bovis* have been identified as separate species. They are both responsible for abortion and they have been identified as one cause of the milk drop syndrome and can also be involved as a cause of infertility. In the UK there are two vaccines available, both are inactivated. These vaccines are summarized in Table 59.7.

When planning a vaccination programme ideally cattle should be vaccinated before the period of greatest risk, which in the UK is when they are out at grass. Cows in the UK should, therefore, be inoculated in the

spring before turn-out. If it is necessary to vaccinate a herd at other times of the year the first booster dose should always be given the following spring and thereafter repeated annually. Calves can be vaccinated, but if they are less than five months old then a further initial course must be given after five months as maternal antibodies may interfere with their immune response. All stock (including bulls) of unknown leptospiral immune status which are brought into a vaccinated herd should be isolated, treated with antibiotics and vaccinated. Antibiotics are used to remove leptospiral infection from the kidneys. The recommended antibiotic is dihydrostreptomycin at a dosage rate of 25 mg/kg (not currently available in the UK) or amoxycillin at a dosage rate of 15 mg/kg of the long acting preparation. Ideally the new stock should be kept isolated until seven days after the second vaccination.

It has been suggested that the two vaccines are not compatible and it is not possible to predict what protection will be afforded when there is a switch from one to another. Cows can be vaccinated during an outbreak to good effect; they are less likely to become infected and shed organisms in their urine. The time for immunity to develop and have its effect on the syndromes associated with leptospirosis varies:

- The response with milk drop is rapid.
- Abortions may continue for some months – as the incubation period associated with leptospiral abortion is 3 months.

- Infertility – once diagnosed as a cause of infertility the herd should be vaccinated as soon as possible but it can be 12 months for the full effect to develop.

Cattle that have been vaccinated may still be carriers of leptospires as a result of prevaccination infection and as such are still a zoonotic risk. They will also show positive to diagnostic serology, which may be important when cattle are to be exported or screened in a health scheme.

Mastitis

Coliform mastitis (see pp. 334, 383)

The development in the USA in the early 1990s of the *E. coli* J5 vaccine and its subsequent release in the UK in 2000 has been a great advance in the control of coliform mastitis. The principle of the J5 vaccine is the mutation of *E. coli* 0111:B4. This strain lacks the O antigen found in the outermost part of the cell wall and so the core polysaccharide antigen is exposed. This core antigen is strongly immunogenic and is common to many Gram-negative bacteria. The bacteria most often associated with coliform mastitis are *Escherichia coli*, *Klebsiella* species and *Enterobacter aerogenes*, but *E. coli* is predominant.

The vaccine is given by subcutaneous injection in the neck and three doses are recommended (see Fig. 59.2). The first dose is given to cows at drying off and heifers two months before calving. This is followed by a second dose four weeks later and a third dose two weeks after calving. The protection afforded by this regime increases with each inoculation and is 10 per cent, 30–40 per cent and 60–80 per cent, respectively. Field studies in the USA have demonstrated the value of this vaccine (see Tables 59.8 and 59.9). In another trial involving 845 cows over one year after vaccination relatively similar results were obtained (see Table 59.9).

The vaccine does not claim to totally prevent intramammary infection in the first 100 days of lactation, but it does significantly reduce the severity of

clinical signs. It is best considered as an aid to the control of coliform mastitis, but there will never be a substitute for good dairy cow management. The cost-benefit of its use has been assessed. Herd vaccination has been shown to be profitable when more than 1 per cent of cows in the herd are affected with clinical coliform mastitis.

Foot-and-mouth disease

(see Chapter 43c; pp. 700–707)

This is an acute and very contagious viral disease of cloven footed animals. The aetiological agent of foot-and-mouth disease (FMD) is a picornavirus of which there are seven serotypes and very many subserotypes (>80). The three commonest serotypes are A, O and C, whilst the others are SAT1, SAT2, SAT3 and Asia1. Vaccines are available and many cattle throughout the world are vaccinated. All the vaccines are produced from virus grown in tissue culture, on bovine tongue epithelia or more commonly on baby hamster kidney cells. The virus is inactivated using formalin or other agents and adjuvanted.

A single dose gives immunity in 7 to 21 days; this is followed by a booster after one month and then immunity lasts from four to eight months. Young stock can be vaccinated from a very early age (<3 months). However, if they come from vaccinated cows they

| | Vaccinated J5 | Non-vaccinated |
|--|---------------|----------------|
| No. of cows | 233 | 227 |
| No. of cows showing clinical coliform mastitis | 6 | 29 |
| Incidence (%) | 2.57 | 12.77 |

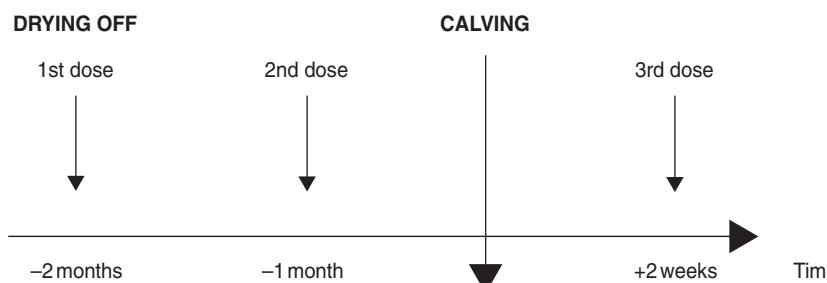

Fig. 59.2 Vaccination schedule for J5 vaccine.

Table 59.9 The number of coliform cases in 845 cows over a one-year period with or without use of the J5 vaccine.

| | Vaccinated J5 | Non-vaccinated (placebo) |
|--|---------------|-----------------------------|
| No. of cows | 424 | 421 |
| No. of confirmed cases of <i>E. coli</i> mastitis | 16 | 45 |
| Incidence (%) | 3.77 | 10.69 |

should be revaccinated again at four and five months and possibly again at six months of age. This is due to maternally derived colostral antibody.

The vaccines are usually marketed as monovalent vaccines, for example type A or type O. Ideally, the vaccine used should be homologous with the serotype or strain of the virus found in an outbreak. In many cases, where a new virulent subserotype is isolated the vaccine may be manufactured specifically from this locally isolated virus. In countries where more than one serotype causes disease then bi- and trivalent vaccines are used. Live vaccines are available but are not in common use since there is a narrow safety margin between loss of virulence and loss of immunogenicity.

Vaccination programmes

These need to be planned with specific local knowledge. In some countries adult stock are vaccinated annually and young stock every six months, whereas in others such as South America or Saudi Arabia all cattle are inoculated every four months or less.

Where an outbreak of FMD occurs within a disease-free area a ring vaccination policy can be employed to prevent the spread of infection – for example Holland in 2001. Following a single dose of vaccine, immunity will develop in 7 to 21 days, but if a high potency vaccine is used immunity to aerosol challenge can develop within four days. This immunity would be short lived but may be sufficient to control the disease for long enough to consider the next steps, which may be to give a second dose of vaccine or to slaughter out all the ‘ring vaccinates’.

Frontier vaccination can also be employed to prevent transmission from one country or area to another. A buffer zone is created between an infected and a non-infected area.

In Europe, in January 2000, a European vaccine bank was established to hold stocks of FMD virus antigen. Originally in three locations, but now in two, it holds in stock five million doses of type O Manisa vaccine. This

is considered to be sufficient for strategic vaccination purposes.

Disadvantages of vaccination

- (1) Current vaccines are sometimes not very effective. A high challenge may overcome immunity and there can be partial vaccination breakdown. This has occurred in Saudi Arabia where vaccinated animals were found to have oral lesions.
- (2) Symptomless carriers can occur, especially where the disease is very common.
- (3) It is difficult to distinguish the immune titre derived from vaccination from that produced by natural infection. It is possible, however, by measuring non-structural protein antibody which is produced in greater amounts following infection, but this is not always reliable.
- (4) Vaccination only protects against FMD for a short time (two to six months). The time varies with different vaccines and with individual response.
- (5) Repeated vaccination can lead to anaphylactic reactions in some cases, although the reported incidence is low.
- (6) On occasions following vaccination lesions similar to FMD may develop.
- (7) In an FMD-free country when vaccination is used to control and eradicate the disease then the time taken for international recognition of disease-free status is extended. There are agreed definitions for the designation of FMD disease-free status. These are laid down in Articles of the Office International des Épizooties (OIE). Many countries with endemic FMD have no alternative but to control the disease by mass vaccination.

Ringworm (see pp. 878–80)

A vaccine is available in Europe; it was originally developed in Russia. It is a live attenuated strain (LTF-130) of *Trichophyton verrucosum*, presented in a freeze-dried form. Calves as young as two weeks can be vaccinated. The inoculation is given by intramuscular injection; the neck is the recommended site and two doses are required, 10–14 days apart. Initially the whole herd should be vaccinated and then, in a closed herd, only the young calves need to be injected. All new animals introduced to the herd should be given a full vaccination course. Once vaccinated, booster injections are not required. Heavily pregnant cows (7 months +) should not be vaccinated. Occasionally a small crusty lesion may develop at the site of injection. Cattle infected with or exposed to ringworm should not be

vaccinated, as such animals can develop very severe signs of ringworm.

Rabies (see Chapter 70; p. 908)

Rabies is an invariably fatal neurotrophic disease of all warm-blooded animals. A vaccine is available, prepared from inactivated rabies virus adjuvanted with aluminium phosphate. It is used in dogs, cats and horses as well as cattle. Vaccination is advised from six months of age. The primary dose is given by intramuscular injection and boosters are given annually. Calves can be vaccinated from two months of age, but at this age a booster at six months of age is recommended. Immunity develops in 30 days. In cattle, treatment with rabies vaccine after exposure to infection is not successful as death usually intervenes before an effective immunity develops.

Other vaccines

Infectious bovine keratoconjunctivitis (see p. 921)

A vaccine against *Moraxella bovis* is available in some countries. It is made by exposing the pili of *Moraxella bovis* to high frequency sound waves (sonification) and is used to give passive protection. It is not available in the UK.

Bluetongue (see Chapter 43a; pp. 691–3)

Modified live virus vaccines against bluetongue virus are available in some countries. Ideally, the specific serotype vaccine should be used. The practice of using one serotype followed by a different serotype one month later is adopted and is more effective than using mixed vaccines. However, vaccination interferes with diagnostic serology used in health schemes and for export purposes.

Rift Valley fever (see pp. 769–70)

This is a condition found only in Africa, where vaccines are available. One vaccine is prepared from neurotrophic virus passaged through mouse brain. It is known to cause abortions. A killed vaccine is also available and is said to produce good immunity.

Vesicular stomatitis (see Chapter 43e; pp. 710–13)

Vesicular stomatitis (VS) is endemic in Central and South America and also occurs in the southern and western states of the USA. Its importance really lies in its confusion with FMD. Serologically there are two principal strains, New Jersey (NJ) and Indiana (IND). Modified live virus and formalin-killed virus vaccines are available against VS-NJ. The dead vaccine reduces clinical disease whereas the live vaccine conveys better immunity. Inactivated autogenous vaccines prepared from clinical outbreaks have also been used.

Introduction

The control of parasitic diseases in cattle, as with other domestic animals, relies heavily on the use of antiparasitic drugs. A vast array of drugs has been developed for their antiparasitic activity and these are often classified according to the target parasites they control. For the purposes of this chapter, parasites are classed as either internal parasites (endoparasites) or those on the outer body, the skin, dermal tissues or hair (ectoparasites). Endoparasites include a wide and diverse range of organisms from simple, single-celled protozoa through to large metazoan helminths.

Protozoan parasites are responsible for several major economic diseases globally and are classified into several main groups, the most important of which are the Sarcomastigophora (flagellates and amoebae) and Apicomplexa (coccidia). Protozoa are found in the blood, muscles, internal organs and the gastrointestinal (GI) tract of cattle. Antiprotozoal agents are generally referred to by target parasites and include anticoccidials, trypanocides, theilericides, babesicides, etc.

Helminths are divided into three main groups: roundworms (nematodes), which parasitize the GI tract and lungs, the flukes (trematodes), which parasitize the GI tract and liver, and the tapeworms (cestodes), which parasitize the intestines as adult stages or the muscles and viscera as larval forms. Drugs used in the treatment of helminth infections are generally referred to as anthelmintics, although these can be further subdivided into nematocides, flukicides or taenicides according to the target parasites they control. Some of the more

recently introduced anthelmintics have a broad spectrum of activity against a wide range of target helminth parasites.

The external ectoparasites affecting cattle are predominantly arthropods and include insects (flies and lice) and arachnids (ticks and mites). Ectoparasitic treatments (ectoparasiticides) can be classed as pesticides, insecticides or acaricides according to their activity. The more recent introduction of the endectocide antiparasitics, which have activity against both endo- and ectoparasites, has led to new approaches in the treatment and control of parasite infections.

ENDOPARASITICIDES

Anthelmintics

Anthelmintics are widely used in both the treatment and prevention of internal parasite infections of cattle. Their use has been documented from ancient times when it was first recognized that certain disease conditions were associated with parasitic helminth infections. Up to 1938, before the discovery of phenothiazine, few useful drugs existed for the treatment of nematode and trematode infections of domestic animals. Since then, and particularly over the last 30 years, considerable advances have been made in the development of safer and more effective drugs. Modern, highly effective anthelmintics with increased safety margins and ease of application have superseded the potentially toxic chemicals in use less than half a century ago. The introduction in 1961 of thiabendazole, the first of the benzimidazoles, saw the beginning of broad-spectrum anthelmintic therapy that has since led to the development of drugs with activity against GI nematodes, lung-worms, tapeworms and liver fluke. The discovery of the avermectins in 1976 has led to the subsequent introduction of a number of endectocidal compounds that has taken parasite therapy one step further.

Classification of anthelmintics

On the basis of chemical structure and mode of action, anthelmintics can be divided into several main groups

(Table 60.1). These include the broad-spectrum groups comprising the benzimidazoles (group 1), imidazothiazoles and tetrahydropyrimidines (group 2) and avermectins and milbemycins (group 3).

Broad-spectrum anthelmintics are highly effective against the majority of nematode species reported in cattle (Table 60.2). Some of the benzimidazoles may also have activity against liver fluke (*Fasciola hepatica*) and cestodes (*Moniezia* spp.). Avermectins and milbemycins (often collectively referred to as endectocides) are active against both endoparasites (nematodes and some larval insects) and certain ectoparasites (species of mites and lice) of cattle.

Narrow-spectrum anthelmintics are more specific in their activity, and are available specifically for liver fluke, although individual compounds may also have activity against some nematode species (Table 60.2). Anthelmintics in this group mainly belong to the salicylanilide and substituted phenol groups of che-

mical compounds, with the exception of cloresulon (available in combination with ivermectin) which is a sulphonamide derivative. Flukicides may be formulated with a broad-spectrum anthelmintic to increase their range of activity to include nematodes and flukes.

Benzimidazoles and probenzimidazoles (group 1-BZ)

Most anthelmintics available for cattle belong to a group of chemicals referred to as the benzimidazoles. Since their appearance in the early 1960s, the benzimidazoles have been subjected to continuous structural modifications to improve their safety and spectrum of activity. Thiabendazole was the first to be introduced in 1961 and was followed by parbendazole (1967), oxibendazole (1973), fenbendazole (1974), oxfendazole (1975), albendazole (1976), triclabendazole (1981) and ricobendazole [albendazole oxide] (1987). Three other chemicals, febantel, netobimbin and thiophanate, usually referred to as probenzimidazoles, are also included in this group because they are metabolized in the body by ruminal and hepatic pathways to active benzimidazole metabolites. Netobimbin is unusual because, as an ionic salt, it shows good solubility in water, which offers flexibility for its administration. The benzimidazole group is derived from substitution of various side chains and radicals on the parent benzimidazole nucleus, giving rise to individual members of the group. Modification of a particular benzimidazole can affect the pharmacokinetic behaviour of the drug through changes in relative insolubility, slowing the elimination of the parent drug and/or active metabolites (Fig. 60.1). The greater efficacy, and wider spectrum of activity, of the most recently introduced (second-generation) benzimidazoles appears to be due to the relative insolubility of

Table 60.1 Broad-spectrum anthelmintic groups.

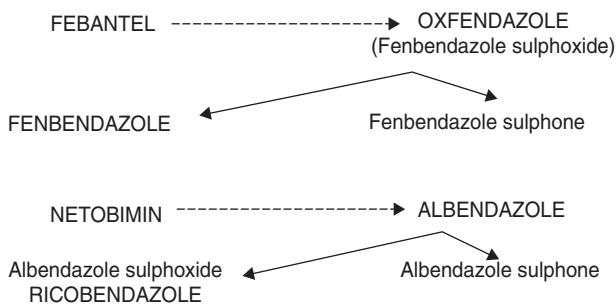

Fig. 60.1 *In vivo* metabolic pathways of the common benzimidazole and probenzimidazole anthelmintics in cattle.

these chemicals, which affects the absorption, transport, passage along the GI tract and metabolism within the host, and ultimately the final excretion of the anthelmintic compound from the host. The longer the persistence in the animal body, the more effective the anthelmintic appears to be.

Pharmacokinetics: Following oral drenching, benzimidazole anthelmintics usually pass to the rumen which acts as a reservoir, allowing gradual release and absorption of the drug into the bloodstream. Thereafter, concentrations of the principal circulatory metabolites can be found in the plasma from where they are extensively recycled between the circulation and the gut wall, along the whole length of the intestinal tract. Nematodes attached to the gut wall may be more exposed to the recycled drug than to a drug present in the digested food passing down the intestinal tract.

Host physiological factors may affect the efficacy of benzimidazoles administered orally. For example, the oral administration of anthelmintic solutions may result in closure of the oesophageal groove in some animals, with subsequent bypass of the rumen and delivery of the anthelmintic to the abomasum. From here absorption, metabolism and excretion of the drug may be rapid, resulting in reduced exposure of the parasite to the drug and lowered efficacy. In some disease and nutritional states, the pH of the abomasum may be altered. This may not only reduce exposure of parasites in the abomasum to some of the anthelmintics, but it may also reduce solubilization of relatively insoluble drugs and thus reduce absorption.

Benzimidazoles are highly effective against most of the GI nematodes of cattle. The range of activity of second-generation benzimidazoles available for cattle, notably albendazole, fenbendazole, netobimin, oxfendazole and ricobendazole (albendazole oxide), also includes arrested (hypobiotic) larvae of nematodes such as *Ostertagia* and also lungworms and tapeworms. Albendazole, netobimin and ricobendazole have activity against adult liver fluke at increased dose rates. Tri-

clabendazole lacks activity against roundworms and tapeworms but is highly effective against immature and adult liver fluke. All benzimidazoles and probenzimidazoles are ovicidal to nematode eggs. This group of chemicals is amongst the least toxic of all the anthelmintics available. However, several members of the group have been found to be teratogenic in cattle (parbendazole, oxfendazole, albendazole and netobimin) and therefore have limitations on their use in pregnant animals.

Benzimidazoles are poorly soluble and are generally given orally as a suspension or as an active ingredient in a bolus. Netobimin can be solubilized and administered via drinking water. Fenbendazole can also be incorporated into drinking water using specialized metering equipment. Benzimidazoles have also been incorporated into a range of controlled release devices, which will be discussed in more detail later (see section on Anthelmintic delivery devices; p. 1026); these include pulse-release devices, containing oxfendazole, and several sustained-release devices available in various countries that contain either fenbendazole or albendazole.

Mode of action: All members of the benzimidazole (BDZ) class have a similar mode of action and act by disrupting energy metabolism in worms by binding to parasite tubulin, a constituent protein present in microtubules (MT) and in plasma and mitochondrial membranes. The formation of MT is a dynamic process involving the polymerization of tubulin rings at one end (Fig. 60.2) and depolymerization at the other end. BDZ anthelmintics bind to β -tubulin causing capping and inhibition of further MT formation. The resultant effect is starvation of the parasite due to inhibition of glucose uptake, protein secretion and MT production. There is also a reduction in enzyme activity such as acetylcholinesterase secretion and in carbohydrate catabolism by the fumarate reductase system.

The mode of action of triclabendazole on *Fasciola hepatica* is at present unknown. It appears to have limited tubulin-binding properties, unlike other members of this group, and it must therefore act along alternative pathways.

Imidazothiazoles (group 2-LM)

The two anthelmintic drugs in this chemical group are tetramisole and levamisole. Tetramisole is a racemic mixture of dextro and levo forms; levamisole is the levo-isomer and it is with this form that anthelmintic potency resides. The dose rate of levamisole is therefore half that of tetramisole, and it has twice the safety index.

Levamisole has good activity against a range of adult and developing larval stages of GI nematodes of cattle, but not against arrested larvae. It is also highly

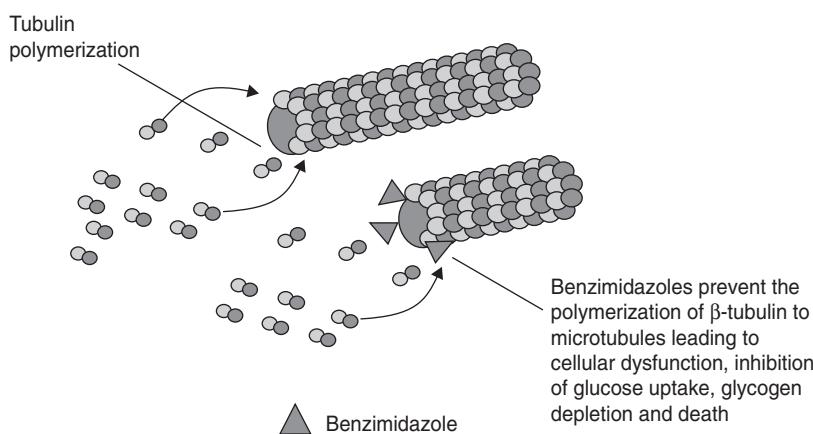

Fig. 60.2 Benzimidazoles – mode of action.

effective against lungworms. Unlike the benzimidazoles it is not ovicidal. Levamisole is non-teratogenic and is therefore safe to use in pregnant animals. The therapeutic index in relation to other anthelmintics is, however, low. Animals given levamisole may be hyperactive for a few minutes after receiving the recommended therapeutic dose. Toxic signs, due to a stimulant effect on nerve ganglia, may manifest as salivation, bradycardia, muscular tremors and, in extreme cases, death from respiratory failure. Injectable levamisole may cause inflammation at the site of injection.

Levamisole can be administered orally, by injection or pour-on, according to the formulation, and is active against GI worms and lungworms, but not against tapeworms or liver fluke. A levamisole sustained-release bolus is also available in certain countries. It is combined in a number of products with a specific flukicide (oxylozanide or triclabendazole) to form a broad-spectrum drench for worms and fluke.

Pharmacokinetics: Levamisole is rapidly absorbed and excreted, most of the dose being lost from the system within 24 hours of administration. Because of the mode of action of these compounds nematode paralysis occurs quickly and removal of the worms is rapid. Unlike the benzimidazoles it is therefore not as essential to maintain high drug levels over a protracted period.

Mode of action: Levamisole appears to act as a selective agonist, mimicking the action of acetylcholine (Ach), and affecting transmission of nerve impulses at synaptic and extrasynaptic nicotinic Ach receptors on nematode muscle cells, causing a rapid, reversible spastic paralysis (Fig. 60.3). Paralysed worms are expelled by normal gut peristalsis. At high concentrations, it has also been shown to affect nematode metabolism by inhibition of the fumarate reductase system. The extent to which this contributes to overall anthelmintic efficacy is unknown. In addition to its

anthelmintic properties, levamisole has been shown to stimulate the mammalian immune system by increasing cellular activity. The relationship between the immunostimulatory and nematocidal properties of levamisole is unknown.

Tetrahydropyrimidines (group 2-LM)

Pyrantel and morantel are the only members of the tetrahydropyrimidine group available for cattle. Morantel, as its tartrate salt, is the more potent and the most widely available in the form of a sustained-release bolus. Morantel has higher activity against adult gut worms and luminal stages, but not against mucosal or arrested stages or against established lungworm infections. Like levamisole, it has no activity against tapeworms and flukes. Neither morantel nor pyrantel are particularly toxic and can be used safely in pregnant and young animals.

Pharmacokinetics and mode of action: The pharmacokinetics and mode of action of this group of chemicals are similar to those of levamisole. They act as nerve ganglion stimulants, causing a spastic reversible paralysis of the worms that results in rapid expulsion from the host.

Macrocyclic lactones: the avermectins and milbemycins (group 3)

Avermectins, and the structurally related milbemycins, are macrocyclic fermentation products of *Streptomyces avermitilis* and *Streptomyces cyanogriseus*, respectively. Avermectins differ from each other chemically in side chain substitutions on the lactone ring, whilst milbemycins differ from the avermectins through the absence of a sugar moiety from the lactone skeleton. The avermectins include abamectin, doramectin, eprinomectin and ivermectin, and are active against a wide range of nematodes and arthropods. Moxidectin is a milbemycin and has a similar wide ranging activity.

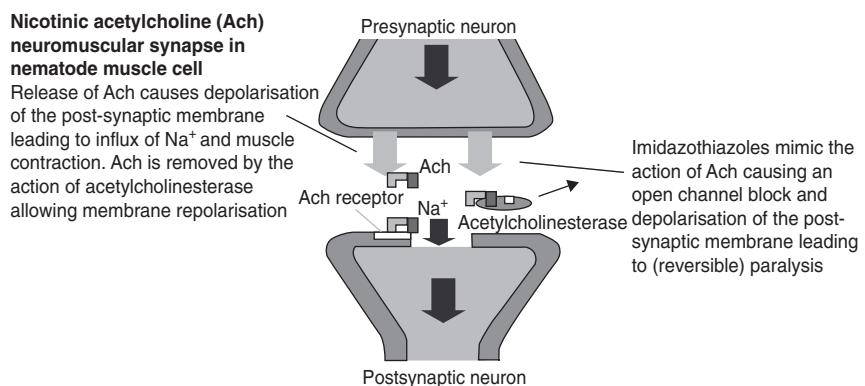

Fig. 60.3 Mode of action of imidazothiazoles.

With the exception of eprinomectin, which is only available as a pour-on formulation, these groups of drugs are available as both injectable and pour-on preparations for cattle. Drench formulations of abamectin, and a sustained-release device containing ivermectin, are also available for cattle in some countries. As well as being effective against adult and larval GI roundworms (including arrested *Ostertagia ostertagi*) and lungworms, most have activity against other helminths of cattle such as the eyeworm, *Thelazia rhodesii*, and the filarial parasite, *Parafilaria bovincola*. None of these compounds has activity against tapeworms or liver fluke, although ivermectin is available in combination with the flukicide clorsulon to broaden the spectrum of activity. Ectoparasite activity includes warbles (*Hypoderma* spp.), sucking lice (*Haematopinus*, *Linognathus*, *Solenopotes* spp.) and mange mites (*Psoroptes*, *Sarcoptes*, *Chorioptes*). More detailed information on the efficacy of the endectocides against ectoparasites is provided in the section on ectoparasiticides (see p. 1030).

Pharmacokinetics: Avermectins and milbemycins are highly lipophilic and, following administration, are stored in fat tissue from where they are slowly released, metabolized and excreted. Ivermectin is absorbed systemically following oral, subcutaneous or dermal administration, but is absorbed to a greater degree, and has a longer half-life, when given subcutaneously or dermally. A temporary depot appears to occur in the fat and liver, from which there is a slow release. Excretion, of the unaltered molecule, is mainly via the faeces, with less than 2 per cent excreted in the urine. The reduced absorption and bioavailability of ivermectin when given orally in cattle may be due to its metabolism in the rumen. The affinity of these compounds to fat explains their persistence in the body and the extended periods of protection afforded against lungworms and stomach worms. Individual variances in these periods of protection reflect differences in drug distribution, metabolism and excretion.

Injectable and pour-on preparations provide protection of 7–42 days for lungworms and 7–35 days for stomach worms, depending on the product and formulation. The ivermectin bolus provides protection against GI worms and lungworms for up to 135 days following administration. The prolonged half-life of these compounds also determines levels of residues in meat and milk, and subsequent compulsory withdrawal periods following treatment. For meat these may vary between 14 and 42 days according to the product and method of administration. With the exception of eprinomectin, which has a zero milk withdrawal period, treatment with this class of compounds cannot be given to lactating cows, or during the last two months of pregnancy.

Mode of action: The mode of action of the avermectins has been studied but has still not been completely elucidated. Ivermectin is known to act on γ -aminobutyric acid (GABA) neurotransmission at two or more sites in nematodes, blocking interneuronal stimulation of excitatory motor neurones and thus leading to a flaccid paralysis (Fig. 60.4). It appears to achieve this by stimulating the release of GABA from nerve endings and

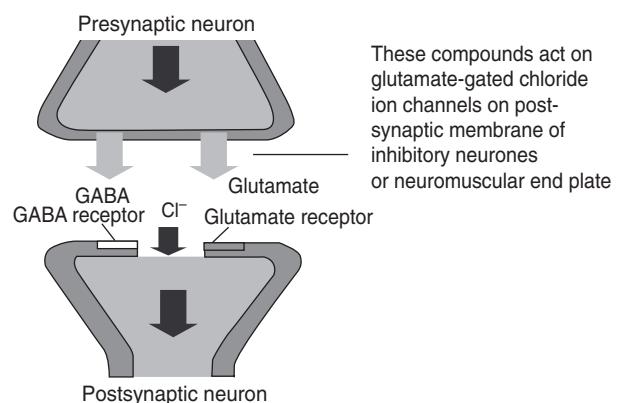

Fig. 60.4 Mode of action of avermectins/milbemycins.

enhancing the binding of GABA to its receptor on the postsynaptic membrane of an excitatory motor neurone. The enhanced GABA binding results in an increased flow of Cl^- ions into the cell, leading to hyperpolarization. In mammals, GABA neurotransmission is confined to the central nervous system; the lack of effect of avermectin on the mammalian nervous system at therapeutic concentrations is probably because, being a large molecule, it does not readily cross the blood-brain barrier. More recent evidence suggests that ivermectin may exert its effect through action on glutamate-gated Cl^- ion conductance at the postsynaptic membrane or neuromuscular end plate.

Salicylanilides and substituted phenols (group 4)

With the exception of niclosamide, the salicylanilides and substituted phenols are usually marketed as flukicides, being highly effective against adult and, to a lesser extent, immature *F. hepatica*. Some also possess activity against blood-sucking nematodes such as *Haemonchus*. Most drugs in this group are given orally to cattle, although nitroxynil is usually given by subcutaneous injection.

The salicylanilides, substituted phenols and bisphenols can be regarded as close analogues and include the bromsalans, clioxanide, oxy clozanide, brotianide, rafoxanide and closantel (salicylanilides), nitroxynil (substituted phenol) and bithionol, hexachlorophene, niclofolan (bisphenols). Niclosamide (salicylanilide) is highly effective against tapeworms and possibly against immature paramphistomes.

Pharmacokinetics: Salicylanilides and substituted phenols appear to be extensively bound to plasma proteins (>99 per cent), which may explain their high efficacy against blood-feeding parasites. Fasciolicidal activity is dependent on the extent to which these drugs persist in the plasma. Rafoxanide and closantel have long plasma half-lives when compared with oxy clozanide. Evidence suggests that the apparent efficacy of these drugs, particularly against immature *F. hepatica*, may be due more to their persistence in the plasma and the effect they have on maturing adult flukes when they reach the bile ducts, rather than the effect they have on the immature stages themselves. Young flukes probably ingest mainly liver cells, which contain little anthelmintic. As they grow and migrate through the liver they cause extensive haemorrhage and come into contact with anthelmintic. Finally, when the flukes reach the bile ducts they are in contact with even greater concentrations of anthelmintic as the bile ducts are important in the excretion of these compounds, as evidenced by the high proportion of these, and their metabolites, excreted in the faeces rather than the urine.

Mode of action: Salicylanilides and substituted phenols uncouple oxidative phosphorylation and therefore decrease the availability of high-energy phosphate compounds such as adenosine triphosphate (ATP) and reduced nicotinamide-adenine-dinucleotide (NADH^-) in the mitochondria. They have also been shown to inhibit succinate dehydrogenase activity and the fumarate reductase system, which is associated with oxidative phosphorylation. Because of the long half-life of the plasma protein-bound molecules, the parasites experience prolonged exposure to the drugs which reduces the energy available to the parasites. Plasma binding reduces incorporation of the drugs into host tissues and accounts for the selective parasite toxicity. Looseness of faeces and slight loss of appetite may be seen in some animals after treatment at recommended dose rates. High doses may cause blindness and signs of uncoupled oxidative phosphorylation, i.e. hyperventilation, hyperthermia, convulsions, tachycardia and ultimately death.

Others (group 5)

Piperazines

Diethylcarbamazine is still marketed in certain parts of the world, for the treatment of lungworm infections in cattle. It is primarily active against immature lungworms and because it has to be given over a period of three days to achieve its effect, more modern anthelmintics such as the benzimidazoles, levamisole and the avermectins/milbemycins have tended to replace it. It is also active against microfilariae, the mode of action being incompletely understood, but it is thought to enhance phagocytosis of the microfilariae by the host immune system. The action of diethylcarbamazine on immature lungworm larvae is thought to be a flaccid paralysis due to hyperpolarization of neuronal postsynaptic membranes resulting from an increased flow of Cl^- ions into the cell. This mode of action, similar to the GABA agonist action of piperazine, is probably unrelated to its antifilarial action.

Organophosphates

Several organophosphorus compounds have been marketed for use in cattle and are still available in a limited number of countries for the treatment of GI nematode infections. Haloxon and metriphonate are usually effective against the adults of some species of GI nematodes, but not against arrested larvae and lungworms. The mode of action of the organophosphates is discussed in greater detail in the section on ectoparasiticides (see p. 1032).

Clorsulon

The sulphonamide clorsulon is available as an injectable solution for cattle and is highly effective against both adult and immature liver flukes over eight weeks of age. It has been shown to inhibit the glycolytic enzyme phosphoglyceromutase in *F. hepatica* by competition with 3-phosphoglycerate and 2,3-diphosphoglycerate, leading to a gradual suppression of motility and paralysis.

Praziquantel

Praziquantel is a quinoline-pyrazine compound and is a highly effective cestodicidal and trematocidal drug for use in both human and veterinary medicine. The drug appears to modulate cell membrane permeability, leading to both spastic muscle contraction and disintegration of the parasite tegument. Praziquantel is active against larval cestodes and schistosomes found in cattle, but the high dosage required is probably uneconomic in these infections.

Treatment of parasitic gastroenteritis in cattle (see pp. 267–72)

The activities of the available anthelmintics have been described under their respective anthelmintic groups and are summarized in Tables 60.2 and 60.3. All are highly effective against adult and developing larval stages of the common GI nematodes. When selecting an anthelmintic for treatment of parasitic gastroenteritis (PGE) in calves during the summer months there is little difference, in terms of efficacy, between any of the currently available anthelmintics. Abamectin, doramectin, eprinomectin, ivermectin and moxidectin injections and respective pour-on formulations have persistent anthelmintic activity against abomasal nematodes and lungworms and can be used at extended treatment intervals in strategic dosing strategies. For treatment of type II ostertagiosis, or for treating animals on housing, it is advisable to use a product with high activity against arrested fourth-stage larvae. An anthelmintic that lacks such efficacy may necessitate repeated treatment as it will only remove adult worms and developing larvae, leaving arrested larvae to resume development and cause damage to the abomasal wall. Here there is some variability in efficacy between products and evidence suggests that at recommended dose rates, albendazole, fenbendazole, netobimbin, oxfendazole, ricobendazole, abamectin, doramectin, eprinomectin, ivermectin and moxidectin are more active against arrested fourth-stage larvae than other anthelmintics. The activities of the probenzimidazoles, febantel and thiophanate are increased if they are given in feed over several days.

Strategies for controlling helminth infections of cattle (see p. 271 onwards)

Strategies for the control of parasitic GI nematode infections of cattle are generally targeted at the first year grazing animal, although increasingly control measures are being applied to cattle in their second grazing season. Currently employed control strategies are based on detailed epidemiological studies conducted over several decades. Calves can either be dosed at the onset of disease or used preventatively in the early part of the grazing season, as a means of limiting pasture contamination and subsequent exposure to infective larvae later in the season. This approach is particularly used in temperate climates where there is a fairly predictable cyclical appearance of GI nematode species on the herbage throughout the year. The major disadvantage of strategic single-dose treatments is the labour costs involved in gathering and handling the cattle. As such, the advent of novel methods of presentation of anthelmintics and those with greater persistence in the body has meant that strategic control of PGE in calves can be achieved with the minimal handling of stock. The use of pour-on preparations, for example, is convenient, less traumatic to both animal and handler and is gaining widespread acceptance. The most important development over recent years, and for the foreseeable future, has been the introduction of controlled-release devices which deliver anthelmintic at targeted times throughout the grazing season.

Strategic anthelmintic dosing (see p. 271 onwards)

On farms where 'clean grazing' in the form of new leys or aftermaths is available, GI nematodes can be controlled by integrating systems of grazing management with parasite control strategies. These clean grazing systems can be designed for the effective control of PGE, but offer little protection for the control of lungworm because of the unpredictable nature of the disease. On many conventionally managed enterprises, where cattle are grazed on permanent pasture, control can be achieved through strategic anthelmintic dosing at three and six weeks post turn-out (sometimes referred to as to the 'poor man's clean grazing system'). Further developments of this system include the 3, 8, 13 strategy for ivermectin, the 0, 8 dosing strategy for doramectin, and the use of boluses (see p. 271). Calves dosed with a bolus or treated strategically with anthelmintic should remain set-stocked on the pasture or moved to clean pasture, when available, for maximum benefits. Many of the anthelmintic strategies described claim to protect calves against lungworm disease during their first season at grass. There is much

Table 60.3 Anthelmintics effective against helminth parasites of cattle.

| Parasite group | Parasite genus/species | Anthelmintics |
|------------------------|---|---|
| Gastrointestinal worms | <i>Ostertagia, Trichostrongylus, Cooperia, Haemonchus, Nematodirus, Chabertia, Bunostomum, Oesophagostomum, Strongyloides</i> | Albendazole, ricobendazole, febantel, fenbendazole, netobimin, oxfendazole, thiophanate, levamisole, morantel, abamectin, doramectin, eprinomectin, ivermectin, moxidectin Closantel and nitroxynil (<i>Haemonchus, Bunostomum, Oesophagostomum</i> only) |
| Lungworms | <i>Dictyocaulus viviparus</i> | Albendazole, febantel, fenbendazole, netobimin, oxfendazole, levamisole, abamectin, doramectin, eprinomectin, ivermectin, moxidectin Diethylcarbamazine (available in some countries) |
| Cestodes | <i>Moniezia expansa, M. benedini</i> | Albendazole, febantel, fenbendazole, netobimin, oxfendazole Oxyclozanide (some activity against proglottids) |
| | <i>Taenia saginata</i> (metacestode) <i>Cysticercus bovis</i> | Praziquantel |
| | <i>Echinococcus granulosus</i> (hydatid) | Praziquantel |
| Trematodes | <i>Fasciola hepatica</i> (adults) | Albendazole, ricobendazole, netobimin, triclabendazole, nitroxynil, oxyclozanide, clorsulon, closantel Rafoxanide, bithionol, niclofan |
| | <i>Fasciola hepatica</i> (immatures) | Triclabendazole, nitroxynil (>6 weeks), closantel |
| | <i>Fasciola gigantica</i> | Triclabendazole, clorsulon |
| | <i>Fascioloides magna</i> | Triclabendazole, clorsulon, closantel |
| | <i>Dicrocoelium dendriticum</i> | Netobimin |
| | <i>Schistosoma</i> spp. | Praziquantel |

debate as to whether these strategies compromise immunity to both GI worms and lungworms and, in part, explain the increasing reports of lungworm in older animals seen over the last few years in parts of western Europe. On farms where lungworm is endemic, or if there is a high risk of introduction of disease, then vaccination is the recommended method of control (see p. 1011).

The two grazing strategies commonly used for the control of PGE in first-year cattle are commonly referred to as 'preventative' and 'evasive'. In a preventative strategy clean grazing is provided at the start of the grazing season, usually in the form of new leys. When weaned, parasite-naïve calves are turned out onto the clean pasture where they should remain set-stocked for the whole grazing season and should not require any anthelmintic dosing. In an evasive strategy, animals are dosed and moved onto clean aftermaths from mid-summer onwards (see p. 271).

Anthelmintic delivery devices

Intraruminal devices represent a new approach to administering anthelmintics for the control of parasitic helminths and are becoming a popular labour-saving means of worming cattle. The reticulo-rumen provides

an ideal site for the location of these devices, which can release anthelmintic over an extended period either continuously (sustained-release devices, SRD), or at pulsed intervals (pulse-release devices, PRD). Ruminal retention is achieved either on the basis of density or the variable geometric configuration of the device.

Several devices are available for cattle in certain countries and include:

- A morantel sustained-release device (MSRD);
- A levamisole sustained-release bolus (LSRB);
- A fenbendazole sustained-release bolus (FSRB);
- An ivermectin sustained-release bolus (ISRB); and
- Oxfendazole pulse-release devices (OPRB).

These range in shape and design, each being administered by the use of specially provided dosing guns. Care is required when administering as dosing injuries can easily occur or the bolus may be regurgitated if not swallowed properly.

The MSRD consists of a coiled trilaminated sheet composed of a central core matrix of morantel tartrate. The entire sheet is punched with holes which allow the controlled release of morantel into the rumen from the edges of the perforation as well as the perimeter.

The device is retained in a rolled shape by a special tape. Following administration, the tape releases and the device unrolls and is retained in either the first or second stomach of the animal. The device remains active for about 90 days, after which it gradually disintegrates and is eliminated.

The LSRB bolus consists of a compressed polyvinyl chloride (PVC) matrix containing levamisole encased in an outer impermeable shell. Anthelmintic is released from the internal surface area through a single outer pore over a period of up to 90 days.

The FSRB is a cylindrical bolus consisting of ten flat-faced tablets in two magnesium alloy tubes joined and enclosed by alloy rings. The bolus is designed to release fenbendazole by galvanic erosion over a period of 140 days.

The ISRB consists of an external semipermeable membrane surrounding a semisolid formulation of ivermectin. The bolus is retained in position in the first or second stomach by the presence of an iron densifier at one end. The bolus is designed to release anthelmintic over a period of up to 135 days.

The OPRB consists of either five or seven annular tablets of oxfendazole, mounted on a central metal core with a stainless steel weighted end. The release of each annular tablet is determined by the corrosion rate of the central core. The first dose of oxfendazole is either released within 24 hours (for use in animals already at grass) or at approximately three weeks after administration for either first (seven tablet) or second year animals (five tablet) prior to turnout. Remaining doses are released at regular intervals thereafter (approximately 21 days) giving the boluses active lives of 105, 126, or 147 days depending on the number of tablets and release profile. Devices of this nature are subject to some variation in release intervals dependent on factors such as diet, rumen pH and gut motility, so that release may vary by a few days either side of the optimum.

A novel development from this type of corrosion-based pulse-release system is the electronic bolus based on microchip technology. As well as offering the potential of multiple anthelmintic therapy, the system could be used to pulse release other drugs such as growth promoters and mineral supplements.

Bolus devices are normally administered at the start of the grazing season, although some can be given later in the season. If the animals are turned out early, or moved to pasture grazed by untreated animals during late summer, subsequent protection from infective larvae may be lost, as will any benefits of anthelmintic treatment. The result may be that either the calves experience sufficient challenge to develop clinical disease in the autumn or, alternatively, they acquire large numbers of arrested larvae that may cause clin-

ical disease in the following spring. In this situation calves may require dosing in the autumn while still at grass, or on housing, to remove arrested burdens.

With some delivery system designs the dose/weight ratio reduces as the animals grow, whilst at the same time release rates may decline with time. Both of these factors may result in considerable selection pressure for the development of drug resistance and since these systems are recommended as a form of clean grazing system, the build-up of resistant over susceptible species could rapidly occur.

Anthelmintic resistance

Although widely reported in sheep, anthelmintic resistance appears less of a problem in cattle. This may be a reflection of the relative frequency of treatment and also of differences in parasite population dynamics between the two hosts. It may also reflect the prolonged survivability of free-living larval stages within the bovine faecal pat, thus ensuring a supply of susceptible worms.

The effects of intraruminal devices on the development of resistance, given the selection pressures they exert, are not yet apparent. Until the inheritance of anthelmintic resistance is completely understood, this will remain a matter for speculation. In the meantime, recommendations aimed at limiting the development of resistance in sheep nematodes should be followed wherever possible. The ultimate choice of anthelmintic product may therefore be influenced by a number of factors of which group type or mode of action may become one of the overriding factors, when considered as part of an anthelmintic rotation programme designed to delay the onset of resistance.

Treatment of parasitic bronchitis (see pp. 273–4)

The anthelmintics fenbendazole, oxfendazole, albendazole, ricobendazole, febantel, levamisole, ivermectin, abamectin, doramectin, eprinomectin and moxidectin are all highly effective against developing fourth-stage larvae and adult *Dictyocaulus viviparus*. Diethylcarbamazine (available in some countries) is primarily active against immature larvae if given over a three-day period.

Some degree of control of parasitic bronchitis in calves can be achieved by early season suppression of pasture contamination in much the same way as for the control of GI nematodes. However, the epidemiology of lungworm infection is complex and still not fully understood, and it is the opinion of the author that the vaccination of calves with an irradiated larval vaccine is the most reliable form of control (see p. 1011).

Treatment of trematode infections in cattle (see pp. 276–80)

Fasciolosis

Table 60.4 shows the comparative efficacy of flukicidal drugs against *F. hepatica*. All are effective against adult fluke and are therefore suitable for the treatment of chronic fasciolosis in cattle. Few compounds have activity against immature fluke stages, limiting the choice in suspect cases of acute fasciolosis. As a general recommendation for cattle in temperate countries, housed cattle should be dosed once in mid-winter in average rainfall years. Wherever possible, the most effective drugs with efficacy against mature and immature flukes should be used. Further treatment should then be unnecessary. If a flukicide with activity against mature flukes only is used, a second dose at turnout may be necessary to remove any fluke missed by the first treatment. Where animals were housed for at least eight weeks prior to the first treatment, the second dose should be unnecessary.

In outwintered stock, two doses of anthelmintic may be necessary. The first is given in early winter to remove adult and immature fluke burdens acquired from the autumnal flush of pasture metacercariae. A second dose in early spring may be required to prevent heavy pasture contamination and infection of the intermediate snail host, especially if rainfall has been heavy in previous years. In these situations the treatment interval will depend on the activity of the flukicidal drug against immature stages.

Other *Fasciola* spp. (see p. 277)

The drugs and dose rates given for the treatment of *F. hepatica* are also generally applicable for the treatment

of *F. gigantica*. Only triclabendazole and clorsulon are effective against both mature and immature stages of *F. gigantica*. *Fascioloides magna*, a parasite of deer that can affect cattle, is susceptible to triclabendazole, clorsulon and closantel.

Only limited information is available on the treatment of paramphistomes in cattle (see p. 279). Niclofolan or albendazole has been recommended, but these have only variable activity against intestinal juvenile forms. Oxyclozanide given on two occasions, three days apart, has been shown to be effective against adult flukes in the rumen.

Schistosomes (see p. 280)

In contrast to the chemotherapy of schistosomes in humans, little information is available on the treatment of schistosomosis in cattle. For economic reasons, anthelmintic treatment is not suitable for the control of schistosomosis in cattle, except during clinical outbreaks when praziquantel may be administered orally at 15–20 mg/kg. Repeat doses two to three days apart are usually required or high dose rates (25/mg per kg) at three to five weeks apart.

Treatment of cestode infections in cattle

Adult stages of tapeworms parasitizing cattle are usually of little consequence. Several of the benzimidazoles used in the treatment of GI nematodes are also effective against cestodes (Tables 60.2 and 60.3). Certain flukicidal drugs also have cestocidal activity (Table 60.4). Larval stages of cestodes affecting cattle, notably *Echinococcus* spp. and *Taenia saginata*, are generally refractory to treatment with anthelmintics. However, praziquantel has been shown to have activity

Table 60.4 Activities of anthelmintics against liver fluke in cattle.

| Chemical group | Chemical | Recommended dose rate (mg/kg) | Active against | | | Comments |
|---------------------|-----------------|-------------------------------|----------------|---|---|---|
| | | | A | B | C | |
| Salicylanilides | Rafoxanide | 7.5 | + | + | – | No longer available in many countries |
| | Closantel | NR | + | + | ± | Available for cattle in some countries |
| | Oxyclozanide | 10 | + | – | – | Some activity against tapeworm segments |
| Substituted phenols | Nitroxynil | 10 | + | + | – | Also active against blood nematodes |
| | Bithionol | 30 | + | – | – | Also has anticestodal activity |
| | Niclofolan | 3 | + | – | – | |
| Benzimidazoles | Albendazole | 10 | + | – | – | Also active against nematodes and cestodes |
| | Triclabendazole | 12 | + | + | + | Do not give to dairy cows within 7 days of calving |
| Probenzimidazoles | Netobimbin | 20 | + | – | – | Do not administer to cattle in the first 7 weeks of pregnancy |
| Sulphonamide | Cloresulon | 7 | + | + | ± | |

A, adult fluke; B, 6–12 week old fluke; C, 1–6 week old fluke.

NR, no recommended dose rate.

against the intermediate stages of both these parasites, although the cost of treatment may preclude its use.

Antiprotozoals

Ruminants carry large numbers of protozoa in their stomach and intestines, the vast majority of which are entirely harmless. Some species of protozoa, however, are significant as causes of disease in cattle or because of their potential for zoonotic transmission. Antiprotozoal compounds are listed in Table 60.5.

Protozoal diseases of economic importance throughout various regions of the world include trypanosomosis, theileriosis, babesiosis and trichomoniasis. Coccidiosis in cattle is caused by parasites of the genus *Eimeria* spp. and can be a serious cause of disease in young animals (see p. 282). A protozoan disease of increasing importance is cryptosporidiosis. The

causative organism, *Cryptosporidium parvum* (see pp. 204, 286), is a significant cause of disease in neonatal calves and is also an important zoonosis.

Haemoparasites

Cattle are infected with a number of haemoparasites that include some highly pathogenic species, e.g. the piroplasms (*Babesia* and *Theileria*) (see p. 748) and the haemoflagellates (*Trypanosoma*) (see p. 756). Transmission of these blood parasites normally occurs via a biting tick or insect vector. *Babesia* species occur in most parts of the world where there are ticks. They are of greatest importance in the tropics, but some species occur in temperate climates where they can cause disease in non-immune cattle. The merozoites of *Babesia* occur in the erythrocytes of infected animals where they multiply asexually by binary fission and are described as 'large' and 'small', depending on size.

Table 60.5 Antiprotozoal compounds for cattle.

| Compound | Trade name | Manufacturer | Dose rates (mg/kg) Route | Comments |
|------------------------|------------|--|--|---|
| Diminazene aceturate | Berenil | Intervet | 3.5–7.0 im or sc | For treatment of trypanosomosis (<i>T. congolense</i> , <i>T. brucei</i> , <i>T. vivax</i> [nagana]) and babesiosis (<i>B. bigemina</i> , <i>B. bovis</i> and <i>B. divergens</i>) |
| Imidocarb | Imizol | Schering-Plough (Mallinckrodt Veterinary) | 1–3 sc | For treatment of babesiosis (<i>B. bigemina</i> , <i>B. bovis</i> and <i>B. divergens</i>). Prophylactic effect for up to 8 weeks depending on dose and species involved. Causes cholinergic effects and is slowly metabolised and excreted |
| Homidium chloride | Novidium | Merial | 1.0 im | Treatment of trypanosomosis (<i>T. congolense</i> , <i>T. brucei</i> , <i>T. vivax</i> [nagana]) |
| Isometamidium chloride | Samorin | Merial | 0.25–1.0 im or iv | Treatment or prevention of trypanosomosis (<i>T. brucei</i> , <i>T. congolense</i> , <i>T. vivax</i> [nagana]). Toxic above 2 mg/kg |
| Suramin | Naganol | Bayer | 10 iv | Treatment of trypanosomosis (<i>T. brucei</i> , <i>T. congolense</i> , <i>T. vivax</i> [nagana]) |
| Amicarbalide | Diampron | Merial | 5–10 im | Treatment of babesiosis (<i>B. bigemina</i> , <i>B. bovis</i> , <i>B. divergens</i>) |
| Buparvaquone | Butalex | Schering-Plough (Mallinckrodt Veterinary) | 2.5 2 doses at 48 h intervals | Treatment of East Coast fever (<i>Theileria parva</i>) and Mediterranean Coast fever (<i>T. annulata</i>) |
| Parvaquone | Clexan | Schering-Plough (Mallinckrodt Veterinary) | 10–20 2 doses at 48 h intervals | Treatment of East Coast fever (<i>T. parva</i>) and Mediterranean Coast fever (<i>T. annulata</i>) |
| Halofuginone | Stenoral | Intervet | 1.2 po 2 doses at 48 h intervals | Treatment of East Cost fever (<i>T. parva</i>) and Mediterranean Coast fever (<i>T. annulata</i>) |

im, intramuscular; sc, subcutaneous; iv, intravenous; po, per os (oral).

Several species are highly pathogenic in cattle and include *Babesia bigemina*, found in Africa, Australia, Europe and Central and South America, and *B. bovis*, found throughout most of the world and being particularly common in southern Europe. Transmission occurs following a bite from an infected tick of the genera *Boophilus*, *Rhipicephalus*, *Haemaphysalis* and *Ixodes*, the species involved varying with geographical location. The species found throughout temperate Europe is *Babesia divergens* (a small piroplasm), transmitted by the tick *Ixodes ricinus*. Clinically affected animals develop a haemolytic anaemia leading to haemoglobinuria, fever and death.

A number of *Theileria* species have been reported in cattle and are significant causes of disease in many tropical countries. The parasites occur within lymphocytic and erythrocytic cells and are transmitted by the bites of various species of ticks. *T. parva* (the cause of East Coast fever) and *T. annulata* (Mediterranean Coast fever) are the main pathogenic species occurring in East and North Africa, southern Europe and parts of the former Soviet States, respectively. Transmission of these parasites occurs following the bite from an infected tick belonging to various species of the genus *Hyalomma*.

Trypanosomosis is one of the most important diseases of domesticated cattle in central parts of Africa. Trypanosomes are broadly divided into two groups depending on the site of development in the insect vector. The salivarian trypanosomes, transmitted in the saliva of biting flies, are responsible for 'nagana' in domestic ruminants (see p. 757), as well as diseases such as 'surra' of horses and other animals, and African Sleeping Sickness in humans. The stercorarian trypanosomes are transmitted by contamination with infected insect faeces and include diseases such as Chagas disease in humans in Central and South America, which is transmitted by reduviid bugs.

Coccidiosis (see p. 282)

At least 18 different species of coccidia are known to infect cattle worldwide. Bovine coccidiosis is primarily a disease of young animals aged between three weeks and nine months, but can occur in older cattle. The disease is usually associated with a previous stressful situation such as shipping, overcrowding, changes of feed, severe weather or concurrent infections. Clinical signs, often presenting as bloody diarrhoea, are associated with the presence of *Eimeria zuernii* or *E. bovis*, which occur in the lower small intestine, caecum and colon. Another species of coccidia, *E. alabamensis*, has been reported to cause enteritis in yearling calves in some northern European countries.

The incidence of coccidiosis can be reduced by avoidance of overcrowding and stress and increased atten-

tion to hygiene. Raising of food and water troughs, for example, can help avoid contamination by reducing the levels of infection. Young animals should be kept off heavily contaminated pastures when they are most susceptible. The anticoccidial decoquinate is licensed in many countries for the prevention of coccidiosis in calves. Other compounds, such as monensin and amprolium, are available in some countries.

Cryptosporidiosis (see pp. 204, 286)

Bovine cryptosporidiosis is often seen as part of the neonatal diarrhoea complex, symptoms of which are profuse watery diarrhoea, dehydration, and death if left untreated. Infections are usually, although not always, associated with the presence of other pathogens such as *Salmonella* spp., *E. coli*, rotavirus and coronavirus. Specific antiparasitic therapy is not available for cryptosporidiosis and treatment relies on the use of supportive antidiarrhoeals and fluid therapy for animals showing dehydration. Recently halofuginone lactate has been licensed for the prevention of diarrhoea caused by *Cryptosporidium parvum* by treating daily for seven consecutive days.

ECTOPARASITICIDES

Introduction (see Chapters 45, 50)

Ectoparasites can cause intense irritation leading to loss of condition and effects on performance such as weight loss, reduced milk yield or hide damage. In addition they may be responsible for transmission of disease. The choice and use of ectoparasiticide chemicals and the method for their control depend to a large extent on husbandry and management practices as well as the type of ectoparasite causing the infestation.

Parasites that live permanently on the host, such as lice and mites, are relatively easily controlled and, once eradicated, reinestation only occurs from contact with infested stock. Non-permanent parasites (ticks and flies) are less easily controlled because only a small proportion of the population can be treated at any one time and other hosts may maintain them.

Most infestations in cattle are seasonal and predictable and can be countered by prophylactic use of ectoparasiticides. For example, biting and nuisance flies occur predominantly from late spring to early autumn, tick populations increase in the spring and autumn, and lice and mites may increase in winter-housed stock.

Ectoparasiticide groups

Available ectoparasiticides act either systemically or by direct contact with the target parasites and have an

effect on the ectoparasite's nervous system. Systemic ectoparasiticides may be given parenterally or applied topically to the skin from where the active ingredient is absorbed percutaneously and taken up into the blood circulation. Topical ectoparasiticides have a direct effect on the target parasite on the surface of the skin. Different formulations of a drug preparation may be indicated for different target parasites (Table 60.6).

Both topical and systemically acting formulations can be applied by various methods including dips, sprays, 'pour-ons', 'spot-ons', dusting powders or ear tags. Typically, a number of formulations are available as liquid concentrates requiring dilution with water to produce an emulsion for application by spray or dip. However, more convenient ready-for-use pour-on and spot-on application methods provide a broad choice of systems depending upon individual circumstances, for example availability of spraying, dipping and animal handling

facilities, in addition to labour requirements for such operations.

Organochlorines

Organochlorines (OCs) are no longer in general use but several compounds are still available in some countries. OCs fall into three main groups:

- (1) Chlorinated ethane derivatives such as DDT (dichlorodiphenyltrichloroethane), DDE (dichlorodiphenyldichloroethane) and DDD (dicofol, methoxychlor);
- (2) The cyclodienes that include chlordane, aldrin, dieldrin, heptachlor, endrin, tozaphene;
- (3) Hexachlorocyclohexane (HCH), also known as benzene hexachloride (BHC), which includes the γ -isomer lindane.

Table 60.6 Chemicals active against cattle ectoparasites.

| Ectoparasite group | Parasite species | Ectoparasiticides |
|--------------------|---|--|
| Biting flies | <i>Haematobia (Lyperosia) irritans</i> , horn fly <i>Stomoxys calcitrans</i> , stable fly <i>Simulium</i> spp., blackfly | Ivermectin, ^a doramectin, ^a eprinomectin, ^a moxidectin, ^a cypermethrin, deltamethrin, fenvalerate, permethrin |
| Nuisance flies | <i>Hydrotaea irritans</i> , head fly <i>Musca autumnalis</i> , face fly <i>Musca domestica</i> , house fly <i>Morellia simplex</i> , sweat fly | Cypermethrin, deltamethrin, fenvalerate, permethrin |
| Warble flies | <i>Hypoderma bovis</i> <i>Hypoderma lineatum</i> | Abamectin, doramectin, eprinomectin, ivermectin, moxidectin, famphur, fenthion, phosmet |
| Sucking lice | <i>Haematopinus eurysternus</i> <i>Linognathus vituli</i> <i>Solenopotes capillatus</i> | Abamectin, doramectin, eprinomectin, ivermectin, moxidectin, phosmet, cypermethrin, deltamethrin, fenvalerate, permethrin, Amitraz Closantel |
| Biting lice | <i>Bovicola (Damalinia) bovis</i> ^b | Doramectin, ^b eprinomectin, ^b ivermectin, ^b moxidectin, ^b famphur, fenthion, phosmet, cypermethrin, deltamethrin, fenvalerate, permethrin, amitraz |
| Mites | <i>Psoroptes bovis</i> <i>Sarcoptes scabiei</i> <i>Chorioptes bovis</i> | Abamectin, ^c doramectin, ^c eprinomectin, ^c ivermectin, ^c moxidectin, ^c phosmet, amitraz |
| Ticks | <i>Ixodes</i> spp. <i>Boophilus</i> spp. <i>Rhipicephalus</i> spp. <i>Amblyomma</i> spp. <i>Dermacentor</i> spp. <i>Hyalomma</i> spp. | Amitraz Flubenzuron Closantel |

^a Pour-on preparations with activity and protection against horn flies [*Haematobia (Lyperosia) irritans*]

^b Efficacy varies depending on method of application. Injectable preparations aid in the control of biting lice.

^c Efficacy varies depending on method of application. Injectable preparations aid in the control of chorioptic mange.

Chlorinated ethanes cause inhibition of sodium conductance along sensory and motor nerve fibres by holding sodium channels open, resulting in delayed depolarization of the axonal membrane. This state renders the nerve vulnerable to repetitive discharge from small stimuli that would normally cause an action potential in a fully repolarized neuron.

The cyclodienes appear to have at least two component modes of action:

- Inhibition of γ -amino butyric acid (GABA)-stimulated Cl^- flux and
- Interference with Ca^{2+} flux.

The resultant inhibitory postsynaptic potential leads to a state of partial depolarization of the postsynaptic membrane and vulnerability to repeated discharge. A similar mode of action has been reported for lindane, which binds to the picrotoxin side of the GABA receptor resulting in an inhibition of GABA-dependent Cl^- flux into the neuron.

Organophosphates and carbamates

Organophosphates (OPs) are neutral esters of phosphoric acid or its thio analogue and act by inhibiting the action of acetylcholinesterase (AchE) at cholinergic synapses and at muscle end plates. This results in an accumulation of acetylcholine (Ach) at the postsynaptic membrane, leading to neuromuscular paralysis. OP compounds include azamethiphos, chlorpyriphos, coumaphos, dichlorvos, diazinon, fenitrothion, heptenophos, metriphonate, phoxim, propetamphos or tetrachlorvinphos and there are many preparations available worldwide for cattle. Carbamate insecticides are closely related to the OPs and are also anticholinesterases but, unlike OP compounds, are spontaneously reversible. The two main carbamate compounds in use in veterinary medicine are carbaryl and propoxur. OP compounds can be extremely toxic in animals and humans. Inhibition of AchE, and other cholinesterases, can occur in higher vertebrates as well and accounts for host toxicity seen at higher dose rates. Typical signs of overdosage, or overexposure, include salivation, miosis, diarrhoea and muscle tremors. Death may occur through respiratory failure. Toxic clinical signs can be treated with atropine. Chronic exposure may lead to damage to the nervous system and clinical signs including headaches, anxiety and irritability in operators. OP compounds are generally active against warble fly larvae, flies, lice, ticks and mites on cattle, although activity will vary between compounds, formulations and against different target parasites.

Pyrethrins and synthetic pyrethroids

Natural pyrethrins are derived from pyrethrum, a mixture of alkaloids from the chrysanthemum plant. Synthetic pyrethroids (SPs) include bioallethrin, cypermethrin, deltamethrin, fenvalerate, flumethrin, lambda-cyhalothrin, phenothrin and permethrin. The content of some SPs is also expressed in terms of the drug isomers; for example, cypermethrin preparations may contain varying proportions of their *cis* and *trans* isomers. Thus, cypermethrin (*cis:trans* 60 : 40) 2.5 per cent is equivalent to cypermethrin (*cis : trans* 80 : 20) 1.25 per cent. In general terms, *cis* isomers are more active than the corresponding *trans* isomers. The mode of action of SPs appears to be an interference with sodium channels of the parasite nerve axons, resulting in delayed repolarization and eventual paralysis. The lethal activity of pyrethroids seems to involve action on both peripheral and central neurones, while the knockdown effect is probably produced by peripheral neuronal effects only.

Pour-on, spot-on, spray and dip formulations are available in many countries with activity against biting and nuisance flies, lice and ticks. Some compounds are active against sarcoptic and chorioptic mange mites. For non-permanent ectoparasites, treatments are generally applied during periods of anticipated peak challenge. Treatments for lice are best administered in the autumn. Periods of protection against flies vary between products and methods of application, but generally last for up to one month for most species of flies. Some SPs are also available as ear tags for use on cattle, providing protection against biting and nuisance flies for several months during the fly season. One tag is usually sufficient but in severe cases of head or face fly attack, both ears can be tagged.

Amidines

The main member of this group is amitraz, which acts at octopamine receptor sites in ectoparasites giving rise to increased nervous activity. When applied as a spray it is active against mites, lice and ticks in cattle. In severe cases of mange, lice and tick infestations, treatments may have to be repeated during the risk period.

Avermectins and milbemycins

Avermectins and the structurally related milbemycins have been discussed earlier under anthelmintics. As well as being effective against GI roundworms and lungworms, all have activity against warbles, sucking lice and mange mites. Control against the biting louse, *Bovicola (Damalinia) bovis*, the mite, *Chorioptes bovis*, and the hornfly, *Haematobia (Lyperosia) irritans* varies between products and the method of administration.

Insect growth regulators

Insect growth regulators (IGRs) are a group of chemical compounds that do not kill the target parasite directly, but interfere with growth and development. IGRs act mainly on immature stages of the parasite and as such are not usually suitable for the rapid control of established adult populations of parasites. Where parasites show a clear seasonal pattern, IGRs can be applied at the start of the grazing season as a preventative measure. Based on their mode of action they can be divided into chitin inhibitors and juvenile hormone analogues. Chitin inhibitors appear either to interfere with the assembly of chitin chains and microfibrils or to inhibit the deposit of chitin into the cuticle. The juvenile hormone analogues mimic the activity of naturally occurring juvenile hormones and prevent metamorphosis to the adult stage.

IGRs are widely used for flea control in domestic pets and for blowfly control in sheep, but have limited use in cattle. The phenylbenzyl urea flubenzuron is marketed in Australasia as a tick development inhibitor. When applied as a pour-on it provides long-term protection against the one-host tick *Boophilus microplus*.

Introduction

The choice of a suitable antimicrobial agent is very difficult. It first depends on deciding whether the problem encountered is an infection and even then whether it warrants such therapy. The site of infection needs to be located and the type of microbe established. Then the *in vitro* antimicrobial sensitivity of the organism and the minimal inhibitory concentration need to be determined. The likely ability to penetrate the area, the action of the antibiotic in the local environment and the maintenance of an effective concentration at the area must be considered. The selection also has to include the possibility of any potential toxic side-effects as well as the meat and milk withholding times. Once all these factors have been taken into consideration, the drug to be used, its dosage, route and frequency of administration can be determined. All the above, however, has to be undertaken on an economic basis.

There are various ways of defining antimicrobial preparations. Chemotherapy can be defined as the use in the treatment of a disease of pure chemicals that have a special antagonistic effect(s) on the organism causing the disease.

Antibiotics are complex organic chemicals synthesized by micro-organisms during their growth and which, in minute quantities, have a detrimental effect

on other organisms. These chemical compounds are the metabolic products of bacteria and fungi. Most commonly, antibiotics are effective against bacteria but some have activity against viruses, *Rickettsia*, *Mycoplasma*, fungi and helminths (see Table 61.1).

At present all prescribing of antimicrobial agents for therapy, prophylaxis or control of disease is under veterinary control and prescription in the UK. The level of control in some countries is greater than in Britain, e.g. Sweden, although in many parts of the world it is less or almost non-existent.

Identification of the causal agent

Some decisions regarding therapy can only be made once a diagnosis is reached. Clinical examination is used to identify the nature of the infection, its site and possible cause. The signs of some diseases are so clear-cut that diagnosis is easy to establish and the organism is readily identifiable, e.g. wooden tongue, actinomycosis. In such cases the choice of drug is easy to make as well as its dosage, rate and duration of treatment. The likely outcome of therapy can also be predicted with some confidence. However, in many cases the disease signs are not clear-cut, the area of infection is difficult to localize or the sensitivity pattern of the organism is irregular. In such cases the identification of the causal agent is important not only for treatment of the individual animal affected but also for possible future action on a herd basis. However, in many situations, the site of infection and the cause of the condition are not known. In such instances laboratory diagnosis, other than haematological examination to indicate that an infection is present, is of no value. Therapy in these cases usually involves the use of one or more antimicrobial agents to ensure a broad spectrum of activity. Subsequent progress will depend on evaluation of the effect of the chosen treatment.

Sampling

Wherever possible sampling should be undertaken to try to determine the causal organism. This will be

Table 61.1 Non-antibacterial activity of some antibiotics.

| | |
|---------------------------------|--|
| <i>Mycoplasma</i> | Chlortetracycline, doxycycline, erythromycin, fluoroquinolones, lincomycin, methacycline, oleandomycin, oxytetracycline, spiramycin, tetracycline, tylosin |
| <i>Rickettsia</i> | Chloramphenicol, chlortetracycline, doxycycline, fluoroquinolones, methacycline, oxytetracycline, tetracycline |
| Protozoa | Monensin, sulphonamides, tetracycline |
| Fungi | |
| <i>Candida albicans</i> | Amphotericin, nystatin |
| Dermatophytes | Griseofulvin, natamycin |
| Ectoparasites and endoparasites | Ivermectin |

considered academic by many, but if it is looked at objectively, it has much to commend it. At the first examination and, hopefully, before any therapy has been initiated is the best time to obtain samples to establish the likely cause of the problem. In addition, the cost of micro-organism determination is usually less, or at least no more, than the cost of appropriate therapy. In almost all cases the value of the individual animal will be sufficient to make it worthwhile and this is multiplied many times when problems are encountered on a herd basis. There is virtually no justification for not sampling problems of a herd nature when infections are suspected. In addition, the treatment of chronic conditions or those that have responded poorly is important. Besides positively determining the cause, sampling may help to eliminate other potential agents.

The method of sampling is important in that it should involve fresh clinical cases rather than those of a chronic nature. The sample should be taken from as near the inflamed area as possible. This is difficult with problems such as salmonellosis, as organisms in the faeces may be diluted by those further down the gut, which in themselves may be much faster growing. Sampling of pneumonias is always difficult as the organisms present in the upper respiratory tract may be unrepresentative of those in the lung.

Direct examination of the sample after staining is of use as in some circumstances organisms will not subsequently grow. Rapid staining methods are now available and these allow the shape of the organism and whether it is Gram-positive or Gram-negative to be determined. This in turn can be useful in making a quick decision about the drug most likely to be effective.

Table 61.2 Drugs with reasonable penetration of various fluids and tissues.

| | |
|---------------------|--|
| Bile | Erythromycin |
| Bone | Chlortetracycline, doxycycline, fucidin, lincomycin, methacycline, oxytetracycline, tetracycline |
| Cerebrospinal fluid | Chloramphenicol, florfenicol, fluoroquinolones, sulphonamides, trimethoprim and sulphonamides |
| Eye | Amoxycillin, ampicillin, cephalexin, cephaloridine, cephalothin, chloramphenicol, lincomycin |
| Milk | Benzylpenicillin, erythromycin, lincomycin (but toxic), oleandomycin, penethamate, spiramycin, tylosin |
| Prostate | Erythromycin, trimethoprim |
| Serosal fluids | Chloramphenicol, dihydrostreptomycin, erythromycin, framycetin, gentamicin, kanamycin, lincomycin, neomycin, paromomycin, streptomycin |

Sensitivity testing

Identification of the causal organism allows a decision to be made as to whether or not to test for antimicrobial sensitivity. In many cases there is no need to undertake this. Thus organisms of *Clostridium* spp. are sensitive to high doses of penicillin G. However, in cases involving *Escherichia coli* and *Salmonella typhimurium* there will be considerable variations in the sensitivity pattern, bearing in mind the origin of the organism.

The Kirby–Bauer disc sensitivity test is that most commonly used for *in vitro* testing. The aim is to determine if an organism is likely to be affected by specific antimicrobial agents at the usual therapeutic levels. While the drug concentration reflects levels achieved in the plasma, it does not take into account quantities in various tissues such as the brain or udder. The test organism is usually classified as sensitive, intermediate or resistant to the specific antimicrobial agent. The test was produced for use in human medicine where it provides a quantitative assessment. However, in animals it is a useful guide. Quantitative tests involve determining the minimal inhibitory concentration and usually consist of tube sensitivity tests. In general, an organism sensitive *in vitro* may be sensitive *in vivo*, but one resistant *in vitro* is also likely to be resistant *in vivo*.

Penetration

The ability of a drug to penetrate the infected area needs to be considered (see Table 61.2). Penetration depends on the degree of the pathological process as is seen with

abscess or thrombus formation. It also depends on the tissue involved and whether there are natural limits to penetration such as in the brain (see p. 897) or in milk. The location of the organism is also important, i.e. whether it is intracellular or extracellular.

The ability of an antimicrobial drug to cross biological membranes depends on many factors. These include protein binding, lipid solubility, pH of the drug in relation to environmental pH, molecular size and in some cases specific cellular transport mechanisms. Antibiotic is absorbed into the circulation, partly becoming bound to plasma protein. Binding varies, e.g. from less than 50 per cent with amoxycillin, streptomycin or oxytetracycline to more than 80 per cent with cloxacillin or erythromycin. Binding is readily reversible and the bound fraction is in equilibrium with the unbound (active) form. Protein binding can be a disadvantage, as with sulphonamides, which are highly protein bound. As purulent fluids often contain much protein, sulphonamides can be relatively inactive.

Water-soluble drugs are useful for extracellular organisms and where intracellular organisms have a

high turnover rate, usually in the lysis of cells and release of the organisms into fluids containing the antimicrobial agent. Lipid solubility does have advantages for organisms that spend most of their time within cells or behind tissue barriers. Inflammation can also alter penetration of drugs. Thus penetration of the central nervous system by many drugs is minimal in the healthy animal although penicillin G and other antibiotics can enter during inflammation. However, the effect of inflammation on the penetration of many drugs is unknown. Thus it can be the local environment in which the organism is present that is important. Most antimicrobial agents do maintain their activity; however, aminoglycosides are more active in aerobic conditions with a slightly alkaline pH. As such conditions do not exist around staphylococcal abscesses this group of drugs is relatively inactive in such circumstances. Activity of antibacterial agent in urine is often influenced by the pH (see Table 61.3.) The problem of sulphonamides and pus has already been mentioned. Some antibiotics do have more effect on anaerobic bacteria than others under such conditions (see Table 61.4).

Table 61.3 Antibacterial drug activity in urine. Urinary infections are relatively uncommon in cattle but can lead to therapeutic problems.

| Not affected by urine pH | Most active in alkaline urine | Most active in acid urine |
|--------------------------------|-------------------------------|---------------------------|
| Cephalexin | Colistin | Carbenicillin |
| Cephaloridine | Dihydrostreptomycin | Chlortetracycline |
| Cephalothin | Erythromycin | Doxycycline |
| Chloramphenicol | Framycetin | Methacycline |
| Nalidixic acid | Gentamicin | Nitrofurantoin |
| Sulphonamides | Kanamycin | Oxytetracycline |
| Trimethoprim and sulphonamides | Neomycin | Penicillin G |
| | Paromomycin | Tetracycline |
| | Polymyxin B | |
| | Streptomycin | |
| | <i>Alkalinization</i> | <i>Acidification</i> |
| | Sodium bicarbonate (oral) | D-Methionine (oral) |
| | | Ascorbic acid (oral) |

Table 61.4 Antibiotics effective *in vitro* against anaerobic bacteria.

| High efficacy | Moderate efficacy | Low efficacy |
|-----------------|-----------------------|---------------------|
| Amoxycillin | Chlortetracycline | Dihydrostreptomycin |
| Ampicillin | Erythromycin | Framycetin |
| Carbenicillin | Oxytetracycline | Gentamicin |
| Chloramphenicol | Procaine penicillin G | Kanamycin |
| Clindamycin | Tetracycline | Neomycin |
| Metronidazole | | Paromomycin |
| | | Streptomycin |

Antibiotic resistance

The advent of antimicrobial drugs has resulted in the emergence of resistance to these drugs (see Table 61.5). The use of antibiotics in therapeutic concentration results in an alteration of the microflora within the host. There is a tendency for a loss of the sensitive strains with the resistant ones remaining. This selection allows multiplication of resistant strains within the less competitive environment. The resistant organisms can remain in the animal and also contaminate the environment, thereby allowing passage to other animals. The prevalence of the resistant organisms tends to reduce the longer the period since the drug was used.

Spontaneous mutation of organisms can occur but it is probably only of limited importance in practice. However, transferable drug resistance is of significance. This resistance, as determined in the form of plasmids or transposons, is transferred to susceptible strains. Plasmids are extrachromosomal genetic material that can replicate independently of the chromosome. These plasmids can be transferred by conjugation within or between bacterial species and they can also act as vectors for transposons. This allows the transfer of single or multiple antibiotic resistance and has produced many of the resistant bacteria found in enteric calf infections including both *E. coli* and *S. typhimurium* as well as in *Staphylococcus aureus* and some *Pasteurella* and *Mannheimia* spp. infections. In some countries the use of chloramphenicol in food animals is restricted or banned because of the usage in humans and also due to potential human toxicity from handling it. Increasing concern has been expressed about microbial resistance to antibacterials in human beings caused by contact directly with, or indirectly from food produced from, farm animals. While the risks appear to be minimal in creating human microbial resistance compared with other causes, all veterinarians should bear the problem in mind when treating or prescribing for cattle.

Table 61.5 gives examples of antimicrobials which still have activity in the presence of penicillinase.

Dosage

When an antimicrobial agent is selected it must be in a high enough concentration and used for a long enough period to result in contact with the organism and its consequent demise. Various factors influence this, including the dose, formulation and rate of administration. Doses are usually based on body weight. The recommended dose usually provides good blood and tissue

Table 61.5 Penicillinase (β -lactamase) active antimicrobials.

| | |
|------------------|---|
| Penicillins | Cloxacillin, methicillin |
| Cephalosporins | Cefoperazone, cephalexin, cephalonium, cephaloridine, cephalothin |
| Aminoglycosides | Amikacin, framycetin, gentamicin, kanamycin, neomycin, paramomycin |
| Macrolides | Erythromycin, oleandomycin, spiramycin, tylosin |
| Nitrofurans | Furazolidone, nitrofurantoin, nitrofurazone |
| Fluoroquinolones | Danofloxacin, enrofloxacin, marbofloxacin |
| Others | Bacitracin, chloramphenicol, florfenicol, lincomycin, novobiocin, sulphonamide and trimethoprim, vancomycin |

levels that are effective against most susceptible organisms, with minimal side-effects. In most cases the recommended dose is the minimal dose. This is particularly so for farm animals where both the interval between therapy and the suggested dose level tend to be lower than for man or small animals due to cost.

Less susceptible organisms require higher levels to ensure success. Increasing the dose needs to be considered carefully, but it is of little danger if the drug has a low toxicity. However, when the antimicrobial agent is of high toxicity any increase in dosage should be undertaken with caution. Different dosages may also influence the drug withdrawal time. It should be remembered that when different companies produce the same antibiotic it may well contain different amounts of the drug and the vehicle in which it is presented may vary.

Route of administration

The choice of administration route depends on the speed with which infection has to be counteracted as well as the volume to be given, ease of administration, etc. The principal routes used are given in Table 61.6.

Duration of therapy

In general terms, most injections are used for three to five days and for at least one day after normality is reached. However, there is a tendency not to treat for long enough in chronic conditions such as some cases of chronic joint or thoracic infections when therapy should be continued for at least 10–14 days. If it was a

Table 61.6 Routes of administration of antimicrobial drugs.

| | |
|--|---|
| <i>Intravenous (iv): always give slowly</i> | Disadvantages |
| Advantages | |
| Rapid high blood and tissue levels, therefore useful for septicaemias | May provoke marked fluid reaction |
| Always higher circulating levels than im or oral | Only slowly absorbed |
| Increased levels at areas where levels usually low, e.g. necrotic areas, chronic abscesses | Speed of absorption less than im |
| Useful for large volumes | <i>Intra-articular</i> |
| Useful for painful injections | Increased level in joint |
| Useful for irritant injections | Must be sterile technique |
| Only method of obtaining accurate blood and tissue levels | <i>Intrapleural</i> |
| Disadvantages | Increased level in thorax |
| Acute toxic reactions more common | Must be non-irritant |
| Specific formulations necessary | Must be a sterile technique |
| Requires good technique | |
| Perivascular and intravascular thrombosis can occur | |
| <i>Intramuscular (im)</i> | <i>Subconjunctival</i> |
| Advantages | Useful for ocular conditions |
| Most common route | Must be non-irritant |
| Only 20ml per injection site | Must be sterile technique |
| Peak blood and tissue levels within 2 hours | |
| Slightly less irritant injections than those given iv can be given by deep im injection | |
| Allows a reasonable level to be maintained over a period of time | <i>Oral (water or feed)</i> |
| Disadvantages | |
| Muscle damage | Advantages |
| Try not to do within 3 weeks of slaughter | Easiest method of administration |
| Severe reactions to some drugs | Can be undertaken by owner |
| Some injections painful | Disadvantages |
| Accurate blood and tissue levels not obtained | Blood and tissue levels less than for comparable parenteral dose |
| <i>Intrapерitoneal (ip)</i> | Higher doses usually used |
| Advantages | Absorption is variable (depends on gut motility, type of feed, volume of feed, drug binding, e.g. calcium, kaolin impair absorption of tetracycline, oxytetracycline, chlortetracycline, methacycline, doxycycline, ampicillin, lincomycin) |
| Speed of absorption similar to im injection | Blood levels do not peak for 12–18 hours |
| Usually well absorbed | Antibiotics may influence normal ruminal flora |
| Useful for peritonitis | Some antibiotics not absorbed, e.g. streptomycin, dihydrostreptomycin, neomycin, framycetin, phthalylsulphathiazole |
| Useful if very toxic | Some antibiotics destroyed, e.g. benzylpenicillin |
| Useful for irritant drugs | |
| Useful in severe respiratory distress (especially tetracyclines) | <i>Topical</i> |
| Large volumes can be given | Ointments, powders, aerosol sprays |
| Disadvantages | |
| Possible sepsis | <i>Ophthalmic preparations</i> |
| Accurate blood and tissue levels not obtained | Ointments and drops. Limited retention at site except some special preparations |
| <i>Subcutaneous (sc)</i> | <i>Aural preparations</i> |
| Advantages | Drops and ointments |
| Little used for antimicrobials except sulphonamides | <i>Intramammary (use aseptic technique)</i> |
| Large volumes can be given | Advantages |
| Less irritant than im | Convenient |
| | Good efficacy |
| | Disadvantages |
| | Often diffusion reduced by blocked lactiferous ducts, etc. |
| | Used for clinical treatment |
| | Dry-cow therapy used for subclinical mastitis and prophylaxis |
| | If intramammary tube used in one quarter all milk should be withheld |

human or small animal there would often be no dispute about such a length of therapy. Many antibacterial preparations are now available that can be injected at extended intervals to provide adequate drug concentrations for several days. However, in some cases the duration of effective therapy can be overestimated.

Spectrum of drug activity

Antibacterial drugs vary in their degree of activity against various classes of organism. They are usually considered narrow spectrum if they are only active against bacteria, but broad spectrum if they also have

activity against *Mycoplasma*, *Rickettsia* and *Chlamydia*. The antibacterial activity of drugs can also vary (see Table 61.7): some have a narrow spectrum, only inhibiting either Gram-negative or Gram-positive organisms; others have most activity against Gram-positive organisms but will inhibit some Gram-negative agents. However, some have a broad spectrum inhibiting both Gram-positive and Gram-negative bacteria.

Bacteriostatic or bactericidal activity

At times it is important to know the activity of a drug. Some drugs are bactericidal, e.g. penicillin,

Table 61.7 Antibacterial activity other than for anaerobic bacteria.

| Gram-positive bacteria | Gram-negative bacteria | Broad spectrum: Gram-positive and Gram-negative bacteria |
|------------------------|-------------------------------|--|
| <i>Penicillins</i> | <i>Penicillins</i> | <i>Penicillins</i> |
| Cloxacillin | Carbenicillin | Amoxycillin |
| Methicillin | | Ampicillin |
| Penicillin G | <i>Polymyxins</i> | Clavulanic acid and amoxycillin |
| Penicillin V | Colistin | |

| Bacitracin | |
| Panfloxacin | |

Whether a drug is bactericidal or bacteriostatic needs to be known as problems can occur with combinations.

aminoglycosides, while others are bacteriostatic and require the animal's own defence mechanism to help in the organisms' removal (Table 61.8). These definitions are only relative and some agents are bactericidal in high concentrations but only bacteriostatic at low levels.

Drug combinations

These are frequently used in veterinary practice but are often best avoided. They are used where infection is due to mixed organisms. They can be helpful where

synergism has been shown with the combination, e.g. penicillin and aminoglycosides, or trimethoprim and sulphonamides. Although the bacteriostatic or bactericidal nature of many drugs is dependent on the concentration used, it is still a good ploy to combine antibiotics with a similar activity. This is of particular importance when treating immunocompromised animals. Besides the broader spectrum of activity attained with some combinations, cost may be less and in some cases there may be a reduction in toxicity.

When using combinations it is best to give each drug individually at the correct dose with an interval between administrations. When two drugs are combined in commercial preparations then the dosage of each is fixed regardless of the needs of the particular situation or the interval between doses. Care should be taken in the choice of antimicrobial agent when used in combination with corticosteroids.

Cost

This is a major drawback in that often the best therapy cannot be instituted because of the expense. Repeat doses also cause problems, especially as oral therapy is not often advisable in ruminants. The problem can be overcome by long-acting preparations or providing combination injections for the farmer or stockworker to administer. It must be remembered there is an indirect cost, particularly to the dairy farmer, in the length of time the milk has to be withheld after the end of treatment. The beef farmer encounters a similar problem regarding meat withdrawal time but to a lesser extent.

Toxicity

Except where there is routine usage of antimicrobial drugs in adult animals, few problems of toxicity arise. Some of the more common are given in Table 61.9.

Drug withdrawal times

Following use of an antimicrobial agent there is now usually a period between finishing therapy and the use of the milk or the slaughter of the animal for meat. Milk or meat containing antibiotics can present a public health risk. There is the possibility of allergy to penicillins or other antibacterials following medical prescription. Documented cases are rare and are now almost non-existent in countries with adequate anti-

biotic testing. Where they have occurred they involved usage of milk. Another possible hazard is drug resistance in humans but adequate documented evidence for the occurrence of this following consumption of milk or meat is still required. The main effect of antibiotics in milk is a commercial one in that it can affect the starter cultures for cheese or yoghurt.

Various factors influence the withdrawal time and these include the drug dose rate, age, disease, duration and role of therapy. The injection site will obviously contain higher levels than other sites. Depending on how the drug is metabolized, the kidney and liver may have higher levels than other tissues. In all cases it is the duty of the veterinary surgeon to ensure that any withdrawal time is observed and that the owner of the animal is made aware of this. It is always best to write the time down either on the drug vial if doses are to be provided for administration by the farmer, or on an invoice or note to the farmer. Where a withdrawal time is not known then the manufacturer or distributor of the drug should be contacted. However, in general, when no withholding time is stated then milk must be discarded for seven days and cattle may not be slaughtered for human consumption for 28 days. In the USA veterinarians can obtain information on withdrawal times and residues by contacting the Food Animal Residue Avoidance Data book (FARAD).

Legal considerations

The availability of antimicrobial agents in most countries is first dependent on their being licensed for use by a regulatory authority. This can be the Veterinary Medicines Directorate, Food and Drug Administration or another similar body. Some antibiotics are available in certain countries but are banned in others, e.g. chloramphenicol, which is prohibited from use in North America and most of Europe.

Frequency of dosing

The frequency of administering therapeutic preparations varies. Some compounds are placed in slow-release boluses to facilitate this. The rate of absorption also varies between different preparations, dependent on the particle size; thus those with micronized particles are rapidly absorbed. The form of the antibiotic will also influence the level of activity. Thus with penicillin, benzylpenicillin is rapidly absorbed (in minutes) to reach peak levels but only persists for about 6 hours. However, procaine benzylpenicillin

Table 61.9 Toxicity of antimicrobial drugs.

| | |
|----------------------|---|
| Penicillins | Very low toxicity, hypersensitivity. Occasional severe adverse reactions |
| Sulphonamides | Toxicity rare, rapid intravenous injection causes collapse and respiratory distress, crystalluria |
| Macrolides | Pain and reaction following sc or im injections. Crystalluria not a problem in large animals. Erythromycin and tylosin irritant following injection |
| Lincomycin | Diarrhoea, reduced milk production (oral) |
| Aminoglycosides | Ototoxicity (unlikely), cardiovascular damage, hypotension (for toxic and shocked animals), renal toxicity |
| Tetracyclines | Acute collapse syndrome (iv). Alimentary tract dysfunction (if oral). Deposition in bone and teeth |
| Chloramphenicol | Little toxicity. Superinfection (oral). Anaemia in humans |
| Polymyxyn B Colistin | Usually only used topically as toxic shock and death can occur following parenteral use |
| Nitrofurans | Acute – nervous signs Chronic – haemorrhagic syndrome |

Table 61.10 Some possible antibacterial therapy for infections in cattle.

| <i>Calves</i> | |
|--|--|
| Diarrhoea (acute) bacterial | Amoxycillin, ampicillin, (chloramphenicol), chlortetracycline, clavulanic acid and amoxycillin, danofloxacin, enrofloxacin, framycetin, marbofloxacin, neomycin, oxytetracycline, trimethoprim and sulphonamide |
| Diarrhoea (subacute) bacterial | Neomycin, nitrofurazone, oxytetracycline, sulphonamides |
| Joint ill | Lincomycin, oxytetracycline |
| Meningitis | (Chloramphenicol), danofloxacin, enrofloxacin, marbofloxacin, trimethoprim and sulphonamide |
| Navel ill | Amoxycillin, ampicillin, clavulanic acid and amoxycillin, oxytetracycline, trimethoprim and sulphonamide |
| Pneumonia | Amoxycillin, ampicillin, cefquinone, ceftiofur, cephalexin, clavulanic acid and amoxycillin, danofloxacin, enrofloxacin, florfenicol, marbofloxacin, oxytetracycline, penicillin and streptomycin, tilmicosin, tylosin |
| Ringworm | Griseofulvin, natamycin |
| <i>Salmonella</i> spp. | Amoxycillin, ampicillin, apramycin, (chloramphenicol), clavulanic acid and amoxycillin, danofloxacin, enrofloxacin, marbofloxacin, neomycin, nitrofurazone, trimethoprim and sulphonamide |
| Septicaemia | Amoxycillin, ampicillin, (chloramphenicol), clavulanic acid and amoxycillin, danofloxacin, enrofloxacin, marbofloxacin, trimethoprim and sulphonamide |
| <i>Older cattle – injections</i> | |
| Actinomycosis | Amoxycillin, cephalexin, oxytetracycline, penicillin, sulphonamides |
| Anthrax | Amoxycillin, oxytetracycline, penicillin and streptomycin |
| Blackleg | Benzylpenicillin |
| Clostridial infections | Oxytetracycline, penicillin |
| Diarrhoea (acute) | Sulphonamide |
| Infectious bovine keratoconjunctivitis | (Chloramphenicol), oxytetracycline |
| Leptospirosis | Amoxycillin, oxytetracycline, streptomycin |
| Mastitis (peracute) (parenteral) | Amoxycillin, ampicillin, cefquinone, cephalexin, oxytetracycline, trimethoprim and sulphonamide |
| Metritis | Amoxycillin, ceftiofur, cephalexin, clavulanic acid and amoxycillin, oxytetracycline |
| Peritonitis | Sulphonamides, trimethoprim and sulphonamides |
| Pneumonia (acute) | Amoxycillin, ceftiofur, danofloxacin, enrofloxacin, marbofloxacin, oxytetracycline, trimethoprim and sulphonamide |
| Pneumonia (subacute) | Amoxycillin, ampicillin, ceftiofur, oxytetracycline, penicillin and streptomycin, trimethoprim and sulphonamide |
| Pyelonephritis | Procaine penicillin |
| <i>Salmonella</i> spp. | Amoxycillin, ampicillin, (chloramphenicol), danofloxacin, enrofloxacin, marbofloxacin, neomycin, trimethoprim and sulphonamide |
| Tetanus | Benzyl and procaine penicillin |
| Wooden tongue | Amoxycillin, oxytetracycline, penicillin and streptomycin, sulphonamide |

Note: Not all these drugs are registered for the species or for the use suggested.

Box 61.1 Advantages and disadvantages of slow-release antibiotic preparations.

Advantages

Often used in prophylaxis
Post-operatively
Post calving where there has been intervention
Dry cow therapy: most remain about 3–4 weeks in udder but some persist six weeks or longer
Less stress to animal
Reduced handling
Less pain to animal
Convenience

Disadvantages

Animals may not be examined as regularly as when injected often
Thus animal less monitored
Usually tissue and blood levels lower than routine injections
Increased withholding time for milk or injection-to-slaughter time

reaches a maximum level in 2–4 hours and persists for 24 hours, benethamine benzylpenicillin has a slow absorption (6–24 hours) and may be effective for three to four days, and benzathine benzylpenicillin is slowly absorbed over 6–24 hours and is often effective for four to seven days.

The advantages and disadvantages of slow-release antibiotic preparations are given in Box 61.1.

Possible antibacterial therapy for cattle

A survey of some of the drugs used in the treatment of cattle is given in Table 61.10. It is emphasized that this list is not complete and some preparations are not permitted in all countries.

The nature of inflammation

Inflammation (from the Latin *inflammare*, to burn) is common to many diseases involving injury to living tissues. Inflammation is, in fact, the basis of most pathology. Acute or chronic inflammation occurs as a consequence of chemical, physical or microbiological damage to tissues. Acute inflammation has been described as the response of the living microcirculation and its contents to injury. A range of defence mechanisms including the immune system may be utilized. If the inflammation is caused by micro-organisms, tissue damage may proceed as far as host cell death. An avascular tissue like cartilage, as with dead tissue, cannot respond to injury by mounting an acute inflammatory response, although in some circumstances it may degrade.

The microcirculation therefore plays a crucial role in tissue response to injury. Blood vessels dilate and, ini-

tially, local blood flow increases. Vascular endothelial cells change their shape, with the formation of inter-endothelial cell gaps through which plasma leaks. This leads to the formation of protein-containing exudate (oedema fluid) in the interstitial compartment. At this stage blood flow slows and eventually becomes static.

The contents of the microcirculation include plasma and the cellular elements of blood. The phagocytic leucocytes (neutrophils and monocytes) emigrate from the circulation during the inflammatory process and engulf the tissue irritant, including micro-organisms, in the inflammatory exudate. The initial step is margination and adherence of leucocytes to the vascular endothelial wall, followed by pavementing, the process whereby the cells roll along the wall to the inter-endothelial cell gaps. Passage through the wall and directional movement to the site of injury occurs by the process of diapedesis. Neutrophils are the first cell type to enter the lesion, followed after several hours by mononuclear phagocytes. Other circulating cells (platelets, eosinophils and basophils) may also migrate to the extravascular space.

Inflammation, if associated with infection, may be accompanied by fever, as the result of resetting of the 'thermostat' in the hypothalamus. These changes at the level of the tissue or organ comprise Celsius' four classical signs of inflammation, *rubor et calore cum tumor et dolor* (redness and heat with swelling and pain). To these Virchow added a fifth sign, *functio laesa* (loss of function), many centuries later. The essential features of the acute inflammatory process are outlined in Fig. 62.1.

The suffix '-itis' is appended to the name of the affected tissue to describe organ-based inflammation in the conditions of mastitis, bursitis, colitis, cystitis, metritis, arthritis, tendonitis, laminitis and many others. Severe local inflammation or more widespread inflammation, particularly associated with infection, may be accompanied by fever.

The outcome of acute inflammation may be resolution and hence restoration of normal tissue architecture and function. However, particularly if the stimulus persists, tissue destruction may occur with fibrous tissue formation and repair, potentially compromising normal function. In some cases, there may be delayed healing

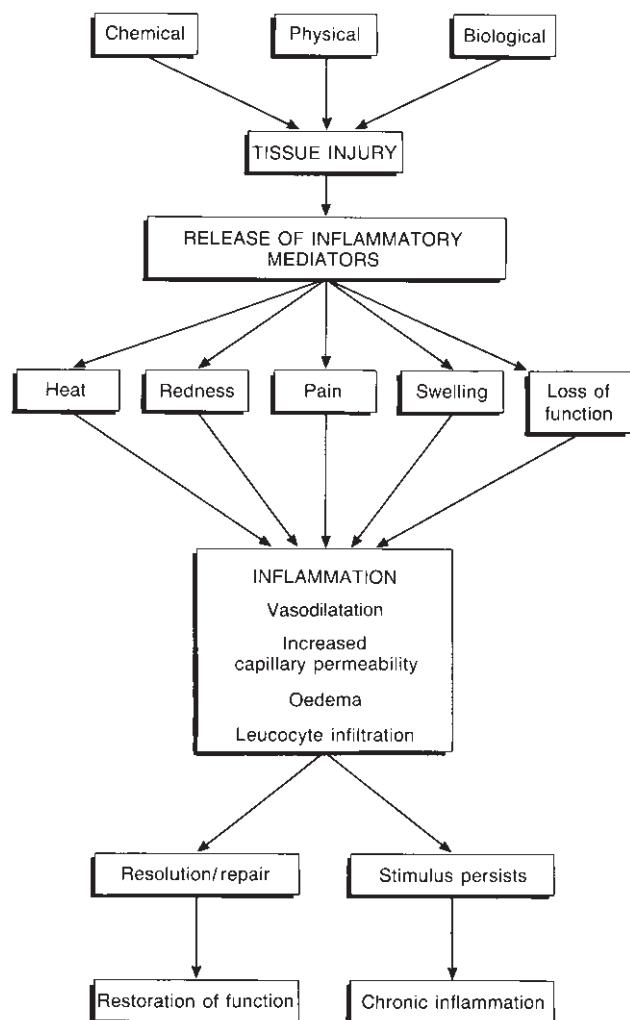

Fig. 62.1 The inflammatory process.

or even persistent chronic inflammation, with local proliferation of connective tissue and mononuclear cell accumulation. The granulation tissue in chronic inflammation comprises highly vascularized connective tissue. In some forms of chronic inflammation lymphocytes are present, suggesting an immune response superimposed on the inflammatory response.

Pain associated with inflammatory disease is probably the major source of pain in ruminant species. The measurement of pain in animals is fraught with difficulties and, to date, pain research in animals has focused primarily on mechanisms of acute pain (e.g. Lascelles *et al.*, 1997; Dolan & Nolan, 2000). Pain is a complex experience, dependent not only on the severity of the insult to pain pathways and the degree of tissue or nerve damage, but also on previous pain experiences and on social position within a herd. The most significant inflammatory diseases likely to be associated with pain in ruminants are mastitis and inflammatory limb

lesions, including sole ulceration, white line disease and acute digital tissue infection, leading to lameness. The pain component of inflammation arises from activation and sensitization of fine unmyelinated and some myelinated sensory fibres to the actions of chemicals released from a variety of sources during inflammation (Ferreira, 1983). Information from the periphery is conducted to the spinal cord and from there to the brain, where pain is perceived. Inflammation induces alterations in nociceptive information processing which may have serious consequences for the animal. Allodynia (perception of innocuous stimuli as noxious) and hyperalgesia (exaggerated responses to noxious stimuli) are common features of inflammatory pain (Coderre & Melzack, 1987; Nolan, 2000).

Mediators and modulators of inflammation

The characteristic pathophysiological changes of acute and chronic inflammation are produced by the action of chemicals, either released from cells such as mast cells, macrophages and fibroblasts or formed by *de novo* synthesis. If there is an immune basis to the inflammatory response, lymphocytes are also involved. Compounds like histamine, that act directly to produce microvascular changes, or like bradykinin, to cause pain are called inflammatory mediators or, if their role has not been firmly established, they are termed putative mediators.

The number of putative mediators identified is considerable. Moreover, there are some species differences in mediators, so that, for example, 5-hydroxytryptamine (5-HT) is probably an acute inflammatory mediator in rodents only. Some mediators, such as complement fragments C5a and C3a, not only act directly on the microcirculation but also cause mast cell degranulation, leading to histamine release and hence reinforcement of the inflammatory response. In addition, there is a sequential release of mediators, such that histamine, 5-HT and bradykinin are involved in the early part of the acute phase, whereas lysosomal and other proteolytic enzymes are involved subsequently. Much is now known about acute inflammatory mediators; information on the mediators responsible for the transition to, and the subsequent persistence of, chronic inflammation is more sparse. Examples of mediators inducing vascular leakage are bradykinin, histamine and platelet activating factor (PAF), which act directly, and leukotriene B₄ (LTB₄) and complement fragment C5a, which exert their effect through neutrophil-dependent mechanisms (Williams, 1983). Mediators of cell migration and accumulation include C5a, PAF, LTB₄,

interleukin-1 (IL-1) and many other chemokines and cytokines, whilst mediators responsible for producing tissue damage include the neutral proteases and the highly reactive oxygen (free) radicals, notably the hydroxyl radical.

Mediator interactions are complex, and there are compounds whose principal role is to interact synergistically with inflammatory mediators. For example, the vasodilator prostanoid prostaglandin (PGE₂) enhances

markedly both the pain produced by kinins such as bradykinin and the increased vascular permeability produced by simple amines, like histamine (Davies *et al.*, 1984). Those compounds that amplify the actions of others are described as modulators of inflammation. The properties and sources of some important mediators and modulators of inflammation and joint disease are described in Table 62.1. It should be noted that the list is not comprehensive!

Table 62.1 Mediators and modulators of acute and chronic inflammation.

| Putative mediator/modulator | Properties and source |
|--|--|
| Histamine | An amine produced from histidine by decarboxylation. Stored in mast cells, basophils and platelets. Mast cell degranulation leads to release into extracellular environment in immune and non-immune inflammation. Causes vasodilatation and increased permeability of small postcapillary venules. Local administration causes pain and itching |
| 5-Hydroxytryptamine (serotonin) | Another simple amine stored in platelets and mast cells. Increases permeability of small venules in rodents but probably at most a minor mediator in other species |
| Bradykinin | A peptide containing nine amino acids that act on bradykinin receptors. Synthesized from plasma kinins <i>de novo</i> . Produces vasodilatation, increased vascular permeability and pain |
| Neuropeptides | Main peptides involved are substance P, serokinin A (both tachykinins) and calcitonin gene related peptide. Induce mediator release, contract smooth muscle and induce vasodilation |
| Complement system | Several complement components including C3a, C5a, C8, C9 exert proinflammatory actions, e.g. vasodilatation, increased vascular permeability, mast cell degranulation, leucocyte chemotaxis and cytosis |
| Eicosanoids | |
| PGE ₂ | Derived from cell membrane phospholipid, following release of the precursor arachidonic acid. Produces prolonged dilatation of small arterioles and potentiates the increased vascular permeability and pain produced by other mediators like histamine and bradykinin |
| PGI ₂ | A potent dilator of small arterioles. Possesses similar properties to PGE ₂ but with shorter duration of action |
| PGJ ₂ | A derivative of PGD ₂ . Believed to play a role as anti-inflammatory prostanoid in the resolution of acute inflammation |
| LTB ₄ | Potent chemoattractant for polymorphonuclear leucocytes and mononuclear cells. Enhances vascular permeability produced by other mediators such as PGE ₂ , PGI ₂ and bradykinin |
| Lipoxin A | Produced from cell membrane phospholipid by polymorphonuclear leucocytes. Stimulates leucocytes to generate superoxide radical and causes release of lysosomal enzymes. Lipoxins also possess anti-inflammatory properties and are probably involved in resolution of acute inflammation |
| Platelet activating factor (PAF) | An ether-linked analogue of phosphatidylcholine. Derived from cell membrane phospholipid. Produces platelet and neutrophil aggregation, bronchoconstriction, vasodilatation, increased capillary permeability and chemotaxis |
| Interleukins and other cytokines, e.g. IL-1, TNF- α | Produced by macrophages, chondrocytes and synovial cells. Chemotactic for leucocytes and possess mitogenic and pyretic properties. Stimulate release of PGE ₂ and collagenase by chondrocytes, synovial cells and dermal fibroblasts. Possibly involved in cartilage breakdown. Other cytokines possess anti-inflammatory properties |
| Enzymes | Lysosomal enzymes such as lysozyme and acid phosphatase concerned with lysis of foreign and host cells in acute and chronic inflammation. Non-lysosomal metalloproteinases such as stromelysin, concerned with proteoglycan breakdown in arthritis |

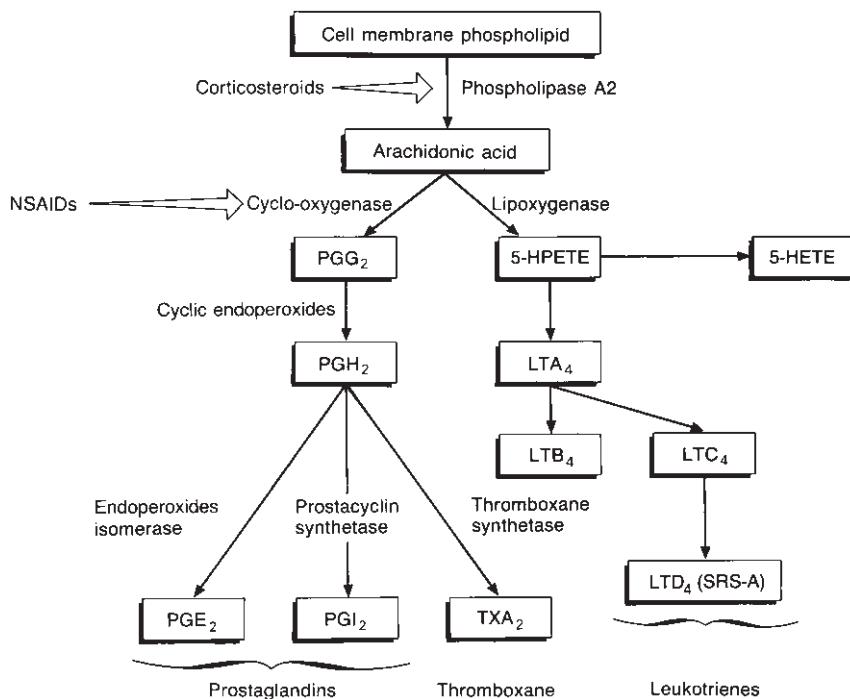

Fig. 62.2 The arachidonic acid cascade illustrating pathways of generation of eicosanoids and proposed sites of action of steroids and NSAIDs.

The eicosanoid group of mediators and modulators is particularly important to a consideration of the two most important anti-inflammatory drug groups in cattle medicine, steroids and non-steroidal anti-inflammatory drugs (NSAIDs). Eicosanoids are formed from the 20-carbon unsaturated fatty acid substrate arachidonic acid (Willoughby, 1968). Arachidonic acid is released from an esterified form in which it is bound as a natural component of the phospholipid of cell membranes. The release is catalysed by phospholipase A₂, an acylhydro-lase enzyme that is activated by tissue injury. Arachidonic acid may act as a substrate for two enzyme groups, the cyclo-oxygenases (COX) and lipoxygenases (LO). Cyclo-oxygenases catalyse the production of prostanoids such as prostaglandin (PG)E₂ and PGI₂ and thromboxane A₂ (TXA₂) from the cyclic endoperoxides PGG₂ and PGH₂ (Fig. 62.2). Lipoxygenases, of which there are three groups, 5-LO, 12-LO and 15-LO, on the other hand, are responsible for the synthesis of hydroxyeicosatetraenoic acids (HETEs), leukotrienes and lipoxins (Fig. 62.2). The importance of the arachidonic acid pathway in inflammation in general, and in veterinary therapeutics in particular, lies in the fact that the steroids and NSAIDs act, at least partially, by inhibiting enzymes in the arachidonic acid pathway (Fig. 62.2) (Higgs *et al.*, 1981). The NSAIDs act by inhibiting COX and thus they decrease the release of PGE₂ and TXA₂, since COX catalyses the conversion of arachidonic acid released from cell membranes when they are damaged (Vane, 1971).

Classification of anti-inflammatory drugs

In view of the complexity of the inflammatory process and the involvement of many mediators and modulators in determining the time course of inflammatory reactions, it is inevitable that those anti-inflammatory drugs with activity against a single mediator have only limited clinical effectiveness. With currently available drugs, it is easier to inhibit the pain, increased blood flow and oedema associated with acute inflammation than it is to suppress chronic inflammation or the cartilage breakdown that characterizes degenerative joint disease. However, there have been some interesting recent advances in the latter field.

Table 62.2 gives a general classification of drugs that either possess anti-inflammatory properties or that have been used to treat various joint diseases. Drugs that inhibit COX are the classical aspirin-like drugs collectively known as NSAIDs (Higgs *et al.*, 1980, 1981). The first compound of this class in clinical use was salicylate, derived initially from the bark of willow and poplar trees. Aspirin was the first synthetic NSAID; it is the acetyl derivative of salicylate and was introduced into clinical medicine by Hoffman in 1898.

More recently introduced are the drugs that inhibit both 5-LO and COX enzymes, so-called dual inhibitors. By inhibiting the synthesis of leukotrienes such as LTB₄ as well as prostanoids like PGE₂, these novel com-

Table 62.2 Classification of anti-inflammatory drugs and drugs used in the treatment of joint disease.

| Drug class | Examples | General properties |
|-----------------------------|--|---|
| Antihistamines | Tripelenamine, mepyramine, diphenhydramine | Classical histamine (H) ₁ -receptor antagonists. Produce some suppression of acute inflammation but limited to early phase of acute inflammation |
| COX inhibitors | Aspirin, phenylbutazone, flunixin, carprofen, meloxicam, tolfenamic acid, vedaprofen, ketoprofen | Provide analgesia in inflammatory pain and some suppression of vascular changes in inflammation. Little or no effect on leucocyte migration. Gastrointestinal ulceration may occur and blood dyscrasias; hepatotoxicity and renotoxicity may arise occasionally |
| Dual inhibitors of COX/5-LO | Tepoxalin | Inhibit most changes in acute inflammation, possess fewer side-effects than pure COX inhibitors |
| Corticosteroids | Hydrocortisone, cortisone, dexamethasone, betamethasone, prednisolone, prednisone, triamcinolone | Suppress all components of acute and chronic inflammation but side-effects associated with medium- to long-term use (adrenal atrophy, immune suppression, decreased bone strength, Cushingoid symptoms, delayed wound healing, muscle wastage, etc.) |
| Disease modifying agents | Penicillamine, gold salts | Retard the degenerative changes in immune-based arthritides. Very slow onset of effects (several weeks). Potentially severe side-effects, little veterinary use |
| Cytotoxic agents | Cyclophosphamide, chlorambucil | Used in rheumatoid arthritis in the dog. Immune suppression and other toxic effects to rapidly dividing cells limit clinical value |
| Free radical scavengers | Orgotein, copper-containing compounds, DMSO, some NSAIDs | Possess superoxide dismutase activity. Scavenge toxic free radicals, e.g. superoxide, hydroxyl |
| Miscellaneous | Hyaluronic acid, polysulphated glycosaminoglycan, pentosan sulphate | Inhibit prostaglandin synthesis and proteolytic enzymes, e.g. stromelysin. Administration by intra-articular injection may be required for some drugs |

pounds may provide the basis for the introduction of agents with a broader spectrum of activity than inhibitors of COX enzymes alone. They may be of use in immune-based diseases such as asthma, chronic obstructive pulmonary disease and insect bite allergies. However, only one compound of this class, tepoxalin, is currently in veterinary use in the dog. An interesting feature of dual inhibitors is their excellent gastrointestinal tolerance.

Corticosteroids are the anti-inflammatory agents that provide a greater control of all elements of both acute and chronic inflammation than any other class of drug. They exert membrane-stabilizing properties on lysosomal and cell membranes. Through this and other actions, they suppress the release of inflammatory mediators and act to preserve cell integrity. Their mode of action is multifactorial. It is attributable partly to their action on the cell nucleus to promote, by protein transcription, the synthesis of a group of endogenous polypeptides with antiphospholipase activity, the lipocortins or annexins (Fig. 62.2). However, they also

inhibit induction of one isoform of COX, described as COX-2 (see below).

Of other drug classes listed in Table 62.2 several, including immune stimulants, disease modifying agents and cytotoxic agents, have been used extensively to treat rheumatoid arthritis in man. They slow the progressive degenerative changes in cartilage and soft tissue inflammation in this disease. Some have also been used for similar therapy in veterinary medicine, notably in the dog, but their use has been limited by several factors such as slow onset of action and potentially severe side-effects have prevented extensive veterinary use. They are not used in bovine medicine.

Other drugs which have been used in the therapy of joint disease, especially in the horse, are the free radical scavengers orgotein and dimethyl sulphoxide (DMSO) and drugs with uncertain mechanisms of action, hyaluronic acid and chondroprotective agents. Again, the use of these compounds in bovine medicine has been very restricted to date, mostly due to lack of licensed products for use in food producing species.

Non-steroidal anti-inflammatory drugs (NSAIDs)

Classification and mechanism of action

The organic acid drugs in this important group of compounds can be divided into two subclasses, carboxylic acids ($R-COOH$) and enolic acids ($R-COH$). Further subdivisions can be made on the basis of chemical structure. For example, the main enolic acid groups are pyrazolone derivatives, such as phenylbutazone and oxicams, like piroxicam; the carboxylic acid groups include the propionic acid drugs such as ketoprofen. Most non-steroidal anti-inflammatory drugs (NSAIDs) possess three principal types of pharmacological activity: peripheral analgesic and anti-inflammatory actions and central antipyretic, anti-inflammatory and analgesic actions (Table 62.3). Some differences between drugs have been reported for the three types of activity. Paracetamol possesses weak peripheral actions and does not produce significant gastrointestinal irritation. However, it is a relatively weak anti-inflammatory drug and is principally a centrally-acting analgesic (Lees *et al.*, 1991; McKellar *et al.*, 1991).

An important action of NSAIDs, underlying their therapeutic uses, is inhibition of COX and consequent inhibition of production of the eicosanoids, which

produce hyperalgesia, inflammation, pyrexia and platelet coagulation (Fig. 62.2). Differences in relative potency between drugs for these activities are probably due to tissue differences in enzyme structure, i.e. the existence of isoenzymes. Two forms of COX have been identified, COX-1, a constitutive enzyme, and COX-2, which is expressed constitutively in some tissues, but is also inducible. The existence of COX isoenzymes may also explain species differences in plasma concentrations required for efficacy. Therapeutic concentrations of phenylbutazone in the horse are of the order of 10–30 µg/ml (Gerring *et al.*, 1981), however, in cattle even higher concentrations produce only limited COX inhibition (Arifah & Lees, 2002).

All NSAIDs can have antithrombotic effects by blocking platelet COX-1, and thus inhibiting production of the proaggregatory eicosanoid, TXA₂. However, at therapeutic doses most NSAIDs do not impair clotting mechanisms or prolong bleeding time. Aspirin is unique in this respect since it irreversibly binds to COX so that production of TXA₂ is inhibited for the life-span of the platelet. Consequently, aspirin is a potent anti-thrombotic drug.

COX-1 may also contribute to the inflammatory process and in particular to the pain component and, consequently, COX-2 selective inhibitors may not be as efficacious as mixed inhibitors in their anti-

Table 62.3 Principal therapeutic and toxic effects of NSAIDs.

| Site of action | Pharmacological or toxicological action/therapeutic use |
|---------------------------------------|--|
| <i>Therapeutic effects</i> | |
| CNS | Antipyretic. Lowering of body temperature in patients with fever but not in normothermic subjects. Action on temperature regulating centre in hypothalamus Analgesic and anti-inflammatory. Mechanisms poorly understood |
| Peripheral | Anti-inflammatory in acute inflammation and analgesic against inflammatory, but not against non-inflammatory pain Antithrombotic through inhibition of platelet COX. Aspirin, irreversible inhibitor of COX Anti-endotoxic. Some effects on endotoxin due to release of eicosanoid synthesis being inhibited by NSAIDs |
| <i>Toxic effects</i> | |
| Gastrointestinal tract | Ulcerogenic following parenteral as well as oral administration. Blood or plasma loss. Melaena. Emesis in simple-stomached animals only |
| Kidney | Nephropathies such as renal papillary necrosis |
| Liver | Both cholestatic and parenchymal cell toxicity |
| Blood cells and cardiovascular system | Various dyscrasias including aplastic and haemolytic anaemias and agranulocytosis described. Methaemoglobinæmia, hypoprothrombinæmia and prolongation of bleeding time. Small vein phlebopathy. Alteration of acid-base and electrolyte balance |
| Skin | Urticaria, erythema |
| Fetus | Teratogenic and embryopathic effects with some drugs. Delayed gestation at term |

inflammatory actions. COX-2 is constitutively expressed in kidney, and mice which have the COX-2 gene deleted suffer from renal failure and are poorly viable, while displaying inflammatory responses similar to normal mice. Both COX-1 and COX-2 are constitutively expressed in the central nervous system (CNS) and their relative expression varies depending on species. More work is required to elucidate the role of these enzymes in CNS function. COX-2 generated PGs are also involved in ovulation, parturition and may be involved in the resolution phase of acute inflammation and wound repair.

Until recently, it was considered that the PGs that mediate inflammation, fever and pain were produced by COX-2, while the PGs that are important in gastrointestinal and renal function are produced via COX-1. This led to the belief that the NSAIDs exerted their therapeutically beneficial effects primarily by inhibiting COX-2, while inhibition of COX-1 was considered to be responsible for some of the toxic side-effects associated with these drugs, e.g. gastric ulceration and renal papillary necrosis.

Recent work has indicated that the distinction between the two roles of COX-1 and COX-2 is not as clear as was once considered (for review see Wallace, 1999). Most commercially available NSAIDs at present licensed for use in animals inhibit both enzymes. There is much controversy over the selectivity of these compounds, with conflicting data being obtained depending on the test systems used for assessing COX-1 and COX-2 selectivity and whether these assays were carried out *in vitro*, *ex vivo* or *in vivo*. In addition, drugs may appear selective for one enzyme over the other, while not being highly potent. Currently, there are no truly selective/specific COX-2 inhibitor drugs licensed for use in veterinary medicine. The balance of evidence currently available suggests that phenylbutazone, flunixin and ketoprofen are non-selective, whereas carprofen, meloxicam and tolfenamic acid are COX-2 preferring, depending on the test systems used. There is, however, evidence of specific differences on COX1:COX2 selectivity in ruminant species.

While most NSAIDs inhibit COX very effectively, other actions, both on the arachidonic acid pathway and on other unrelated enzymes, may contribute to their effects. For example, some fenamate derivatives inhibit some (but not all) actions of PGs by blocking activity at PG receptors in addition to blocking their synthesis. High doses of most NSAIDs also block 5-LO, and thus suppress leukotriene synthesis. However, it is doubtful whether this action contributes significantly to the clinical efficacy of most NSAIDs, although tepoxalin is exceptional in this respect. Finally, some NSAIDs (carprofen is one example), although relatively weak COX inhibitors, are nevertheless effective anti-

inflammatory agents and this suggests that the principal mechanism of action, of at least some drugs, is due to some other effect. Carprofen, for example, has been shown to inhibit secretion of interleukin 6 (IL-6) (Armstrong & Lees, 2002).

In general, NSAIDs do not, at clinical dose rates, affect all components of the inflammatory response. They do not affect cellular events or minimize tissue damage, although high doses of some drugs do possess free radical scavenging properties, suggesting tissue healing mechanisms may be impaired, but more research in this field is required.

Other actions of NSAIDs have been described. Recent evidence suggests that some NSAIDs can act by mechanisms other than COX inhibition; for example, aspirin inhibits the transcription factor NF- κ B pathway (Kopp & Ghosh, 1994), and recently the R(-)- and S(+)-enantiomers of ibuprofen were reported to inhibit activation of NF- κ B (Scheuren *et al.*, 1998), an effect independent of specific COX inhibition. By preventing the translocation of NF- κ B into the nucleus, NSAIDs modify the expression of genes such as the COX-2 gene, which is involved in the cellular response to acute inflammation. Furthermore, activation of the glutamate receptor, N-methyl D-aspartate (NMDA), a key step in both the induction and maintenance of inflammatory hyperalgesia, activates NF- κ B (Guerrini *et al.*, 1995). An action on prostanoid receptors has been described for meclofenamic acid (see above), while some drugs inhibit glucuronidase release from neutrophils. Recent work in humans has indicated a role for COX-2 inhibition in the therapy of colonic cancer. This may represent a new role for NSAID use in the future.

Actions and interactions of NSAIDs and general uses

The analgesic action of most NSAIDs on the CNS is weaker than that provided by narcotic analgesic drugs of the morphine type. To what extent the central analgesic effect accounts for the clinical efficacy of NSAIDs is unclear, but there is increasing recognition of its importance for some drugs. The peripheral analgesic effect is thought to be due to blockade of synthesis of PGs, which exert hyperalgesic actions through synergism with pain-inducing mediators like bradykinin (Ferreira, 1983). Suppression of pain produced by tissue damage is a major use of NSAIDs, together with suppression of the acute inflammation associated with tissue trauma. Post surgical use of NSAIDs to provide analgesia and to reduce oedematous swelling that can lead to wound breakdown is now widespread. These drugs are clearly of value in the former circumstance, but the doses required for anti-oedematous actions may be higher and are less well established in veterinary

medicine. NSAIDs have been used increasingly alone to treat acute inflammatory conditions caused by microbial diseases but, more usually, they are combined with antibacterial agents. Endotoxic shock may result from a number of disease states when endotoxin derived from Gram-negative bacterial cell walls is released into the circulatory system. This may occur, for example, in cases of equine colic, acute and peracute mastitis, metritis and in septic peritonitis. Some of the ensuing effects on cardiovascular function and the respiratory system, together with metabolic and gastrointestinal changes, are produced by the release of eicosanoids such as PGI₂ and TXA₂. Hence, the pathophysiological changes associated with endotoxaemia are generally suppressed, though rarely abolished, by NSAIDs such as flunixin. This is particularly so when, in experimental circumstances, the drugs are administered prior to the onset of endotoxaemia. However, the effectiveness of these drugs once shock is established is likely to be less than when pre-treatment is possible. The clinical value of NSAIDs therefore remains to be established; however, anti-endotoxaemic effects have been demonstrated for flunixin meglumine at doses considerably less than those required for anti-inflammatory or analgesic activity (approximately $\times 0.25$).

Prostaglandin E₂ is a pyretic agent released as a result of the action of endogenous pyrogens such as IL-1. The local release of PGE₂ in the anterior hypothalamus leads to resetting of the thermoregulatory centre. NSAID inhibition of PGE₂ synthesis accounts for their antipyretic action when infections are accompanied by fever. The reduction in body temperature gives symptomatic relief in such patients. However, NSAIDs may theoretically influence adversely viral diseases, since the production and release of interferons are increased in pyrexia. In spite of this, NSAIDs have been used in the treatment of respiratory disease produced by parainfluenza type 3 (PI3) virus in calves and in the therapy of acute interstitial pneumonia caused by *Ascaris suum* in pigs (Selman *et al.*, 1984; Selman, 1988). Both the anti-inflammatory action in the lungs and the central antipyretic action may underlie the therapeutic response in these diseases.

Aspirin differs from other NSAIDs in that its inhibitory action on COX is irreversible (Lees *et al.*, 1987). It covalently acetylates the enzyme, which is, in consequence, permanently inhibited. In most body cells new COX enzyme can be synthesized in the cell nucleus. As aspirin concentration falls the cell's ability to form the products of COX metabolism is restored. However, the platelet cannot do this. The platelet is anuclear and the enzyme is thus inactivated permanently, i.e. for the lifespan of the platelet. Partial inhibition may persist for several days since platelet numbers are replaced at the rate of approximately 10

per cent per day. Longer inhibition can occur if significant amounts of aspirin penetrate to the developing megakaryocytes in bone marrow.

This action of aspirin explains its use in preventing clot formation in humans who may be prone to thromboembolic diseases. It is of interest that low doses of aspirin are preferred in these subjects, because inhibition of synthesis of PGI₂, an endogenous anti-aggregatory agent released from endothelial cells, by high aspirin doses could offset blockade of synthesis of TXA₂ by platelets. Low aspirin doses, administered once daily or every second day, very effectively inhibit platelet COX, without seriously impairing COX in endothelial cells. The full potential for the antithrombotic action of aspirin in veterinary medicine has not yet been fully explored, although it is recommended for use in prevention of aortic embolism in cats and may be of value in conditions such as laminitis, navicular disease and disseminated intravascular coagulation.

The use of two, or more, NSAIDs in combination generally has no clear advantages over the administration of a single drug at a higher dose rate. Most NSAIDs probably act by the same mechanisms and they are likely to be additive in their toxic as well as their therapeutic effects. Non-steroidal anti-inflammatory drugs have been licensed for the treatment of inflammation in animal species and, more recently, their potent anti-hyperalgesic activity has been recognized (Welsh & Nolan, 1994; Cheng *et al.*, 1998). Although the measurement of pain in ruminants has not been described frequently, workers have described the occurrence of hyperalgesia in animals suffering from lameness (Ley *et al.*, 1995; Whay *et al.*, 1998; Dolan & Nolan, 2000) and mastitis (Fitzpatrick *et al.*, 1998). While the magnitude of hyperalgesia does not appear to be related to the stimulus intensity, the duration of hyperalgesia does appear to be correlated significantly to the intensity of the inflammatory stimulus (Nolan, pers. obs. supported by Fitzpatrick *et al.*, 1998; Dolan & Nolan, 1999; Dolan & Nolan, 2000). Inflammatory conditions that induce hyperalgesia therefore probably induce spontaneous pain in the first instance, and contribute to adverse welfare over a longer duration (Dolan & Nolan, 2000). Thus, measurement of hyperalgesia is potentially a useful tool in validating disease severity and since it is a consequence of altered pain processing, it provides a pathophysiological link between disease and pain.

Pharmacokinetics of NSAIDs

The pH of fluids within the gastrointestinal tract varies but at all sites it is usually more acidic than plasma. In the stomach of monogastric species, fluid pH can be as low as 1.0. This marked difference from plasma increases, by the mechanism of ionic trapping, the rate

at which NSAIDs are absorbed. Being weak organic acids they are relatively less ionized in gastrointestinal tract liquor than in plasma and this facilitates absorption. A similar mechanism, enhancing NSAID absorption, will operate in ruminants in the reticulum and rumen, where liquor pH is also acid relative to plasma. However, the normal pH, approximately 4–5, is less acid than the gastric juice of monogastric species. Moreover, other factors are involved in determining rates of absorption. Low drug solubility in acidic conditions for some NSAIDs, such as aspirin, can lead to precipitation in the stomach and this prolongs and slows absorption and may also increase local irritation. Diet can also be an important factor in horses and ruminants, since some NSAIDs may be adsorbed on to hay. Such binding to feed, with subsequent release of the drug by fermentative digestion within the large intestine of the horse, has been suggested as a cause of the ulcerogenic action of phenylbutazone in the distal parts of the gastrointestinal tract (Lees & Higgins, 1985; Maitho *et al.*, 1986). In spite of these factors, absorption of most NSAIDs is generally good after oral dosing in all species and bioavailability generally exceeds 50 per cent.

Another factor that may potentially markedly influence NSAID absorption following oral dosing in ruminants is operation of the oesophageal groove reflex. Closure of the groove can direct orally administered substances directly to the abomasum and this will generally speed absorption into plasma, since dilution within the vast fluid volume in the rumen inevitably extends the time course of absorption. Double peaks in the plasma concentration–time curve of the NSAID meclofenamate after oral dosing in sheep have been attributed to an initial rapid absorption phase from the abomasum and slower subsequent absorption from the rumen-reticulum of that fraction of the administered dose which enters the rumen (Marriner & Bogan, 1979). A similar mechanism of oesophageal closure does not seem to operate for oral phenylbutazone in adult cattle (Lees *et al.*, 1988). Further studies are required to determine to what extent species, drug substance, drug formulation and age determine operation of the oesophageal groove reflex. NSAIDs are usually administered parenterally. Some NSAIDs are irritant to tissues when injected perivascularly but flunixin, meloxicam and carprofen can be given intramuscularly or subcutaneously when absorption is rapid and tissue irritation is minimal. Species differences in pharmacokinetic parameters, particularly clearance and elimination half-life, have been described for many NSAIDs and within the bovine species elimination half-lives vary between drugs and with different studies. However, it should be noted that plasma half-lives of the NSAIDs do not always relate to the tissue half-lives because of the tissue binding properties of the drugs.

Thus many NSAIDs are retained at the site of inflammation for periods long in excess of those predicted by the plasma half-lives. In consequence, there are significant differences in dosing schedules between species. As well as species differences in pharmacokinetics, the possibility of breed differences should be noted, as has been described for naproxen in dogs. Whether similar differences occur for any NSAIDs in other species, including cattle, is not known, but such information is clearly important to the rational setting of efficacious and safe dosage schedules.

A further factor relevant to the activity of some NSAIDs is the formation *in vivo* of active metabolites. The conversion of aspirin to salicylate is one example. Another is the hydroxylation of phenylbutazone in several positions. One such metabolite, oxyphenbutazone, is of similar potency to phenylbutazone and is formed in the liver in quantities that are sufficient to contribute about one-fifth of the overall activity in the horse. Plasma concentrations achieved in the goat may also be significant, but in both young and adult cattle, concentrations are low or undetectable and no contribution of oxyphenbutazone to efficacy can therefore be assumed in cattle.

Age may also affect NSAID pharmacokinetics. In general, both urinary excretion and hepatic biotransformation of drugs are less efficient in very young animals, aged less than two to six weeks depending on species. Aged animals may also metabolize and excrete NSAIDs less readily than young adults. There is some evidence in support of this for phenylbutazone in the horse (Lees *et al.*, 1985). Reduced capacity to metabolize drugs in the liver is likely to be of greater significance than any decreased renal excretory capacity in the case of NSAIDs, since virtually all are highly bound (usually greater than 98 per cent) to plasma protein. Consequently, less than 2 per cent of the drug in plasma is available for excretion in urine by glomerular filtration. This small fraction is readily excreted in the urine of herbivores, since it is 'trapped' in ionized form in the alkaline urine, i.e. tubular reabsorption is limited or absent. Nevertheless, only a very small proportion of the administered dose will be removed from the body by urinary excretion of parent drug. Reduced dosage or longer intervals between doses is probably required in both young and old animals.

Limited and indirect evidence indicates that at least some NSAIDs are excreted by active secretion in bile in cattle, possibly with subsequent reabsorption to create an entero-hepatic shunt. This is suggested, for example, by the 'kink' in the plasma concentration–time curve that occurs consistently following the administration of flunixin intravenously and intramuscularly to calves (Fig. 62.3). Studies of bile:plasma concentration ratio are required to investigate this possibility further.

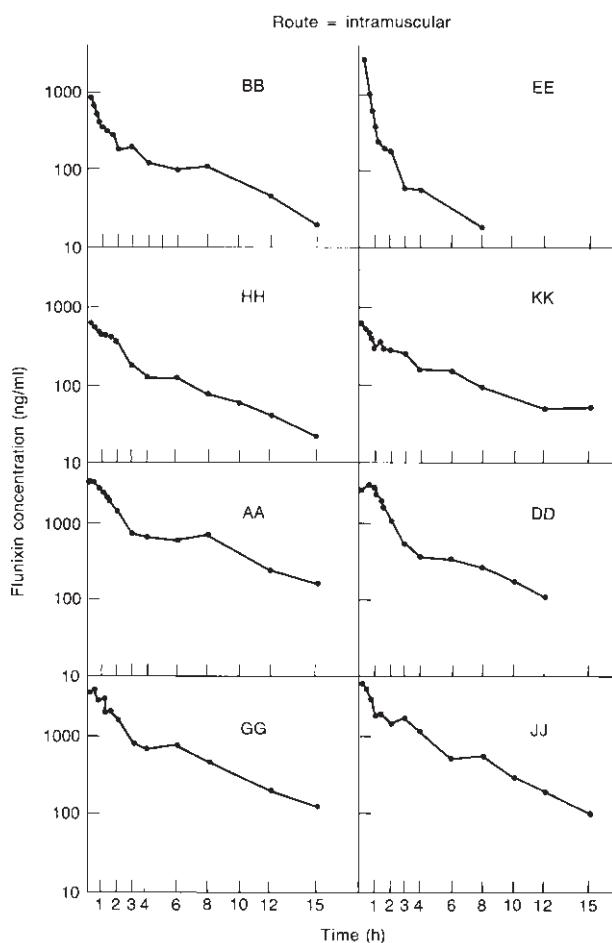

Fig. 62.3 Plasma concentration–time curves for eight calves receiving flunixin meglumine by intramuscular injection at two dose rates: 2.2 mg/kg body weight (BB, EE, HH, KK) and 8.8 mg/kg body weight (AA, DD, GG, JJ).

Knowledge of the pharmacokinetics of particular NSAIDs cannot be transposed between species since interspecies differences are marked. Pharmacokinetic data in cattle are available for flunixin, tolfenamic acid, ketoprofen, carprofen and meloxicam and these drugs have licensed products in the UK for use in food-producing species (*NOAH Compendium of Data Sheets for Veterinary Products 2000–2001*). Pharmacokinetic data are available for other drugs including aspirin and phenylbutazone, neither of which are licensed currently for use in food producing animals. Phenylbutazone has a long half life (40–60 hours) in both calves and adult cattle (Arifah & Lees, 2002). Even when basic pharmacokinetic data are available, it is not possible to define dosage schedules with such data alone for two reasons. First, different plasma and tissue concentrations of NSAIDs are likely to be required for the various therapeutic effects of analgesic, anti-inflammatory, antipyretic and antithrombotic actions. In calves,

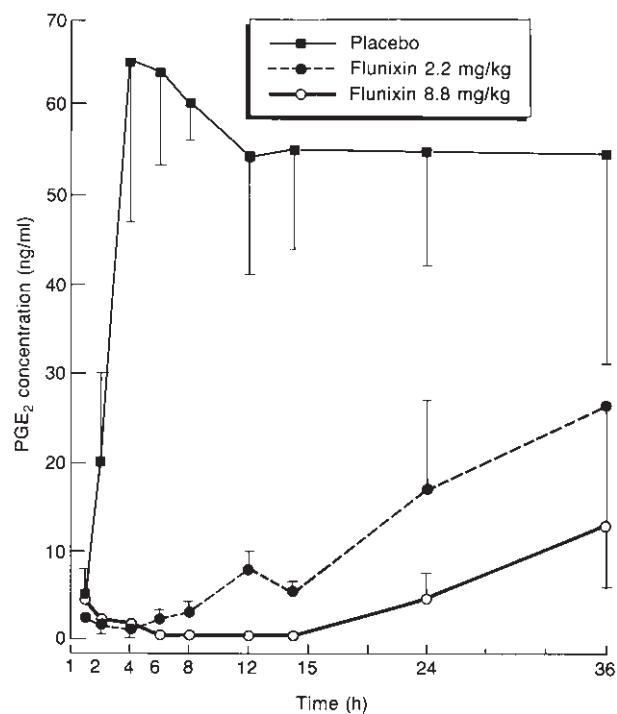

Fig. 62.4 Influence of two dose rates of flunixin (2.2 and 8.8 mg/kg body weight) administered intramuscularly to calves on the generation of the pro-inflammatory mediator, PGE₂, in carageenan-induced inflammatory exudates. Each point is the mean \pm SEM for six animals.

clearance of carprofen was slower in animals aged 8 weeks than in 16 week old animals (Lees *et al.*, 1986; Delatour *et al.*, 1996). Profound differences in ketoprofen pharmacokinetics were demonstrated in young goats compared to adult animals (Eltom *et al.*, 1993). Second, the pharmacological actions may be longer for NSAIDs than might be predicted from plasma clearance data. Studies have shown that relatively prolonged inhibition of production of the inflammatory and hyperalgesic mediator, PGE₂, is produced by therapeutic doses of flunixin, tolafenamic acid and ketoprofen, administered to calves (Landoni *et al.*, 1995a, 1996; Lees *et al.*, 1998) (Fig. 62.4) and, moreover, there are likely to be species differences in IC₅₀ values for inhibition of COX isoenzymes. This has been shown for example in studies comparing COX isoenzymes from the horse and the dog (Brideau *et al.*, 2001; Armstrong & Lees, 2002). In cattle, tolafenamic acid was shown to significantly inhibit serum TXA₂ and inflammatory exudate PGE₂, measured as indicators of blockade of the isoforms COX-1 and COX-2, respectively (Lees *et al.*, 1998). Whilst penetration of these drugs into tissue cage fluid was poor, passage into acute inflammatory exudate was good and clearance from the latter fluid was slow, i.e. there was a strong tendency for them to accumulate.

It is likely that three distribution compartments relating to the different sites of action of the NSAIDs exist: a central compartment and shallow and deep peripheral compartments (Landoni *et al.*, 1995b, 1996). The very high degree of binding to plasma protein probably explains both the relatively high concentration in inflammatory exudate, into which plasma protein passes readily, and the low concentration in interstitial fluid into which it does not. Similar considerations apply to most NSAIDs, since almost all are highly bound to plasma protein (Galbraith & McKellar, 1996).

Side-effects and toxicity of NSAIDs

At high dose rates NSAIDs may affect a number of biochemical pathways. However, with clinical doses the toxic effects of most drugs, like the therapeutic effects, are probably caused primarily by inhibition of COX. There are exceptions, however. Carprofen is a relatively weak inhibitor of COX, except in sheep where it produced marked inhibition (Cheng *et al.*, 2002), but it is, nonetheless, an effective anti-inflammatory agent.

The NSAID side-effect reported most commonly is irritation leading potentially to ulceration of the gastrointestinal mucosa. All NSAIDs produce this effect at high dose rates and with most drugs some gastric irritation is associated with oral dosing with therapeutic dose levels. The mechanism of action may involve back-diffusion of acid, although ulceration is not restricted to the stomach; it may occur throughout the gastrointestinal tract and it may accompany intravenous as well as oral dosing. The vasodilator eicosanoid PGI₂, generated in the COX pathway, may be a local hormone controlling blood flow to the gastrointestinal mucosa. By inhibiting the synthesis of PGI₂, NSAIDs may produce ischaemia and hence hypoxia of the mucosal surface. This may be the mechanism that causes erosion and hence ulceration of the gastrointestinal tract mucosa.

The ratio of doses of NSAIDs producing ulcerogenicity relative to anti-inflammatory and analgesic activities seems to be low for some drugs, e.g. aspirin, intermediate for others such as phenylbutazone and high for some selective agents, e.g. COX 2 inhibitors. It is, however, not possible to draw general conclusions concerning particular NSAIDs since many factors have been claimed to influence their ulcerogenicity (Rainsford, 1977); these include species, age, sex and the animal's nutritional status. Moreover, high drug concentrations in bile for some NSAIDs may explain lesions occurring in distal regions of the gut. When severe, the gastrointestinal ulceration induced by NSAIDs can lead to plasma protein-losing enteropathy or to blood losses into the gastrointestinal tract and

melaena. For example, high doses of phenylbutazone administered to the horse can quickly lead to significant plasma loss, haemoconcentration and death from hypovolaemic shock only a few days after the commencement of therapy. The horse may be particularly susceptible to this effect of phenylbutazone (Lees & Higgins, 1985).

Until recently, it was considered that the prostaglandins that mediate inflammation, fever and pain were produced by COX-2, while the prostaglandins that are important in gastrointestinal and renal function are produced via COX-1. This led to the belief that the NSAIDs exerted their therapeutically beneficial effects primarily by inhibiting COX-2, while inhibition of COX-1 was considered to be responsible for most or all of the toxic side-effects associated with these drugs, e.g. gastric ulceration and renal papillary necrosis. Recent work has indicated that the distinction between these two roles is not as clear as was once considered (for review see Wallace, 1999). Thus, highly COX-2 selective drugs (still in development) are gastro-protective and do not induce gastric ulceration. However, COX-2, while expressed in low amounts in a healthy stomach, appears to play an important role in promoting ulcer healing in the stomach. Consequently where gastric ulceration is present, COX-2 inhibitors may delay healing as, indeed, may non-selective COX inhibitors.

Useful data on the ulcerogenic actions of particular NSAIDs in cattle and any relationship to age, dose administered and route of administration are generally lacking. However, there is no reason to suppose that ruminant species are not susceptible to the ulcerogenic action of these drugs. Attempts have been made to reduce the degree of gastrointestinal tract irritation by the use of slow-release formulations, enteric coating and water-soluble salts. The use of such approaches in cattle does not seem to have been described in the literature. In ruminants, in general, NSAIDs are administered parenterally.

Non-steroidal anti-inflammatory drugs may be nephrotoxic. At high dose rates they may produce tubular nephritis. Renal papillary necrosis has also been reported in man. In horses papillary necrosis has been described in animals that received clinical doses of NSAIDs. However, this occurred only when horses on NSAID therapy also had restricted access to water. Retention of fluid leading to oedema is a commonly reported side-effect of NSAIDs in humans. Oedema seems to be uncommon and transient in animals, but has been described in horses receiving phenylbutazone (Lees *et al.*, 1983). Cholestatic and parenchymal hepatotoxicity have also been reported in animals. Since most NSAIDs are metabolized in the liver, any toxicity to parenchymal cells might, potentially, lead to a cycle

of drug cumulation and toxicity. Again, evidence for drug-induced hepatotoxicity has been described for horses receiving a high dose rate of phenylbutazone, but whether similar effects occur in cattle has not been reported.

A number of blood dyscrasias have been reported in human subjects treated with NSAIDs, generally over long periods. Similar blood cell effects in dogs, cats and horses have been described. However, the data available are limited and it has not been established whether particular drugs or certain species are especially implicated. With the use of clinical dose rates of NSAIDs, the incidence of blood dyscrasias in animals seems to be low.

At high dose rates some NSAIDs, notably aspirin and particularly when administered for long periods, impair platelet aggregation and thereby affect blood clotting. Potentially, this may lead to internal or external bleeding. Another problem of impaired clotting, through an indirect mechanism, may occur when NSAIDs are used together with anticoagulant drugs of the coumarin group. For example, the combination of phenylbutazone and warfarin has been used in the therapy of navicular disease in the horse. Phenylbutazone-induced suppression of warfarin metabolism may lead to warfarin toxicity. Both cardiovascular and respiratory effects result when very high doses of NSAIDs are administered, but acute cardiovascular/respiratory effects do not generally occur with normal dose rates.

Residues

Published data on NSAIDs and their metabolite residues in cattle are sparse. Tissue concentrations of meclofenamate and phenylbutazone are lower than corresponding concentrations in plasma and, for the latter, drug plasma and tissue concentrations decrease in parallel (Toutain *et al.*, 1982). Pharmaceutical manufacturers have submitted residue data to registration authorities to establish meat withholding times for flunixin, carprofen, ketoprofen, tolafenamic acid and meloxicam in cattle. Theoretically, the passage of NSAIDs into milk in healthy cattle will be severely limited by the more acid pH relative to plasma and by the high degree of drug binding to plasma protein. In practice, this has been found to be the case for one drug, phenylbutazone (milk concentration about 1 per cent of plasma concentration), and will almost certainly apply to others. In mastitis, however, the pH of milk is less acid and the 'blood–milk' barrier is much more permeable, so that higher NSAID concentrations in milk may occur and it is necessary therefore that milk withdrawal times following therapy with NSAIDs are adhered to by farmers and veterinary practitioners. Only some of the available NSAIDs are licensed for use

in lactating dairy cattle, including flunixin, ketoprofen, tolafenamic acid and meloxicam.

Steroids

Classification and general properties

Three classes of steroid hormone are secreted by the adrenal cortex into the peripheral circulation: sex steroids (generally in small quantities only), mineralocorticoids and glucocorticoids. The latter two groups together comprise the corticosteroid hormones. The mineralocorticoids, secreted by the zona glomerulosa and zona fasciculata, include aldosterone; their principal endocrinological actions are exerted on electrolyte and water balance. They promote sodium and chloride retention and potassium loss by their actions on the renal distal tubule and on parts of the gastrointestinal tract, notably the large intestine. Sodium retention is accompanied by osmotically obliged water. When administered as drugs or secreted in excessive amounts in some disease states, aldosterone and related compounds cause oedema. Glucocorticoids influence lipid, carbohydrate and protein metabolism and some exert weak mineralocorticoid effects also. The principal glucocorticoid hormone secreted by the zona fasciculata and zona reticularis in most species is cortisol (hydrocortisone).

The main veterinary use of glucocorticoids derives from the fact that they are potent anti-inflammatory agents. Cortisol itself is used as an anti-inflammatory agent, being administered systemically or applied locally. In addition, a number of synthetic steroids with much greater glucocorticoid potency than cortisol and with the advantage of reduced mineralocorticoid potency are available for clinical use. For example, prednisone and prednisolone are some four to five times more potent than cortisol as glucocorticoids, but they possess slightly weaker mineralocorticoid activities. Unwanted side-effects on water and electrolyte balance are therefore less likely when prednisone and prednisolone are used at equi-effective dose rates to hydrocortisone. The relative potencies of a number of corticosteroids in producing glucocorticoid and mineralocorticoid effects (in arbitrary units, cortisol = 1) have been reported by Keen (1987) and are presented in Table 62.4. It will be seen that methylprednisolone and triamcinolone are about five times as potent as cortisol as glucocorticoids and both have little or no mineralocorticoid activity. For dexamethasone and betamethasone, effects on electrolyte balance are also slight, but these drugs are 25–30 times as potent as cortisol as glucocorticoids. In contrast, the synthetic corticosteroid deoxycorticosterone acetate (DOCA) is a potent mineralocorticoid with negligible glucocorticoid activity.

Table 62.4 Relative potencies and biological half-lives of some corticosteroids used in veterinary practice (from Keen, 1987).

| | Relative potency (hydrocortisone = 1.0) | | Biological half-life (h) |
|---------------------------|---|------------------|--------------------------|
| | Glucocorticoid ^a | Sodium retaining | |
| Hydrocortisone (cortisol) | 1 | 1 | 8–12 |
| Cortisone ^b | 0.8 | 0.8 | |
| Prednisolone | 5 | 0.8 | 12–36 |
| Prednisone ^b | 4 | 0.8 | |
| Methylprednisolone | 5 | Minimal | |
| Triamcinolone | 5 | None | 24–48 |
| Dexamethasone | 30 | Minimal | 36–54 |
| Betamethasone | 25 | Negligible | |
| Flumethasone | 100 | Negligible | |

^a Closely paralleled by anti-inflammatory and HPA-suppressant activity.

^b Inactive until converted to active drug in the body.

Anti-inflammatory potency of corticosteroids closely parallels glucocorticoid activity. Clinically, this is most important since it means that whilst mineralocorticoid activity has been divorced from anti-inflammatory activity, glucocorticoid effects have not and this dictates the side-effects associated with clinical usage. An appreciation of the general actions of glucocorticoids will therefore assist an understanding of these potential side-effects, which are described in a subsequent section of this chapter. Glucocorticoids are gluconeogenic, promoting the release of amino acids from skin, muscle and connective tissue, and they subsequently increase the conversion of amino acids to glucose. Glucocorticoids produce hyperglycaemia in many species, especially in ruminants, and they promote the storage of glucose as liver glycogen, although both uptake and utilization of glucose by other tissues are reduced. In general, rates of lipolysis are increased, leading to fatty acid and glycerol release from adipose tissue. Subsequently, the glycerol may be converted to glucose. Calcium metabolism is altered by glucocorticoids in several ways. First, calcium absorption from the intestines is decreased and renal excretion is increased. Second, there is increased parathormone secretion and a resulting osteoclast stimulation whilst osteoblast activity is inhibited. These actions together promote calcium mobilization from bone, and bone strength is reduced. Glucocorticoids cause diuresis by dilating glomerular afferent arterioles and thus increasing glomerular filtration rate and also by depressing tubular water reabsorption in the distal nephron.

The main action of glucocorticoids on blood is to promote leucophilia, principally reflecting an increased number of circulating neutrophils. However, circulating lymphocyte and eosinophil numbers are reduced. In addition, glucocorticoids are depressant to lymphoid

tissue. For example, in some species (rabbit, mouse) high doses reduce thymus weight and reduction in the size of the spleen and lymph nodes occurs. Immuno-suppression by glucocorticoids is reflected in a number of ways, principally by a reduction in cell-mediated immunity and, usually at higher dose rates, by suppression of antibody production. The secretion of mineralocorticoid hormones is regulated in a number of ways, but the principal mechanism involves the renal release of renin from the juxtaglomerular apparatus and subsequent conversion of angiotensin I to angiotensin II, which acts on the adrenal cortex zona glomerulosa cells. Glucocorticoid secretion from the zona fasciculata, on the other hand, is increased in response to stress, but there is also a basal level of secretion that is subject to a diurnal rhythm. In the dog, cortisol secretion peaks during the day, usually late morning, whilst in nocturnal species, like the cat, peak levels occur at night. The regulatory control involves secretion of adrenocorticotrophic hormone (ACTH) from the anterior pituitary, which in turn is regulated by the release of corticotrophin releasing factor from the hypothalamus (Fig. 62.5). There is a negative feedback of cortisol on this system and high levels of glucocorticoid drugs in the circulation similarly suppress ACTH secretion. Long-term suppression induced by steroid drugs leads not only to inhibition of cortisol secretion, but also to reduced cell function to the point of adrenal atrophy.

Mechanism of action

The mode of action of steroids is multifactorial. Unlike NSAIDs, they generally suppress all components of acute and chronic inflammation. Indeed, steroids are the anti-inflammatory drugs 'par excellence'. Steroids inhibit the vascular dilatation in the microcirculation

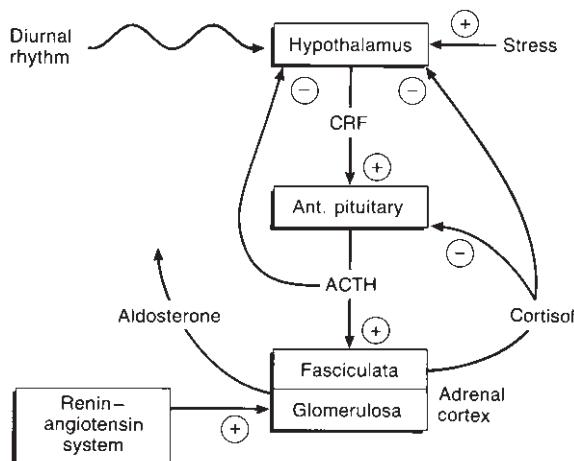

Fig. 62.5 Pathways of mechanisms of control of secretion of adrenal steroids.

and the increased capillary and small vein permeability and they thereby lessen oedema. Steroids also inhibit hyperalgesia and fibrin deposition. The extravascular migration of polymorphonuclear leucocytes initially and subsequent movement of monocytes are reduced. In addition, phagocytic activity of leucocytes is depressed. In the repair stage of the inflammatory response and in chronic inflammation, proliferation and the deposition of collagen are suppressed. In consequence, wound healing and cicatrization are delayed. Glucocorticoids also decrease the production of inflammatory complement components, reduce lymphocyte accumulation and decrease production of interleukin-2 (IL-2) and other lymphokines from lymphocytes.

Glucocorticoids exert a stabilizing action on all biological membranes. Cell, mitochondrial and lysosomal membranes are affected and this suppresses the synthesis or release of acute inflammatory mediators such as PGE₂ and histamine, and subsequently the tissue breakdown arising from the effects of released lysosomal and non-lysosomal enzymes is suppressed. However, these actions, although relevant to the anti-inflammatory effects of steroids, do not explain how they act at the molecular level.

Many studies have shown that one biochemical pathway inhibited by glucocorticoids is the arachidonic acid cascade. Arachidonic acid is released from its esterified form from the phospholipid component of cell membranes by the action of phospholipase A₂ (Fig. 62.2). Anti-inflammatory steroids inhibit this enzyme indirectly by promoting the synthesis of a family of endogenous polypeptides, the lipocortins, which possess antiphospholipase activity. This indirect mechanism of action may account for the lag period of 1–5 hours between steroid administration and the biological

response. Because of this delay, it follows that any relationship between effect achieved and plasma or tissue drug concentration will be complex. Drug effects will generally outlast the period for which they can be detected in biological fluids. This may explain why dexamethasone, which has an elimination half-life of approximately 1 hour in horses and 2.5 hours in cattle (Toutain *et al.*, 1982), possesses a ‘biological’ half-life of 36–54 hours (Table 62.4).

As discussed earlier, arachidonic acid may act as a substrate for two groups of enzymes, COX and LO. Through the production of lipocortins and consequential blockade of phospholipase A₂ steroids can be expected to block the synthesis of COX-derived inflammatory mediators, including PGE₂ and PGI₂, and LO-derived HETE and leukotriene compounds. One of these, LTB₄, is a potent chemotactic agent for neutrophils and the peptidoleukotrienes LTC₄ and LTD₄ are believed to be important mediators of allergic airway diseases. They may be involved in such conditions as fog fever in cattle and chronic obstructive pulmonary disease in horses. The evidence that anti-inflammatory steroids act through the production of lipocortins and blockade of eicosanoid synthetic pathways is, however, controversial (Lane *et al.*, 1990). High doses certainly do affect eicosanoid synthesis, but whether doses used in veterinary therapy effectively do so is far less certain. Another important action of steroids at the molecular level is inhibition of induction of COX-2 in response to inflammatory stimuli.

Administration and pharmacokinetics of steroids

The application of steroids topically to skin and mucous membranes, e.g. the eye, is commonly used in veterinary practice. It provides high drug concentrations at required sites of action and at the same time minimizes the risks of inducing systemic side-effects, although some systemic absorption is likely. In addition, most steroids are readily absorbed from the gastrointestinal tract, so that licking sites of drug application can lead to significant absorption from the gut. In some topical products local activity is high, but systemic absorption from the site of application is low and systemic side-effects are thus unlikely. Betamethasone-17-valerate and beclomethasone dipropionate are examples of esters with activity restricted to local sites.

Oral corticosteroid administration is a frequently used route for medium or long-term therapy. There are unavoidable potential risks of significant suppression of the hypothalamic–pituitary–adrenal axis (HPA) (see Chapter 67) when long-term treatment is employed and ways of reducing this to a minimum have been sought.

A short-acting preparation administered at twice the recommended dose rate on alternate days instead of normal dosing once per day has been proposed on the assumption that HPA suppression will decline on the non-treatment days. The therapeutic effects, on the other hand, may persist since steroid biological half-life is generally much longer than the pharmacokinetic half-life (Table 62.4). Another approach has been to recommend drug dosing in the morning in the dog and in the evening in the cat. Then, maximum circulating concentrations of drug can be expected to coincide with peak circulating concentrations of endogenous cortisol. This, in theory, will produce HPA suppression for the minimum time over each period of 24 hours.

Corticosteroids are frequently administered parenterally and generally this will give less variable plasma concentrations than oral dosing for short- or medium-term therapy. Water-soluble formulations include succinates, phosphates and *m*-sulphobenzoates. They may be administered intravenously or intramuscularly. Pharmacokinetic properties have been reported for commonly used corticosteroids. Thus, with intravenous dosing the half-life of dexamethasone ranges from 290 to 335 minutes in the cow, 53 minutes in the horse to 110 to 130 minutes in the dog (Toutain *et al.*, 1982).

The water-soluble short-acting esters are rapidly absorbed from intramuscular injection sites to give an onset and duration of action almost as quick as and of fairly similar duration to intravenous administration. In addition, water-insoluble esters providing longer duration of action, from 2 to 14 days, are available. These suspensions, providing a depot at the injection site, include acetate, undecanoate, pivalate and phenyl-propionate esters. Some very insoluble esters, e.g. acetonide and adamantoate, provide effective concentrations over several weeks, and the use of these esters involves undesirable, but unavoidable, HPA axis suppression.

Intra-articular injection, for the treatment of joint diseases, is another route employed. Intra-articular dosing reduces but does not prevent the risks of systemic side-effects, since some formulations are rapidly absorbed. Long-acting formulations maintaining local concentrations for several days are sometimes used. A careful aseptic technique is required with all intra-articular injections. Steroids are used in this way to suppress soft tissue inflammation, reduce stiffness and pain and allow more joint movement. Disadvantages are that they may suppress natural repair processes and they may induce osteoporosis and osseus metaplasia. Steroids are chondrodepressant and can lead to 'steroid arthropathy'. However, in recent years it has been increasingly recognized that low dose steroids can

achieve benefits without the undesirable side-effects of high doses.

Some steroids are prodrugs, requiring metabolic conversion in the body. This is true of cortisone and prednisone which are converted, respectively, to cortisol and prednisolone. Such drugs may be used for systemic therapy, but they are not applied locally.

Side-effects of steroids

The side-effects of those steroids with mineralocorticoid activity, e.g. prednisolone and prednisone, include sodium and water retention and resulting oedema, and hydrogen and potassium loss leading to hypokalaemia and metabolic alkalosis. Effects arising from glucocorticoid action on the kidney include a transient polyuria and a compensatory polydipsia. Hyperglycaemia, possibly leading to glucosuria, also occurs. Protein catabolism with long-term therapy causes muscle wasting and in the short term may delay wound healing. The lipolytic action of glucocorticoids is associated with redistribution of body fat with the characteristic 'moonface' appearance in man and pendulous abdomen in animals. With prolonged treatment, changes in calcium metabolism can lead to osteoporosis and bone fractures. Gastrointestinal side-effects include reduced motility, thinning of the gastric mucosa and reduced mucus production. However, unlike NSAIDs, glucocorticoids are not normally regarded as ulcerogenic. Nevertheless, colonic perforation in corticosteroid treated dogs has been described (Toombs *et al.*, 1986). The immunosuppressant actions involve a reduction in cell-mediated immunity, suppression of lymphoid tissue and lymphocyte movement and activity and, possibly, reduced antibody production.

When long- or medium-term steroid therapy is terminated, the HPA axis suppression present during therapy is restored only over several weeks and animals are susceptible to stress during this period. Stepwise reduction in steroid dose rate and increasing the inter-dose interval may be helpful in assisting restoration of HPA axis function.

General uses of steroids

Anti-inflammatory steroids are widely used for the therapy of immune and non-immune inflammatory conditions. Allergic and non-allergic eczemas respond to steroid therapy and steroids are used in the treatment of inflammatory conditions of the eye and the ear. In dogs and cats, steroids have been used to terminate the itch-scratch cycle in non-specific dermatoses. Steroids have been used extensively in the therapy of anaphylactic, endotoxic and haemorrhagic shock, but there are

several disadvantages. The slow onset of action of steroids has been discussed earlier and very large doses are required, making therapy in cattle and other large animal subjects impractical and/or prohibitively expensive. Administration to patients in shock should be by intravenous injection since absorption from intramuscular and subcutaneous sites in shocked patients would be slow.

In inflammatory conditions associated with bacterial infections, steroids are commonly administered with appropriate antibacterial agents. However, the immunosuppressant actions are undesirable and some authorities believe that such combinations are not justified. Where antimicrobial cover cannot be provided, as in some viral infections, corticosteroid therapy is generally totally contraindicated.

Corticosteroids have been used successfully in treatment of bovine iritis, or 'silage eye', a condition that is thought to be associated with infection with *Listeria monocytogenes* (see p. 923) and involves the pathophysiological change iridocyclitis. Corticosteroids are most frequently administered by subconjunctival administration, either alone or in conjunction with antibiotic injections.

There are a number of musculoskeletal conditions for which steroids may be indicated, including traumatic arthritis, osteoarthritis (see p. 453), myositis (see p. 451), eosinophilic myositis, tendonitis (see p. 452) and bursitis (see p. 461). In joint diseases steroids provide relief through their analgesic and anti-inflammatory actions. However, they may suppress natural repair mechanisms and repeated injections or long-acting formulations may produce degenerative changes in cartilage (steroid arthropathy). For this reason, glucocorticoid use in all forms of arthritis is increasingly controversial, and they are definitely contraindicated in septic arthritis. Similarly, in patients with laminitis steroids have fewer and fewer advocates. If they are used, treatment should be limited to the initial 24-hour period after the appearance of signs. Otherwise steroids may exacerbate the condition.

A number of respiratory conditions (see Chapters 17, 20, 49), both allergic and non-allergic, have been treated with systemic steroids. They include acute respiratory distress syndrome in cattle and chronic obstructive pulmonary disease in horses. In these conditions steroids are most useful when disease signs are severe; high doses of water-soluble formulations are administered intravenously. Depot preparations of steroids have been used in severe cases of the equine allergic skin disease 'sweet itch'. Other indications for steroid therapy are ulcerative colitis, cerebral oedema and autoimmune haemolytic anaemia.

In view of the potentially serious side-effects of steroids, guidelines for their use have been recom-

mended and a number of contraindications may be stated.

Guidelines

- (1) As animals vary in their response, depending on disease severity, dosing schedules should be established for individual subjects.
- (2) Single large doses of steroids or short-term therapy are unlikely to produce serious side-effects.
- (3) The incidence and severity of side-effects generally increase with the duration of treatment.
- (4) Corticosteroid treatment is usually symptomatic rather than curative.
- (5) Cessation of therapy abruptly after a prolonged course of treatment may reveal adrenal insufficiency.

Contraindications

- (1) Glucocorticoids are insulin antagonists and may therefore exacerbate or precipitate diabetes mellitus (see p. 930). They should not generally be used in diabetic animals.
- (2) Steroids should be used with extreme caution in acute infections because of their immunosuppressive actions and, if used, this should be in combination with bactericidal antibiotics.
- (3) Steroids are generally contraindicated in viral infections, in late pregnancy due to the risk that they may induce parturition and in subjects with corneal ulcers.
- (4) Administration by intra-articular injection should be avoided when there is sepsis in or close to the joint, in the presence of intra-articular fracture, when the articular cartilage is damaged, when extensive degenerative bony lesions are present, if previous injections were ineffective and when there is any likelihood that the treated joint will be over-exercised.

Therapy with anti-inflammatory drugs

Respiratory diseases (see Chapters 17, 20, 49)

Acute and sometimes overwhelming life-threatening inflammatory conditions occur in cattle and it is possible that the use of anti-inflammatory drugs, especially non-immunosuppressant agents, will reduce morbidity and mortality in such cases. Acute calf pneumonias of viral or bacterial origin and those of mixed aetiology, for example, have been shown to respond to NSAID treatment. Although such treatment is symptomatic it

can be effective in life-threatening pneumonias. Selman and coworkers showed that flunixin reduced significantly lung consolidation scores in calves infected experimentally with PI3 virus (Selman *et al.*, 1984). Flunixin also reduced lung lesions, post-mortem lung weights (reflecting an anti-oedematous action) and clinical signs of the disease in an experimental bovine pasteurellosis model based upon challenge with *Mannheimia haemolytica* A1. However, the benefits of flunixin therapy were not apparent when the drug was used alone but when used in combination with oxytetracycline (Selman, 1988). The additional benefits provided by the combination over oxytetracycline by itself comprised a lower body temperature, decreased respiratory rate and improved food intake.

Anderson (1989) confirmed the benefits of a flunixin/oxytetracycline product in comparison with oxytetracycline alone in field cases of pneumonia, with treatment daily for three days. Reduction in coughing, return to normal food intake and weight gain were improved more with the combination product and there were fewer relapses. Since these early studies, other NSAIDs have been used in combination with antibiotics in calf pneumonia; they include ketoprofen, meloxicam, carprofen and tolafenamic acid (Delaforge *et al.*, 1994). The precise way in which NSAIDs act in these subjects is unclear, but it seems likely that the anti-inflammatory action (reduced pulmonary oedema) improves pulmonary function and respiratory gas exchange, while the antipyretic action may improve the clinical status to the point where animals wish to eat and drink. In this way nutritional and fluid requirements will be maintained. Species such as cattle, which rely principally on respiration for temperature regulation, may be under particular stress from infections causing pyrexia, thus the antipyretic actions of NSAIDs may be particularly useful in such species. NSAIDs are also potent analgesics (against inflammatory pain) and when pain is a significant element in cattle pneumonias, this analgesic action of flunixin is likely to contribute to the improved clinical status.

Ingestion of 3-methylindole (3MI) in cattle produces a chemical toxicosis characterized by respiratory signs and pulmonary lesions (congestion, oedema, interstitial emphysema) that are indistinguishable from naturally occurring acute bovine pulmonary emphysema (fog fever). Intoxication with 3MI is accepted as a valid model of the natural disease. Selman and co-workers have shown that parenteral flunixin (2.2mg/kg) markedly reduces respiratory rate and the extent of lung lesions assessed by lung weights and both pathological and histopathological examinations. Flunixin resulted in a prompt return to normal demeanour and respiratory rate and it reduced the degree and severity of alveolar epithelial hyperplasia.

A study comparing the effectiveness of carprofen to flunixin for respiratory disease showed that a single dose of the former drug had similar beneficial clinical effects to three doses of the latter drug when used as an adjunctive therapy to antimicrobial treatment (Balmer *et al.*, 1997). Meloxicam has been licensed for use in dogs for medium to long term therapy of musculoskeletal pain and inflammation and is available as a suspension and in injectable form. It is available as an anti-inflammatory drug for use in the therapy of calf pneumonia. Further evaluation of NSAIDs in acute life-threatening respiratory infections is needed, since some of the reports have reached conflicting conclusions. Nevertheless, carprofen, flunixin, ketoprofen, tolafenamic acid and meloxicam all possess marketing authorizations for use in pneumonia in calves.

Mastitis and endotoxaemia (see Chapters 22, 23, 24, 30)

Mastitis in cattle also benefits from NSAID treatment. The main indication is in acute and peracute cases in which *Escherichia coli* or other endotoxin-releasing bacteria are involved. Thus, within the udder, the endotoxin-induced increases in PGE₂ and TXA₂ concentrations were significantly reduced by systemic flunixin therapy (1.1mg/kg at 8-hour intervals for seven doses) (Anderson *et al.*, 1986a) and clinical signs of both udder inflammation and depression as well as pyrexia were suppressed (Anderson *et al.*, 1986b). The enhanced phagocytosis of *Staphylococcus* spp., which occurs in milk neutrophils harvested from endotoxin-inoculated quarters, was not affected by flunixin treatment. However, flunixin did suppress significantly the increased whey IgG₁ and IgM concentrations produced by endotoxin inoculation (Anderson *et al.*, 1986c). The local effects of systemically administered flunixin may seem surprising when the high degree of binding to plasma protein and its acidic nature are considered; these properties should severely limit penetration across the blood–milk barrier. However, in the acutely inflamed udder blood flow is increased and milk pH will be much closer to plasma pH than in non-mastitic milk and the permeability of the blood–milk barrier will be increased. Probably of even greater significance in peracute cases will be antagonism of the acute systemic effects of endotoxin by NSAIDs, since these are mediated in part through activation of the arachidonic acid cascade with release of PGE₂ and TXA₂. Clinically, Anderson *et al.* (1986b) also demonstrated improvement, including reduction in rectal temperature, in mastitic cows with coliform mastitis.

Flunixin in combination with oxytetracycline has also been evaluated in cases of peracute mastitis in comparison with the antibiotic alone and clinical appraisal

suggested that the combination product gave better results (Christie, 1988). Similarly, ketoprofen was shown to significantly improve recovery in naturally-occurring clinical mastitis in dairy cows when used in combination with sulphadiazine and trimethoprim (Shpigel *et al.*, 1994). Carprofen has also been evaluated in cows with endotoxin-induced mastitis, at a dose rate of 0.7 mg/kg. Clearance of the drug was slower, elimination half-life longer and penetration into milk greater in endotoxaemic compared with normal cows. In the mastitic animals carprofen reduced heart rate, rectal temperature and quarter swelling significantly (Lohuis *et al.*, 1991), although at the time of writing no licensed product containing carprofen is available for use in lactating cows in the UK. Similarly, flunixin showed antipyretic, anti-inflammatory effects and reduced clinical depression following experimental intramammary infusion with endotoxin.

Mastitis is an inflammatory disease associated with pain (Chapter 23). Indeed bradykinin, a hyperalgesic mediator, has been detected in milk from cases of clinical and subclinical mastitis in cows (Eshraghi *et al.*, 1999). Kinin peptides are released during inflammation and are among the most potent mediators of vasodilation, oedema and pain. Bradykinin was detected in milk from cows with clinical and subclinical disease and the concentrations of bradykinin were shown to correlate with the severity of the disease. Bradykinin concentrations were significantly higher in quarters with high somatic cell counts and from which *Staphylococcus aureus* was isolated compared to high cell count quarters from which no pathogen was isolated. Whether systemically administered NSAIDs are beneficial in clinical cases of mastitis that are not so severe as to be classified as acute or peracute has received little attention to date. However, Pyorala and co-workers (1988) examined the influence of phenylbutazone (10 mg/kg) and flunixin (2.2 mg/kg) administered intravenously in cases of chronic subclinical mastitis. Neither drug influenced bacterial growth, somatic cell count or the levels of inflammatory markers (*N*-acetyl- β -D-glucosaminidase activity and trypsin-inhibitory capacity). Eckersall *et al.* (2001) showed that dairy cows with naturally-occurring clinical mastitis of mild or moderate grades, assessed by farmer observation, had significantly different concentrations of the acute phase proteins serum amyloid A and haptoglobin in serum and in milk compared to normal cows. The cows in this study showed evidence of allodynia for approximately 5 days and 40 days in the case of mild and moderate cases of mastitis, respectively (Fitzpatrick *et al.*, 1998). The allodynia was shown to be abrogated by a single intravenous dose of flunixin (2.2 mg/kg), an effect that lasted for 24 hours, after which the allodynic state resumed. This indicates the potential use of NSAIDs to

provide analgesia in inflammatory conditions in cattle, although further work is required to establish optimal and economical treatment regimens.

There have been few attempts to administer NSAIDs locally by intramammary infusion to establish whether their analgesic and anti-inflammatory effects are of value in providing symptomatic relief in any form of mastitis. No doubt such use has been precluded by the irritant properties of many NSAIDs. One NSAID, ibuprofen, has been administered locally into udders of cows with induced endotoxin mastitis. The drug attenuated reduction in milk yield when compared both with control cows and steroid-treated cows (DeGraves & Anderson 1991), but no licensed product is currently available in the UK. A specially prepared, non-commercial preparation of flunixin was administered via the intramammary route in the study by Fitzpatrick *et al.* (1998), described above. As expected, the somatic cell count increased on infusion of the compound, but there was no evidence of an excessive induced inflammatory response from observation of clinical signs or from milk yield subsequent to the clinical episode. Interestingly, abrogation of the allodynia resulting from the use of intravenous flunixin was not seen when the intramammary route was employed, indicating the possibility that the drug had a central effect on pain processing, probably at the level of the spinal cord.

Steroids with anti-inflammatory actions, such as prednisolone, have been used extensively for the therapy of clinical bovine mastitis. Corticosteroids are incorporated in a number of products containing also one or more antibiotics and used to treat clinical cases during lactation. The popularity of such products is indicated by volume usage; in the UK at the present time the three most widely used lactating-cow intramammary products all contain an anti-inflammatory steroid. The value of steroids in such products is unclear and in view of their potential immunosuppressant actions such usage has been questioned. One suggestion has been that the main value of steroids is not to influence the disease, but merely to suppress the irritancy that inevitably accompanies intramammary infusions and which varies in degree with the product formulation/excipients. However, studies have been undertaken comparing intramammary antibiotic products with and without steroids in bovine models of mastitis induced by *E. coli* endotoxin, *Streptococcus uberis* and *Staphylococcus aureus* (Bywater *et al.*, 1988). Signs of inflammation (swelling, milk consistency) were reduced, but leucocyte infiltration was not impaired. Further studies in this field, for example to establish that the phagocytic capacity of infiltrating neutrophils and immune protective mechanisms are not impaired, would provide confirmation of the value of steroids in some forms of mastitis. In acute and peracute mastitis the slow onset

of action of steroids is likely to limit their value, but in the *Streptococcus uberis* model mentioned above, benefit was obtained when treatment was administered 16–18 hours after challenge (Bywater, pers. comm.).

In summary, it seems at least possible that the anti-endotoxaemic effects of systemically administered NSAIDs may be of value (together with other supportive therapy, including fluids and systemic antibiotic administration) in cases of acute and peracute mastitis, whereas reduced swelling and pain provided by intramammary infusion of steroid/antibiotic products may assist recovery in less severe clinical mastitis. The latter proposal is compatible with the suggestion of Sandholm and co-workers (1990) that inflammatory changes in the mastitic gland seem to improve bacterial nutrition and growth, with potential adverse effects on the host. However, further studies are needed to examine these proposals concerning both steroids and NSAIDs.

Steroids have also been used, usually systemically, to counteract the life-threatening symptoms of endotoxic shock in cattle, commonly together with large volumes of fluids. In addition to their anti-endotoxaemic effects, steroids promote gluconeogenesis and this may contribute to the therapeutic response. The disadvantages of steroids are the large doses required and consequential high cost of treatment and the latent period prior to onset of action. This can be minimized by the use of water-soluble steroids.

Metritis (pp. 520, 521)

While some studies showed no beneficial effect of NSAIDs in the treatment of reproductive disorders such as retained placenta and post-partal endometritis (Konigsson *et al.*, 2001), flunixin was shown to reduce the incidence of pyrexia in cows with either acute and subacute metritis compared to non-treated controls (Amiridis *et al.*, 2001). Uterine involution and onset of oestrus occurred earlier in cows that received flunixin.

Calf scours (Chapter 14)

Early studies by Jones *et al.* (1977) indicated a possible benefit of flunixin in suppressing inflammation, reducing fluid losses in faeces and suppressing morbidity and mortality in calf scours. Until recently, no drugs were available with licensed indications for such use. However, meloxicam is now licensed for use in calf scours in combination with anti-microbial drugs.

Hypersensitivity reactions (p. 927)

Anaphylaxis can be inhibited both *in vivo* and *in vitro* in cattle by the NSAIDs sodium meclofenamate and

aspirin and the actions of these drugs in acute interstitial pneumonia has been described above.

Arthritis and joint diseases (p. 453)

In contrast to the horse and dog, long-term therapy of joint diseases in cattle is not commonly undertaken. This in part relates to economic factors, in part to drug and drug metabolite residue problems in milk and edible tissues and in part to the lack of knowledge of drug pharmacokinetics linked to dosage regimens that are known to be effective and safe. However, some joint diseases of cattle have been treated with phenylbutazone, corticosteroids or NSAIDs but there is, as stated, an urgent need to establish rational dosage schedules. Whether the chondroprotective class of agents, which includes polysulphatedglycosaminoglycans and pentosan sulphate, is likely to be used in the future is not clear. Some increase in therapy in this field can be anticipated, should the economic situation in the farming industry improve, as joint disease is relatively common and can affect individual valuable animals, where treatment may be justified.

Foot-and-mouth disease (Chapter 43(c))

This contagious viral disease is characterized by fever and vesicular eruptions in the mouth and in the interdigital area of the feet. The clinical presentation varies but a proportion of animals suffer severe ulceration with loss of large areas of oral epithelial tissue and under-running of hoof structures. The use of NSAIDs might be of value as adjunctive therapy and one agent, flunixin, has been studied. Artificially infected cattle treated with flunixin showed clinical improvement, indicated by lowered body temperature and increased weight gain, whilst antibody titres were not affected. In light of the recent epidemic of foot-and-mouth disease (FMD) in the UK (2001) and the considerable concerns for the welfare of affected animals prior to slaughter, the role of NSAIDs in palliative therapy could be evaluated and implemented, to allow improved pain management, should future outbreaks of FMD occur.

Pain

Calves that received ketoprofen before and after dehorning following a sedative and a local anaesthetic showed reduced behavioural signs thought to be associated with pain, such as head shaking and ear flicking, compared to untreated controls (Faulkner & Weary, 2000). Different methods of castration such as use of rubber rings, bloodless castrators or surgical methods were shown to result in different levels of pain response, demonstrated by altered behaviour (Robert-

son *et al.*, 1994). This indicates that there may be the potential to use NSAIDs either pre- or post-procedure to reduce or abrogate pain caused by castration.

Conclusions

It seems likely that both steroids and, in particular, NSAIDs, judiciously used, may be of value in a number of cattle diseases in which inflammation, endotoxaemia and/or pain are major components. Further work is needed if such prospects are to be realized and especially if licensed pharmacological products that will improve animal health and welfare are to result from these studies.

Chapter 63

Growth Promoters in Cattle

K. Lawrence

| | |
|-----------------------|------|
| Introduction | 1067 |
| In-feed additives | 1067 |
| Rumen | 1067 |
| Intestine | 1069 |
| Hormonal implants | 1071 |
| Growth hormone (BST) | 1073 |
| Repartitioning agents | 1073 |

Introduction

Bovine growth promoters are divided into four groups:

- In-feed additives
- Hormonal implants
- Growth hormone (somatotropins)
- Repartitioning agents (β -agonists)

In the European Union (EU) the use of hormonal implants and β -agonists has been banned since 1988, followed in 1990 with a moratorium on bovine somatotropin (BST) that became a ban in 2000. Meanwhile the use of in-feed additives is under close scrutiny with a proposed ‘phase out’ by 2006. The EU position on growth promoters has been taken in spite of the increased production costs to farmers and the enormous knock-on costs of increased feed usage and slurry production leading to environmental pollution (Verbeke & Viaene, 1996). The other major cattle-producing countries of the world continue to use a variety of growth promoters, as they have done for over 30 years.

In-feed additives

In-feed additives are divided into two types by the site of primary activity: rumen and intestine.

Rumen

The most widely researched of the rumen active growth promoters is monensin sodium (Romensin, Elanco Animal Health). Monensin is an ‘ionophore’, a group of antibiotics that are used only in agriculture – there are no equivalent products used or in development for

use in human medicine, nor do they share a mode of action with any compound in human medicine. Interestingly, in addition, the ionophores do not have antibiotic resistance encoded by transferable genes. Monensin acts on bacteria by facilitating the carriage of sodium ions in to the cell. This causes the cell to speed up the sodium/potassium pump in the cell membrane to redress the ion balance. As the transport mechanism requires energy in the form of ATP, continuous exposure to monensin could lead the cell to exhaust energy supplies, resulting in death by osmotic disruption of the cell, but more usually it prevents the bacteria from competing in a mixed population and numbers decline (Pinkerton & Steinrauf, 1970; Pressman, 1976).

The mode of action of monensin in the rumen has been elucidated and it can act as model for other products in this class, such as lasalocid (Bovatec, Alpharma Animal Health Division) and laidlowycin (Cattlyst, Alpharma Animal Health Division).

The rumen is a fermentation vat that converts carbohydrates into volatile fatty acids (VFAs) such as acetic, butyric and propionic acids that drive the animal’s metabolism (see Fig. 63.1). While all three VFAs can be used in the nutrition of the bovine, the production of propionic acid is the most efficient leading to an improved efficiency of usage of both compounded feed and roughage. The key to the efficiency of production of the VFAs is the preservation of the six carbons from the final fermentation substrate, usually a hexose sugar such as glucose. With acetic acid only four of the carbon atoms are retained in the rumen, with two being lost as the gases carbon dioxide and methane; butyric acid is similar although only carbon dioxide is produced. Only with propionic acid is there a complete retention of all six carbon molecules in the fermentation products.

Richardson *et al.* (1976) provided the first evidence of the effects of monensin on VFA production using anaerobic batch fermentation. In this study the propionic acid levels rose from 7.4 $\mu\text{M}/\text{ml}$ to 12.5 $\mu\text{M}/\text{ml}$ as the concentration of monensin was increased (Table 63.1).

Similar results were found *in vivo* by Van Maanen *et al.* (1978) in steers being fed both roughage and grain based rations – there was a significant increase in the

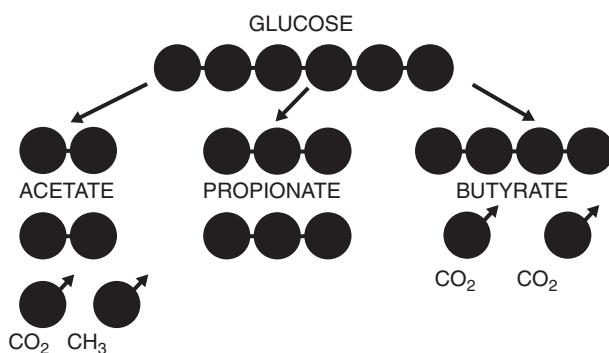

Fig. 63.1 Rumen fermentation pattern for a simple carbohydrate, showing the preservation of carbon molecules.

Table 63.1 The shift of VFA production ratios with increasing levels of monensin, during anaerobic batch fermentation.

| Monensin (mcg/ml) | Acetic (µM/ml) | Propionic (µM/ml) | Butyric (µM/ml) |
|-------------------|----------------|-------------------|-----------------|
| 0.0 | 19.6 | 7.4 | 7.1 |
| 0.10 | 20.8 | 8.6 | 7.2 |
| 0.25 | 20.2 | 9.4 | 6.9 |
| 0.50 | 19.6 | 10.6 | 6.5 |
| 1.00 | 19.1 | 11.1 | 6.3 |
| 5.00 | 17.5 | 11.2 | 5.8 |
| 25.00 | 16.7 | 12.5 | 5.6 |

size of the propionate pool and the production rate. The results are summarized in Table 63.2.

The effect of monensin seems to be mediated by changes in the balance of the bacterial population in the rumen. The sensitivity of a range of rumen bacteria to monensin is reviewed in Table 63.3, along with their fermentation output. Monensin clearly inhibits the major acetate- and butyrate-producing bacteria, allowing a proliferation of the primary propionate producers.

Monensin has also been observed to reduce the concentration of rumen protozoa in many experiments. This has also been associated with an increase in the proportion of propionic acid production, as is shown in the sheep study presented in Table 63.4.

Goodrich *et al.* (1984) and Potter *et al.* (1986) have reviewed the expected performance benefits from the use of monensin and highlighted the different nature of the response in grain-based and roughage-based systems. In all performance trials two measurements are made to derive a third. The feed intake (ADF, average daily feed in kg) and the growth rate (ADG, average daily gain in kg) are measured and the feed conversion ratio (FCR) is calculated by dividing ADF/ADG. While the FCR is improved in all the trials, in grain-based diets the ADG often remains unchanged

Table 63.2 The effect of monensin on rumen propionate pool size and production rate in steers consuming roughage or grain based diets.

| Treatment | Propionate pool size (g) | Propionate production rate (g/day) |
|---------------------|--------------------------|------------------------------------|
| Roughage | 32.0 ± 1.3 | 441 ± 24 |
| Roughage + monensin | 56.5 ± 2.1 | 659 ± 22 |
| Grain | 36.5 ± 2.0 | 510 ± 10 |
| Grain + monensin | 66.3 ± 4.1 | 899 ± 45 |

Table 63.3 The sensitivity of rumen bacteria to monensin and their related products of fermentation. (After Chen & Russell (1989); Chow & Russell (1990); Dawson & Boling (1983); Dennis *et al.* (1981).)

| Products of fermentation | |
|--------------------------------|-----------------------------|
| Monensin-sensitive organisms | |
| <i>Ruminococcus</i> | Acetic acid |
| <i>Methanobacterium</i> | Acetic acid, methane |
| <i>Lactobacillus</i> | Lactic acid |
| <i>Butyrivibrio</i> | Acetic acid, butyric acid |
| <i>Streptococcus</i> | Lactic acid |
| <i>Methanosarcina</i> | Methane |
| Monensin-insensitive organisms | |
| <i>Selenomonas</i> | Propionic acid |
| <i>Bacteroides</i> | Acetic acid, propionic acid |
| <i>Veillonella</i> | Propionic acid |

Table 63.4 The effect of monensin on rumen protozoa and propionic acid production in fistulated sheep.

| Monensin feed inclusion (mg/kg) | Total protozoa ($\times 10^5/\text{ml}$) | Molar % propionic acid concentration |
|---------------------------------|--|--------------------------------------|
| 0 | 10.1 | 20.2 |
| 11 | 9.0 | 23.6 |
| 22 | 6.2 | 24.4 |
| 33 | 7.1 | 25.8 |
| 44 | 5.4 | 28.7 |

but the ADF is markedly reduced. This contrasts with the roughage diets where the ADG is increased while the ADF is unchanged. In balanced rations composing both grain and forage the effects on ADF and ADG are less clear, but there is still an 8 to 10 per cent improvement in FCR.

There are additional benefits from the rumen active growth promoters in the control of acidosis (Nagaraja *et al.* 1985, 1987), bloat control (Sakauchi & Hoshino,

1981; Bartley *et al.*, 1983; Lowe *et al.*, 1991) and the prevention of coccidiosis (Watkins *et al.*, 1986).

Intestine

The growth promoters with a more pronounced effect in the intestine are the bambermycins (Flavomycin, Intervet) and virginiamycin (Stafac, Phibro Animal Health). This does not imply that these products have no effect in the rumen and indeed with virginiamycin there have been reports of significant effects on VFA production and the control of acidosis (Hedde *et al.*, 1980).

Likewise monensin is described as a rumen active growth promoter, but this does not imply it has no effect in the intestine. Indeed, as monensin has been shown to be an effective growth promoter in pigs it must also have a more conventional mode of action in this species (Mackinnon, 1987).

The mode of action of in-feed growth promoters in monogastric animals and in the intestine of a ruminant is complex and still open to debate. The comparison of healthy animals with a normal digestive tract bacterial flora to germ-free animals has produced an insight into the role of the gut flora in inhibiting nutrient absorption. This has been built upon by comparing the response of each group to antibiotic incorporated into their diet (Visek, 1979). Conventional animals grow more slowly and use their feed less efficiently than gnotobiotic or 'germ-free' animals because of the presence of the intestinal flora. When antibiotic was administered, the growth response of the conventionally grown

animals matched that of the germ-free group; there was no effect of the antibiotic on the germ-free group. Antibiotics within the digestive tract of animals inhibit the growth and modify the metabolism of susceptible populations of bacterial flora. Since most of the antibiotics used for growth promotion have a Gram-positive spectrum of activity, such bacteria as *Clostridia*, *Enterococci* and *Bacilli* seem likely candidates. The inclusion of growth promoters in cattle feeds serves to allow a conventionally raised animal to grow at the same rate as a germ-free animal.

Studies on the physiological, nutritional, metabolic and immunological effects associated with the use of antibiotic feed additives demonstrate the complexity of their mode of action (Visek, 1979; Hays, 1979; Coates, 1980; Anderson *et al.*, 2000). The reported effects include:

- Inhibition of the growth or modifying the metabolism of harmful gut bacteria;
- Decreased elaboration of toxic substances, including bacterial toxins;
- Reduced bacterial destruction of essential nutrients;
- Increased synthesis of vitamins and other growth factors;
- Improved efficiency of nutrient absorption by modification of the gut wall;
- Reduced intestinal mucosal epithelial cell turnover;
- Reduced intestinal motility.

The net effect of the changes in the intestine listed in Table 63.5 is an increased availability and absorption of nutrients and a reduced cost/kg gain.

Table 63.5 Some physiological, nutritional and metabolic effects ascribed to in-feed growth promoters (after Ewing & Cole, 1994).

| Physiological effects ^a | | Nutritional effects | | Metabolic effects | |
|------------------------------------|---------|----------------------------|---|--------------------------|---|
| Gut food transit time | ↘ | Energy retention | ↗ | Ammonia production | ↘ |
| Gut wall diameter | ↘ | Gut energy loss | ↘ | Toxic amine production | ↘ |
| Gut wall length | ↘ | Nitrogen retention | ↗ | Alpha-toxin production | ↘ |
| Gut wall weight | ↘ | Limiting amino acid supply | ↗ | Fatty acid oxidation | ↘ |
| Gut absorptive capacity | ↗ | Vitamin absorption | ↗ | Faecal fat excretion | ↘ |
| Faecal moisture | ↘ | Vitamin synthesis | ↘ | Liver protein synthesis | ↗ |
| Mucosal cell turnover | ↘ | Trace element absorption | ↗ | Gut alkaline phosphatase | ↗ |
| Stress | ↘ | Fatty acid absorption | ↗ | Gut urease | ↘ |
| Feed intake | ↗, ↘, → | Glucose absorption | ↗ | | |
| | | Calcium absorption | ↗ | | |
| | | Plasma nutrients | ↗ | | |

^a ↘ denotes a reduction; ↗ denotes an increase; → denotes no change.

In spite of the different emphasis of the mode of action of the rumen and gut-active in-feed growth promoters, their effects on the efficiency of performance is very similar with a 6 to 8 percent improvement in FCR.

Consumer concerns have been raised about the use of in-feed growth promoters in all species. The spectrum of data on this aspect of these products submitted for registration was summarized by Lawrence (1998).

As with therapeutic veterinary medicines, stringent safety studies are necessary for growth promoters. The safety data requirements for registration in the EU are listed below (source: *Official Journal of European Communities L208-21 T025*):

1. Studies on target species
 - 1.1 Safety studies – Biological
 - Toxicological
 - Macroscopic
 - Histological effects
 - 1.2 Microbiological studies of the additive
 - 1.2.1 Antibacterial spectrum of activity
 - 1.2.2 Cross-resistance to therapeutic antibiotics
 - 1.2.3 Tests to find out whether the additive is capable of selecting resistance factors
 - 1.2.4 Tests to determine the effect of the additive:
 - on the microflora of the digestive tract
 - on the colonisation of the digestive tract
 - on the shedding or excretion of pathogenic micro-organisms
 - 1.2.5 Field studies to monitor bacterial resistance
 - 1.3 Studies of the metabolism and residues
2. Studies on excreted residues – ‘ecotoxicity’
3. Studies on laboratory animals
 - 3.1 Acute toxicity
 - 3.2 Chronic toxicity
 - 3.3 Mutagenicity
 - 3.4 Carcinogenicity
 - 3.5 Reproductive toxicity
 - 3.6 Toxicity of metabolites

Microbiological safety of the use of growth promoters has been included in the registration dossiers from the earliest legislation. All the potential hazards of their use have been well recognized from the very beginning. The microbiological safety is assessed in three areas:

- (1) Selection of antibiotic resistance in the gut flora.
- (2) Effect on the excretion of enteric pathogens by animals.
- (3) Residues in the meat and the effect on human gut flora.

(1) *Selection of antibiotic resistance in the gut flora.* In any population of bacteria, there is a range of antibiotic susceptibility from fully sensitive to solidly resistant – even in the absence of antibiotics (Linton, 1982). Usually, the bulk of the bacteria remain sensitive to an antibiotic, unless a therapeutic dose is administered which kills the sensitive and allows the few resistant bacteria to proliferate; thus a resistant population develops (Evangelisti *et al.*, 1975).

It is a truism that the use of a therapeutic dose of an antibiotic selects for the survival of the few resistant organisms in the population; it does not cause individual sensitive bacteria to become resistant. As the growth promoters are included at levels approximately 10 to 100 times lower than therapeutic doses (Corpet, 1996), there is little, if any, selection pressure on the gut flora. A selection of studies on growth promoters that have demonstrated their low resistance selection capacity at authorised use levels are listed below:

- Flavomycin (Dealy & Moeller, 1977; Devriese, 1980; Mee, 1982; Corpet, 1984; Dutta & Devriese, 1984)
- Monensin (Dutta & Devriese, 1984; Newbold *et al.*, 1993)
- Virginiamycin (Gaines *et al.*, 1980; Devriese, 1980; Mee, 1982; Dutta & Devriese, 1984)

It is usual for the antibiotic growth promoters to have a Gram-positive spectrum of activity; therefore they cannot have a selection pressure on the Enterobacteriaceae and do not contribute to antibiotic resistance in *Salmonella* spp. or *E. coli*.

(2) *Effect on the excretion of enteric pathogens by animals.* An increased number of organisms or an extended shedding time in the faeces could lead to an increased risk of contamination of human food. All current growth promoters have been examined for their effect on *Salmonella* and, in many cases, other bacteria including *E. coli*. All modern studies, undertaken with authorized inclusion levels, have given satisfactory results (Nurmi & Rantala, 1974; Hinton, 1988). Ungemach (1996) considered that the use of growth promoters in animal feeds posed no risk to the indigenous gut flora of human consumers.

(3) *Residues in the meat and the effect on human gut flora.* Growth promoters administered in animal feed do not leave detectable residues in the meat. Indeed, they can be used from birth to slaughter, i.e. they have a zero withdrawal. As there is no detectable residue in the meat, there is unlikely to be a selection pressure on human gut flora (Ungemach, 1996).

The public health implications of the use of antibiotics in animal feeds have been examined on many occasions:

All have discussed the hazards but none have proved any risk to human health.

Hormonal implants

Hormonal implants are not currently licensed for use in the European Union. Those listed in Table 63.6 are in use in the rest of the world.

The mode of action of the hormone implants has not been fully elucidated although some work has indicated that changes in serum concentrations of IGF-1 occur in implanted steers, while serum IGF-1 concentration in the control steers remains or changed or, indeed, decreases across time. This suggests that IGF-1, the essential growth hormone, is related to the additional gain of the implanted steers. However, the reason for this linear decrease in serum IGF-1 concentration sometimes reported in control cattle is unclear. For example, it does not appear that the effect can be attributed to the control animals approaching their physiological maturity, because the control and implant animals usually exhibited similar degrees of fatness. The net effect could be an increase in protein synthesis and protein gain, which translates into greater, more efficient liveweight gain and profit for the cattle producer (Simpkins *et al.*, 2000).

The usual explanation is more mundane as bulls grow faster and produce a leaner carcass than steers; steers grow faster and produce less fatty meat than heifers and cows. The differences in growth rate are usually ascribed to hormonal status and the levels of androgen in particular. The hormone implants are used to replace or adjust the circulating hormone levels to achieve optimal growth.

The efficacy of hormonal implants is well accepted, both alone and in combination with in-feed growth promoters (see Table 63.7 for a typical trial). There is some

evidence that the response to an implant varies with the start weight, with the greatest response in finishing cattle being reported from the heaviest cattle (see Fig. 63.2).

Some carcass traits can be changed by the use of implants, with lower dressing percentages (Kuhl *et al.*, 1989), reduced marbling (Eversole *et al.*, 1989) and a reduction in top grade carcasses (Foutz *et al.*, 1989) being reported. These changes vary between implants, but have not been associated with any significant changes in the eating quality of the meat.

While the efficacy of hormonal implants is accepted, the consumer safety of implanted meat has been a focus of conflict between the USA and the EU, leading to a complaint to the World Trade Organization (WTO). The USA consider the hormone ban in the EU to be an unjustified barrier to trade and have effectively won this case at arbitration through the WTO Appellate Body. The findings of the case centred round the lack of a proper risk assessment prior to the imposition of the ban on imports of meat from animals treated with hormones.

This whole debate is best followed by reading the full Joint FAO/WHO Expert Committee on Food Additives (JECFA) assessments:

and the Opinion of the Standing Committee on Veterinary Measures related to Public Health (SCVPH) dated 30 April 1999
http://europa.eu.int/comm/food/fs/sc/scv/out21_en.html

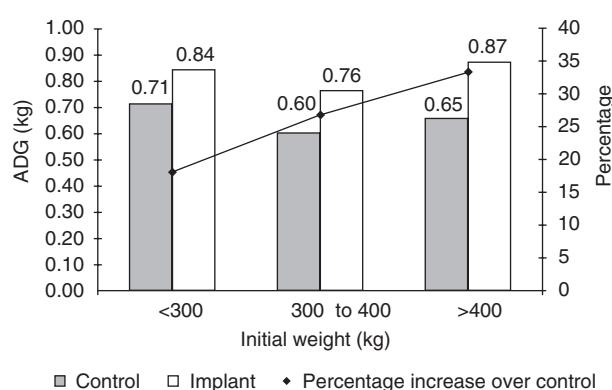

Fig. 63.2 The effect of the initial weight on the percentage response from an implant in finishing cattle.

as well as the recent assessment of the SCVPH report by a subgroup of the Veterinary Products Committee (VPC) of the Veterinary Medicines Directorate (VMD) in the UK on the potential risks to human health from hormone residues in bovine meat and meat products (<http://www.vmd.gov.uk/>) see under Publications.

The main areas of concern have been best summarized in the VPC subgroup report and they are reviewed below:

- (1) Direct consumer exposure to hormone residues in meat. The residues are all very low compared with the acceptable daily intakes (ADIs) identified by JECFA. Therefore consumer exposure to oestradiol, progesterone and testosterone will be very low compared with those naturally produced in the body (see Fig. 63.3). The ADI is an amount of medicine/hormone that can be eaten every day over a lifetime in the practical certainty that, based on current knowledge, no harm will result.
- (2) Hormonal residues can adversely affect the immune system. References used to support this argument in the SCVPH report did not reflect modern physiological understanding of the

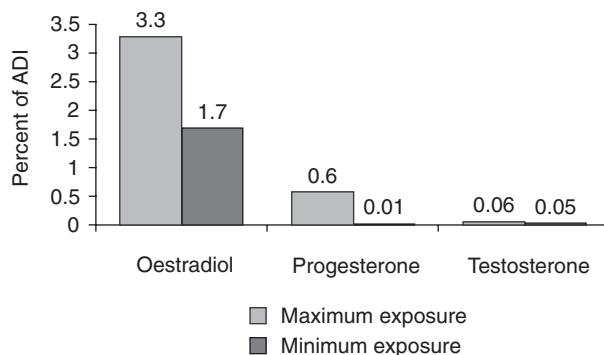

Fig. 63.3 The maximum and minimum consumer exposure to natural hormone residues from implanted meat as a percentage of the JECFA ADI. (JECFA Joint FAO/WHO Expert Committee on Food Additives. ADI (acceptable daily intake) in the amount of a medicine or hormone that can be taken every day during a lifetime in the practical certainty no harm will result.)

immune system. With reference back to the first area of concern, the residues are such a small fraction of daily endogenous hormone production as to be without effect.

- (3) Hormonal residues can lead to an increase in certain common cancers. However, epidemiological evidence only shows a direct link between meat and fat consumption; to relate that to hormone residues is a leap in logic. The leap is difficult to support as these tumours are found equally widely in both men and women in countries where hormonal growth promoters are not permitted.
- (4) Hormone residues in meat could affect many aspects of human development and reproduction. The only evidence of such an effect comes from high levels of hormones injected into experimental animals. No current data show any ground for these suspicions in respect of residues, even with the intensive research in this area.

The ‘hormone’ debate is about politics and the role of science to support obviously conflicting views. Even if the science supporting the safety of hormones wins the politicians can still ensure that there will be no consumer acceptance for this technology in the EU. It is not anticipated that there will be a return of the implant in beef production in the EU, but this should not jeopardize its use in other countries with less political interference in product registration.

Growth hormone (BST)

The use of bovine somatotropin (BST) in cattle has primarily been concentrated on increasing milk pro-

duction. This does not mean that the effects of BST on the growth performance and carcass characteristics in beef animals have been neglected. The earliest trial in 1959 (Brumby, 1959) and those in the late 1980s produced consistent effects leading to increased growth rates, improved feed conversion and carcass lean, while decreasing carcass fat. The effects on eating quality of the meat associated with reduced carcass fat were a reduced acceptability because of lower scores on tenderness. The available data in cattle on growth performance were summarized by Enright (1989) and on meat quality by Allen and Enright (1989). As nearly all the data summarized were from trials involving the daily injection of BST, and even sustained-release injectable formulations only last 14 days, there does not currently seem to be a place for its use in the beef industry as a growth promoter.

A direct comparison has been made between anabolic steroids and BST. Untreated controls (UC) were compared with steroid implants (STI) and 160mg BST injected weekly (Preston *et al.*, 1995). Daily gain was increased by both treatments (UC 1.30kg/day; STI 1.66kg/day; BST 1.51kg/day) and feed conversion was improved (UC 5.92; STI 4.88; BST 5.13). The anabolic effects of STI and BST were considered to be potentially additive.

Repartitioning agents

β -Adrenergic receptor agonists (β -agonists) increase muscle mass and decrease fat mass when fed to cattle. A wide range of compounds has been investigated including cimaterol, clenbuterol, fenoterol, isoprenaline, mabuterol, ractopamine, salbutamol, terbutaline and zilpaterol (see Fig. 63.4). The most extensive review of the use of β -agonists in meat animals was published by Anderson *et al.* (1991), in which nearly 400 papers were reviewed. There are currently no β -agonists registered in the EU for use in cattle as growth promoters, indeed in the EU this class of compound is specifically prohibited under EU Directive 96/22/EU. There is one product registered as a growth promoter in cattle in South Africa and Mexico – zilpaterol (Zilmax, Hoechst Roussel Vet) – and one in pigs in the USA, Mexico, Brazil, Philippines and Korea – ractopamine (Paylean, Elanco Animal Health).

The mode of action is complex, with direct effects on skeletal muscle cells, leading to hypertrophy, and on adipocytes, causing lipolysis, as well as secondary mechanisms mediated by other hormones and changes in blood flow (Mersmann, 1998). Studies attempting to relate the relative density of β_2 -adrenoreceptors on muscle and the local response to β -agonists have failed to find a useful tool to predict efficacy of compounds

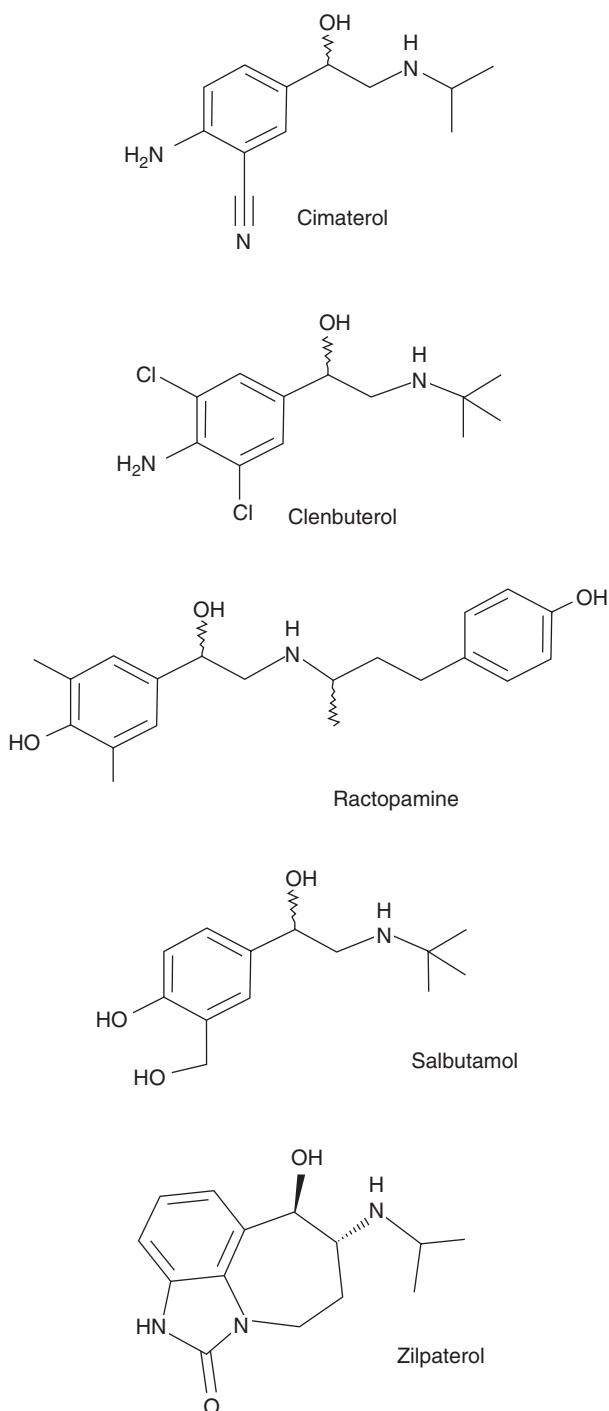

Fig. 63.4 Structural details of a range of β -agonists that have been proposed as growth promoters in cattle.

(Hoey *et al.*, 1995). Moody *et al.* (2000) have undertaken a detailed review of the mode of action of the β -agonists in all species. When β -agonists are used as growth promoters, two major problems arise during chronic exposure. Firstly, receptor downregulation leads to a fall off in effect over time (Peters, 1989; Re *et al.*, 1994)

Table 63.8 The effect of ractopamine on growth performance in finishing cattle. A summary of six trials.

| Dose (ppm) | ADG (kg) | ADF (kg) | FCR |
|------------|-------------------|-------------------|-------------------|
| 0 | 1.26 ^a | 9.40 ^a | 7.46 ^a |
| 10 | 1.34 ^b | 9.31 ^a | 6.95 ^b |
| 20 | 1.39 ^b | 9.40 ^a | 6.76 ^b |
| 30 | 1.48 ^c | 9.31 ^a | 6.29 ^c |

ppm, parts per million; ADG, average daily gain; ADF, average daily feed; FCR, feed conversion ratio; kg, kilogram. Means with different superscripts are significantly different.

Table 63.9 The effect of ractopamine on carcass yield in finishing cattle. A summary of six trials.

| Dose (ppm) | Dressing (%) | Protein (%) | Fat (%) |
|------------|--------------------|--------------------|---------|
| 0 | 60.71 ^a | 15.16 ^a | 30.31 |
| 10 | 60.76 ^a | 15.16 ^a | 30.24 |
| 20 | 61.02 ^b | 15.36 ^a | 29.70 |
| 30 | 61.03 ^b | 15.54 ^b | 28.81 |

ppm, parts per million. Means with different superscripts are significantly different.

and a 'rebound' when the product is removed, leading to an increase in fat deposition and a reduction in muscle mass (Elliot *et al.*, 1993). The most effective use of a repartitioning agent is therefore in the finishing period in the one to two months prior to slaughter. The results from the use of β -agonists in cattle are very consistent and are summarized in Table 63.8, which shows significant increases in growth rates and feed utilization, and Table 63.9, which shows significant increases in dressing percentage, increased carcass lean.

β -agonists are usually divided into two classes (Smith, 1998):

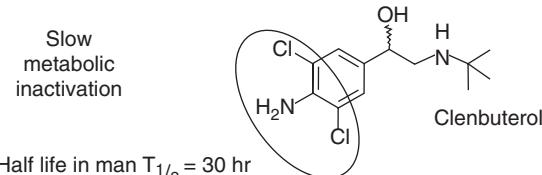

(1) *Halogenated aromatic ring.* This class tends to have a long serum half-life and when coupled with high oral absorption and potency of action in humans there can be a real safety concern from residues in meat. An example of such a compound is clenbuterol (pharmacodynamic dose in man 10 μ g/day – Meyer & Rinker, 1991); levels found in contaminated meat in the EU affected humans who consumed as little as 100g of the product (Kuiper *et al.*, 1998). See Table 63.10 for a summary of some poisoning incidents.

(2) *Hydroxylated aromatic ring.* The metabolism is much simpler with the hydroxylated β -agonists and they tend to have relatively short plasma half-lives and when coupled with a low potency in humans they may pose little risk from residues. An example of this type of compound would be ractopamine, where the phar-

Table 63.10 A summary of some documented cases of β -agonist poisoning in Europe (after Witkamp, 1995).

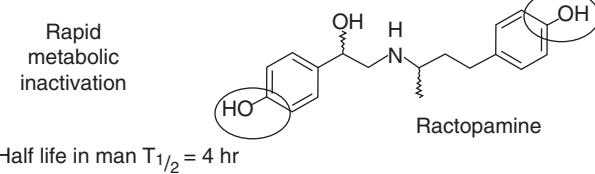

| Year | Source | Compound | No. of people | Symptoms | Country |
|------|--------------------|----------------------------------|---------------|---|---------|
| 1990 | Bovine liver | Clenbuterol (0.16–0.30 mg/kg) | 135 | Tremor, palpitations, tachycardia, nervousness | Spain |
| 1990 | Calf liver | Clenbuterol (0.38–0.50 mg/kg) | 22 | Tremor, headaches, dizziness, palpitations, malaise | France |
| 1994 | Calf liver | Clenbuterol (?) | 127 | Not specified | Spain |
| 1995 | Fillet, rump steak | Clenbuterol (>0.5 mg/kg) | 16 | Tachycardia, tremors, nervousness | Italy |

Class 1 – Halogenated aromatic ring

Pharmacodynamic dose in man 10 µg/day

Class 2 – Hydroxylated aromatic ring

Pharmacodynamic dose in man 25 000 µg/day

Fig. 63.5 A comparison with the metabolic deactivation rate and plasma half-life of halogenated and hydroxylated aromatic ring β -agonists.

macodynamic dose in man exceeds 25 000 µg/day (Paylean Freedom of Information Summary).

Effective doses of ractopamine and zilpaterol are reported to have negligible to undetectable residue levels in the target species (Anderson *et al.*, 1993; *Zilmax Technical Manual*, 1998). These products have only been cleared for use in food animals after extensive reviews of the safety of residues and it is perhaps unreasonable for a class ban to have been introduced in the EU based on the misuse of clenbuterol when safe alternatives were in development.

The classes of β -agonist are contrasted in Fig. 63.5.

The use of highly active β -agonists as growth promoters should not be pursued because of the potential hazards for human and animal health (Anon, 1996), however this should not preclude the development of safe effective products (Smith, 1998).

Chapter 64

Injection Damage

J.H. Pratt

| | |
|--------------------------------------|------|
| Introduction | 1078 |
| Damage produced by injection | 1078 |
| Intramuscular injection sites | 1079 |
| Methods of introducing contamination | 1079 |

Introduction

The faulty administration of veterinary medicines by injection can give rise to complaints from meat wholesalers and retailers and on occasions from consumers. The lesion resulting from the injection of a drug may be aesthetically repugnant to the consumer and commercially unacceptable in the case of abscessation or fibrosis in muscle tissue to the wholesaler, the retailing butcher and the supermarket outlet.

Damage produced by injection

Abscesses deep in the gluteal region of cattle are reported since the site is frequently used for intramuscular injection of drugs. Damage in this area reduces the value of a relatively expensive part of the carcass. Abscessation may render the entire limb unsuitable for human consumption. Intravenous injections can result in haematoma formation and abscess production. In some cases this is due to irritant substances invading the perivascular tissue rather than being delivered properly into the bloodstream. In addition, the deep injection of an irritant substance causing a localized reaction within muscle tissue may elude detection at meat inspection and even later in the cutting premises. The damage may not be revealed until further butchering procedures are performed on the beef in the processing plant or retail shop by which time it may prove difficult to trace the animal back to the farm of origin. Indeed, in countries where complex marketing arrangements exist, the tracing of animals back through marketing chains may prove impossible until unique individual identification of the live animal and the resultant carcass and cuts becomes feasible in all stock. Such an achievement

would constitute a major contribution to future meat quality standards and may now prove possible throughout Western Europe where individual cattle identification is obligatory under European Community law.

Where the farm of origin can be determined, advice on proper injection techniques can be given thereby improving the welfare interests of the animal and enhancing the future profitability of the producer. Losses incurred by the abattoir through the downgrading of affected cuts of beef from incorrect injection procedures would also be reduced.

It is to be regretted that in Britain the use of data collected in the abattoir has not been exploited to its full potential. Such information can play a significant role in future preventive veterinary medicine strategies and in the depiction of regional and national animal disease patterns.

The losses incurred by the meat industry through poor injection technique are spasmodic but nevertheless can be substantial. There are, unfortunately, no reliable figures in UK meat inspection records for condemnation of meat for abscessation due to faulty injection procedures alone. However, on occasions a number of animals within one consignment of cattle exhibit deep muscle fibrosis consistent with damage from injected material, necessitating the rejection of 1.5–2 kg of a high-priced cut of meat. These lesions are formed in the same anatomical area in a number of animals within a group from the same unit. The similarity in age, character and distribution of these lesions suggests a common cause, the introduction of foreign material by injection. Both injectable nemicides and substances used in the regulation of bovine reproduction, e.g. some prostaglandins, may have been responsible for such damage encountered in recent years in this country.

The leather industry also suffers financial loss, as injection damage due to scarring and abscessation can reduce the value of the hide, particularly if the lesion is in a position that prevents the optimal use of the complete hide for large leather or suede items of clothing and upholstery.

Intramuscular injection sites

Alternative siting of injections to that of the gluteal region is therefore desirable. The middle third of the neck, about one-third of the way down from the top, is recommended (see Figs 64.1 and 64.2); this in itself does not reduce the incidence of abscessation or muscle scarring following the injection of drugs but trimming of this less expensive area reduces blemishing of the carcass. This area also tends to be cleaner than the hindquarters and so it is less likely that infection will be introduced with injection.

The factors contributing to muscle damage and abscess formation must therefore be identified to allow the formulation of advice for veterinarians and animal owners to reduce such damage.

The efficiency of the host animal's inflammatory response in removing the foreign protein and devitalized tissue together with the persistence of the stimulus determine the size and progression of the abscess formation. In mild cases no abscess may form, but scar tissue will mark the tissue damage. When an abscess has been formed and the inflammatory stimulus removed the abscess may persist for a prolonged period before resolving to scar tissue.

Methods of introducing contamination

The introduction of foreign protein may occur in a variety of ways.

Contamination of injected drugs: This is most likely to occur prior to administration as a result of poor hygienic procedures employed. To obviate contamination of the contents of a bottle or vial a separate sterile needle to that used for injection must remain attached to the container and used only to refill the syringe. In multiple dosing an automatic injection mechanism avoids this requirement and results in a smoother and more efficient operation. The manufacturer's storage instructions should be followed; unused vaccine should be discarded. When therapeutic agents such as antibiotics are used they should be used up as quickly as possible after opening.

Contamination of needle or syringe: Ideally, a sterile needle should be used for every injection but in practical situations this is often not feasible; however, in special circumstances this approach may be applicable on veterinary advice in certain herds to avoid transfer of specific viral and other infections such as enzootic bovine leukosis (EBL). It is good practice, however, to change needles and syringes regularly, i.e. after every

Fig. 64.1 A growing calf being injected into the neck muscle.

Fig. 64.2 A bull adequately restrained before introducing an injection into the neck muscles.

10–15 cattle, when groups of animals are injected and in any event when contamination of the equipment occurs or is suspected or the needle is in any way damaged.

Punching a fragment of host skin: The introduction of host tissue along with the injection material is most

likely to occur when damaged needles are used. The regular changing of needles will reduce the chances of this occurring. When needle damage has obviously occurred a replacement is necessary in order to avoid possible injury to the animal and to maintain good meat hygiene and quality standards.

Irritant injections: The introduction of an irritant substance that devitalizes tissue locally can be responsible for direct or indirect damage to muscle tissue. Examples used in veterinary medicine are: basic and acidic compounds, such as the sulphonamide drugs and spectinomycin; hypertoxic preparations, e.g. long-acting oxytetracycline; and adjuvants, e.g. aluminium hydroxide, saponin.

Vasoactive substances, e.g. local anaesthetic preparations containing adrenaline and some synthetic prostaglandins, lead to ischaemic necrosis.

Contaminated skin: Pathogenic bacteria may be introduced not only when injecting cattle with a contaminated drug or when the needle or syringe is dirty but when the skin surface is not clean; the introduction of pathogens from the site of injection will occur in a proportion of cattle treated. It is therefore incumbent upon the veterinarian and the stock owner to employ hygienic injection procedures at all times using sterile

equipment and uncontaminated injectable materials. Preparation of the injection site is an integral part of this hygienic approach; the avoidance of contaminated sites of injection is essential. A clean site should be chosen. If not available an area should be cleaned, or if necessary clipped and cleaned.

There are now available multidose syringes with special sterilization caps to reduce the possibility of infections. Caps can also be placed on the tops of therapeutic agents.

The recommended route of administration and the injection technique outlined in the manufacturer's instructions must be followed. The incorrect route can lead to tissue damage, e.g. drugs recommended for subcutaneous administration must not be given by the intramuscular route or intraperitoneally unless specifically indicated.

Proper restraint of the animal will lessen the likelihood of tissue damage and allow hygienic procedures to be followed. The injection of a fractious or nervous animal can lead to unnecessary suffering and damage to the animal, not to say injury to the operator also. Furthermore, struggling while injecting an animal may preclude the proper administration of the medicine with less than the prescribed dose deposited at the recommended site, the remainder forming a depot with ensuing damage. Thus all animals should be adequately restrained (see Figs 64.1 and 64.2).

Introduction

Alternative medicine, in all its many modalities, was the object of a great resurgence of interest in the latter part of the twentieth century. This phenomenon is consistent with the trend towards environmental consciousness (the so-called 'green' movement), which embraces an awareness of the importance and of the mechanisms of health. A large body of consumers now recognizes the vital role played by diet in the maintenance of health. They have an awareness of the effect of additives and of residues upon the value of food items and an understanding of the potential impact of livestock medication upon the health of food animals and upon the wholesomeness of the products of animal husbandry.

As is suggested by the epithet, alternative medicine is relevant to this trend, in that it provides an 'alternative' to what has become the accepted system of medicine, modern conventional drug medicine. There are many so-called systems of alternative medicine (sometimes now described as 'complementary medicine' in an attempt to attenuate the overtones of conflict embodied in the word alternative). The wide range of such systems can present a baffling array to the casual

observer, but they are united in several respects, in that they are:

- Natural, relying on no man-made chemicals for their effect;
- Able to work with and through the body's own mechanisms, stimulating the 'vital force' or 'life energy' in order to achieve health;
- Holistic, embracing the concept of mind and body as a whole in harmony with the environment, and recognizing the interaction of the whole body with each part, and the interaction of the parts with the whole body and with each other; and
- Environmentally and dietarily appropriate, since they give rise to no tissue residues in animals so treated.

Exceptions to this last point are *herbal medicine* and *aromatherapy*, in that they can give rise to residues and taints, thus making the selection and use of herbs and oils, as medicines for food-producing animals, a matter for great caution (see below).

Owing to practical considerations, there are two main systems of alternative medicine that have been developed and refined in the field of bovine medicine and that have become partially accepted by the conventional 'scientific' community. These are *homoeopathy* and *acupuncture*. Of these, the one used to the greater extent is homoeopathy, since it lends itself more easily to rapid, less specialized treatments and is applicable to herd medicine. Acupuncture is more demanding of professional time and is not appropriate to herd applications. Both are very well suited to use on organic farm units, since neither gives rise to any medicinal residues in tissues or in milk.

The title 'alternative' is more appropriate for these therapies than 'complementary', in that each is a complete system of medicine in its own right, demanding a full understanding of its principles and practice for its true value to be manifested. This should embody no contentious sentiments. The following is a brief introduction to the concepts of each of these two, followed by more medical detail. Other therapies, being less appropriate in the context of cattle medicine, are

described in very brief format, in order to act as an introduction only.

Homoeopathy

Founded by a German physician, Hahnemann, in the latter part of the eighteenth century (1790), homoeopathy is a system of medicine embodying the principle '*similia similibus curentur*' meaning 'let like be cured by like'. This classical slogan is often enough in itself to deter the casual student, since it constitutes an entirely opposite stratagem to that of conventional 'school medicine'. It is hoped that the reader will keep an open mind, forming opinions only after searching and objective study into the relative merits of each strategy and the part each system may play in the overall fight against disease. The provision of an objective study requires some comparisons with the 'known' to be made, so as to shed light on the 'unknown' which homoeopathy represents.

The principle of like curing like is elevated from the status of an amusing idea or the product of a fertile imagination by the fact that it exploits a *natural law* (*The Law of Similars*). It was not an invention, therefore, that occurred in 1790 but a discovery. Hahnemann hit on his discovery as a result of objective testing of the effects of Cinchona bark (the parent material of quinine and an accepted cure for malaria even today). He dosed a healthy person (namely himself) in order to try to discover the mode of action of Cinchona bark, as he could not accept the current eighteenth-century explanation for its activity. What happened must have been a great shock to him, for he developed symptoms quite indistinguishable from malaria. Cause and effect he objectively established, by alternately withholding and restarting the administration of the substance. This led him to formulate his hypothesis: '*To cure mildly, rapidly, certainly and permanently, choose in every case of disease, a medicine which can itself produce an affection similar to that sought to be cured*' (quotation from *Organon der Heilkunst* by Hahnemann 1790, translation by Boericke & Dudgeon).

Having carried out tests (Prüfungen in German, which became translated as 'provings') on healthy volunteers, with many substances, he started to use this system of medicine on his patients. He soon found that his crude substances evoked quite serious 'aggravations' in his patients, so he proceeded to dilute the remedies. This led to the second great stumbling block for the modern, conventionally-trained observer in that his commonly used dilutions exceeded those that could reasonably be expected to contain even a single molecule of the original substance. His dilutions, called 'potencies', were often to the extent of 30c and beyond

(i.e. diluted 1/100, 30 times over) giving rise to a dilution of 10^{-60} (at 10^{-23} Avogadro's hypothesis suggests that it is unlikely that a molecule could be carried over to the next stage). What Hahnemann found, with his serial dilution and succussion method (succussion is the violent shaking of the solution at each stage of dilution), were two phenomena. Not only was the toxic power of the substance reduced at each stage (easily understandable) but also the curative power was increased (not so readily acceptable). It is a fact of life that this latter phenomenon exists and that science has not yet found the way to explain it. It therefore remains, unexplained, to puzzle the reader and sadly, in so many cases, to act as a complete blockade to further enquiry.

The big advantage of Hahnemann's discovery of the effects of extreme dilutions, made prior to any understanding of molecules and atoms, is that there can be no drug residues in meat or milk. This makes homoeopathy a front-runner in the choice of medicine for organic cattle units. Whereas herbal medicine, using the primary effects of material doses of pharmacologically active plant material, relies on achieving significant tissue concentrations of medicine, homoeopathy exploits the secondary effects (the body's reaction) for the mediation of its medicinal benefit. It depends not upon material doses but upon energy interactions. The result of this is that, as there has been a rapid growth in conversions of farms to organic status, so there has been an increasing demand for skills in farm homoeopathy, stimulating a burgeoning interest among cattle veterinarians for proper training. With the holistic discipline this study brings, cattle welfare can only be a beneficiary.

In more modern times, and in a veterinary context, clinical trials have revealed good results in many fields. Examples are *Caulophyllum* and its use in controlling porcine stillbirths (Day, 1984a), bovine mastitis prevention studies (Day, 1986), bovine dystokia prevention (Day, 1985), reduction of calf rearing losses (Mahé, 1987) and control of canine kennel cough (Day, 1987a).

Principles

A more detailed approach to veterinary homoeopathy is provided by Day (1984b, 1987b).

How to cure

Hahnemann's four steps to cure (a word he used very objectively, to indicate a removal of symptoms/signs with no further need for therapy to maintain that healthy state) were: (i) know the remedies, (ii) know the disease, (iii) match the remedy to the disease and (iv) remove the obstacles to recovery. Our objective in veterinary medicine is to *cure* disease wherever possible, and it is difficult to argue with the logic of Hahnemann's

four steps. The fourth is, in particular, a little surprising in a positive way, in view of our modern culture's opinion of the soundness of eighteenth century medical beliefs and practices.

Know the remedies

A working knowledge of the 'provings' and actions of each individual 'remedy' or medicine is the basis of this stage. Obtaining this knowledge requires dedication. The remedies are written up in books of *Materia Medica* (e.g. Boericke, 1972; Clarke, 1982; Macleod, 1983; Vermeulen, 1997), which may run into several volumes. These books give an account of the properties of the remedies, in terms of source, general properties, 'provings' and clinical findings with applications. This represents a huge body of knowledge on each remedy's known ('proven' by Hahnemannian tests) capabilities. The information is recorded in very fine detail and for each part of the body and mind, with its assumed capabilities (from clinical data).

It is fair to say that, despite our pharmacological knowledge of modern manufactured drugs, there is not the equivalent amount of knowledge of their actions in the body and, for the most part, very little is known of a drug's possible actions apart from the major primary and local effects. It may also be fair to say that not enough pharmacodynamic studies have been made of homoeopathic remedy actions but, if research is never directed this way, that information will never accrue.

Not even the most learned veterinary homoeopath has a *full* knowledge of even the major remedies (let alone of the full range of several thousand available), since there is so much detail to be learnt. A basic knowledge of major remedies is nonetheless essential to good practice, as well as a superficial knowledge of minor remedies. The hard work and dedication required, to obtain the necessary working knowledge, discourages many would-be practitioners.

Know the disease

Since each set of symptoms and signs, displayed by each individual patient suffering disease, is a product of the individual's own reaction to a disease influence, then each disease occurrence encountered is a unique incident (Fig. 65.1).

Knowledge of each disease incident must depend, therefore, upon one's ability to discern as much as possible of its aetiology in broad terms and upon one's ability to read the symptoms/signs shown by the organism, i.e. its reaction to the disease influence. A detailed effort must therefore be made in history-taking and in clinical examination. The findings can be grouped as follows:

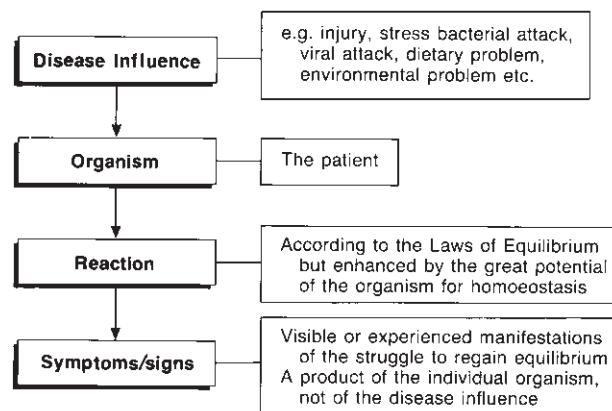

Fig. 65.1 A disease event in an animal.

- (1) *Aetiological or historical influences.*
- (2) *Generals:* symptoms/signs/properties of the whole body, e.g. build, disposition, response to environment, response to food, response to climate, etc.
- (3) *Mentals:* symptoms/signs relating to the mind, e.g. demeanour, behaviour, character, responses to various mental stimuli.
- (4) *Particulars:* the symptoms/signs displayed in each part of the body, in fine detail (the gleanings of a very thorough clinical examination and enquiry). Also any 'modalities' shown by these signs, e.g. 'worse when cold and wet', 'worse after food', 'better after exercise', etc.

Match the remedy to the disease

The findings of a detailed history-taking plus clinical examination and the body of knowledge contained in *Materia Medica* each constitute a picture that can be cross-matched, but this is often a daunting task. As each disease incident is considered to be a unique event and several thousand possible remedies exist, the task may appear impossible. Once a basic knowledge of a good number of remedies is obtained, however, then the ability of the human brain to 'compute' at high speed makes the task achievable, in an acceptable number of cases, for the conscientious student, after several years of practice and study. There are also books to aid the process, which are basically computers in print. These are called *Repertories* (Boericke, 1972; Kent, 1986; Schroyens, 1993) and are basically dictionaries of symptoms (in human terms) listed under 'generals', 'mentals' and 'particulars' (for each part of the body). A dedicated veterinary version of the latter is in preparation. Several remedies are then suggested (with scoring or weighting) that are able to cause the precise symptoms sought and which may therefore be applicable in the

particular patient. If one lists enough symptoms and looks up each in a Repertory, the highest scoring remedy (in theoretical terms at least) is the ideal choice. Resort to the Materia Medica will then help to confirm or negate this choice. Obviously, this is a fairly long-winded process and, although helpful in difficult cases, it is not applicable to rapid, on-farm selection of remedies. Thus, for practical clinical application, a basic knowledge of the remedies is required, together with a practised ability to think rapidly in 'picture' format. No equivalent veterinary Repertory yet exists although, in slightly differing form, help can be found in books by MacLeod (1981, 1983), Brock and Nielsen (1986) and Day (1984b, 1987b). Each of these works gives an easily assimilated guide to remedy choices under given conditions, but (therefore?) is less accurate. Computer programs are being developed for this type of work but, again, are not applicable to practical, on-farm use, with the presently available technology.

Remove the obstacles to recovery

Even in the early stages of the twenty-first century, the insight of Hahnemann in the eighteenth century is remarkable. The single most exceptional example of futuristic perspicacity is in the concept of 'removal of obstacles to recovery'. In trying to observe this fourth provision for cure, very modern ideas must be embraced. Not only must there be obvious remedial efforts, such as splinting or fixation of fractures, dietary investigation and correction, removal of an obstructive foreign body from the bowel, etc. but also, in the herd context, the myriad parameters (environmental, management, dietary, etc.) affecting herd health must be considered. The idea that herd factors are important has been practised by forward-thinking veterinarians for *only the last 40 or so years*. However, Hahnemann made clear provision for it 200 years ago. Sadly, however, the most stringent efforts to improve the husbandry of modern cattle farms will never provide truly *ideal* environmental and nutritional conditions for the animals, although meticulous attention to detail can approach the ideal. Thus, however much effort is applied, one is presented, in modern dairy cattle practice, with an imperfectly fulfilled provision for real cure (Hahnemann's definition). This explains the need, sometimes experienced on intensive farms, for repeated medication (or possibly even continuous, in some of the worst examples), but this must not be an excuse for lack of effort. The unattainability of perfection must not be an excuse for failure to achieve the best conditions possible for the cattle nor for failure of removal, to a maximum possible extent, of the obstacles to recovery.

Conversion to veterinary application

Homoeopathic medicine was developed in humans for humans and therefore presents some difficulties in conversion to veterinary practice. The difficulties can be summarized as:

- Lack of speech in animal patients;
- Interspecies differences in reaction to remedies;
- Lack of family history; and
- Intensivism in farm management.

Hahnemann (1814) did, however, advocate its use in animals and so veterinary homoeopathy has a long tradition.

Lack of speech

The lack of speech in animal patients leads to the loss of a large range of symptoms which would be of value to the prescriber in human medicine. The ability to detail *mental symptoms and feelings* is lost, but much of what is needed in that respect can be discerned by extrapolation from the demeanour and behaviour of the patient. However, the finer details of how the mind is affected by the disease influence, or why it responds in the way it does, cannot be determined. Only the end result of behaviour is seen rather than the mental processes behind that behaviour. Since the mental symptoms of disease are a sure guide to the unique individual response to disease, by each patient, a large proportion of diagnostic (remedy-selecting) parameters is therefore lost to the veterinary prescriber. However, deductions about mental symptoms, extrapolated from the external behavioural signs, can provide an invaluable guide to the sensitive observer. Lack of speech also deprives us of the enormous field of *subjective* symptoms. The adjectives used by human patients to describe pain symptoms are legion. They are again an expression of the individuality of each disease incident and are therefore invaluable. Descriptions of pain such as 'tearing', 'cutting', 'burning', 'aching', etc. are all lost in veterinary medicine. Also hidden, among these symptoms, is the headache in its many forms. We can rarely even diagnose headache in animals, let alone describe it. Approximately 100 pages of Kent's Repertory (1986) are devoted to headache, showing its importance to the prescribing physician.

Interspecies difference

It is not unreasonable to suppose that different species of animals will react differently to the medicines, when compared with *human* reactions. There will also be dif-

ferences between the individual domestic species. To reconstruct the painstaking ‘provings’ of Hahnemann and his followers, for each remedy for each species, would involve several laboratories for many generations, then only with an enormous usage of laboratory animals. This exercise would ethically be unjustifiable. Despite the obvious existence of such a problem, as shown by the varying toxicology and pharmacology, known in different species, for many poisons (Garner, 1967), drugs (Daykin, 1960) and foods, homoeopathy is largely transferable *en bloc*. This is a fortunate fact but one that should never be taken for granted. Thus the astute practitioner of the art will need to be aware of the possibility of failure due to species difference and will use pharmacological and toxicological knowledge to advantage.

Lack of family history

Although not strictly applicable to units where pedigree breeding and recording has gone on down the years, the lack of family history of bovine patients, particularly in terms of disease, will lead to loss of some accuracy in prescribing. Known line susceptibilities are an important factor in choosing remedies in such conditions as cancer, mastitis, lameness, etc., but the loss of some of this material is not likely to be as deleterious, to effective veterinary prescribing, as the lack of speech and the potential interspecies differences.

Intensive farming

This factor has been discussed previously (see. p. 955).

Application

Disease can affect an animal to a greater or lesser depth and, therefore, so can the so-called remedies of homoeopathy, since they are also ‘disease-producing agents’ when administered to a healthy body. These different levels of prescribing can be classified as:

- (1) Pathological
- (2) Local
- (3) Organ-specific
- (4) Constitutional
- (5) Facilitative /regulatory
- (6) Detoxifying
- (7) Historical
- (8) Specific and
- (9) Preventive

These terms require explanation, since their usage in this context is peculiar to homoeopathy alone.

Pathological

To prescribe at the pathological level, one needs to be satisfied that the disease influence has evoked an acute and easily identifiable disease process, that could be easily matched to the actions of a particular remedy. The effects of *traumatic injury*, for instance, are very well covered by the properties of arnica. The administration of arnica, as rapidly as possible after the traumatic insult, will swiftly and effectively initiate a healing process that will reduce the pain, shock, haemorrhage, tissue fluid accumulation and resultant tissue damage that normally follows trauma. The net result is a happier patient, less distortion at the site of injury and, more importantly, less disturbance to the circulation in the area. Therefore there is more effective and rapid restoration of normal tissue integrity and structure. There is also a powerful and often underestimated antiseptic effect of this remedy.

The fact that one remedy covers this process is very convenient for the prescriber and very helpful to the patient. It removes the need to apply the full rigours of the homoeopathic method, in times of emergency. Furthermore, this pathological level of prescribing provides a simple proving ground for homoeopathy to the sceptic and a useful starting point for learning the first steps of the homoeopathic method. Other commonly used remedy/pathological indication pairings are:

| | |
|------------|---|
| Hypericum: | injury to areas rich in nerve endings (e.g. in digit, tail, etc.), injury to nerves, painful grazes, photosensitization |
| Ledum: | puncture wounds |
| Aconitum: | sudden shock to the mind or body, sudden disturbances of the body's equilibrium (e.g. sudden-onset fever, sudden haemorrhage) |
| Calendula: | open wounds – antiseptic and promotes healing |

Local

One would apply this level of prescribing when the nature of the disease is acute and fairly superficial, to an otherwise healthy animal with a robust constitution. Examples of this application are: acute-onset mastitis (see p. 326) resulting from a chill, where aconitum is useful, New Forest eye infection (see p. 919), where mercurius corrosivus may be effective, and foul-in-the-foot infection (see p. 426), where hepar sulphuris could be the correct remedy. To prescribe effectively for these conditions, one only needs to take note of the local presenting signs and match these to a remedy. One does not need, again, to delve into the deeper homoeopathic

method, discussed in previous pages, in order to achieve a good result. However, it is vital to ensure that the disease is not chronic in nature or an acute exacerbation of an underlying chronic disorder. If this should prove to be the case, satisfactory results will not follow from employment of this simplified technique and one would need to apply the constitutional approach (see below).

Organ-specific

Organ-specific remedies may be used when one organ is particularly embarrassed in an illness, when it is considered important to support that organ. Some remedies have a particular affinity for specific organs or tissues and the most important are:

| | |
|---------------------|---|
| Rhus toxicodendron: | muscles |
| Ruta graveolens: | tendons, ligaments, joint capsules, aponeuroses, periosteum |
| Hypericum: | nerve fibres |
| Symphtym: | bone |
| Nux vomica: | liver |
| Flor de piedra: | liver |
| Lycopodium: | liver |
| Berberis: | liver, kidney |
| Kali chloratum: | kidney |
| Digitalis: | heart |

Constitutional

The concept of a 'constitution' embodies everything that is unique to an individual organism. It embraces the idea of the 'programmed' nature of each body's response to a disease influence. Another way to consider this is to think of predetermined tendencies in each individual. Response to disease is determined by a number of factors: genetic make-up inherited from the parents, *in utero* influences during pregnancy, the birth process, postnatal influences, influences during the growing period and influences during adulthood. In the farm context, one can see how breeding, pregnancy, calving, rearing and general management or dietary regimens can affect the make-up of an adult cow. By reading the response pattern of the animal (signs and symptoms) in the face of disease or situations, and by studying her conformation and behaviour, one can formulate an idea of her 'constitutional type'. This whole picture can be matched to a whole remedy picture, as previously discussed. Not many remedies have a combination of wide enough or deep enough effects on the body to rank as constitutional remedies and, in the world of cattle, the major nine examples can be listed, conveniently classified into three groups:

| | |
|----------------------|--|
| Aurum | Corresponding to a great many cows that suffer typically female or hormonal problems as a rule |
| Pulsatilla | |
| Sepia | |
| Antimonium crudum | Fitting those cattle that suffer digestive or liver problems |
| Nux vomica | |
| Lycopodium | |
| Calcarea carbonica | Matching those cows suffering from lactation-induced disorders |
| Calcarea phosphorica | |
| Phosphorus | |

These generalizations are too sweeping to be strictly followed but the pictures of the remedies listed above are suitable to be grouped in the way shown. These are 'big' remedies (Hahnemann's so-called polycrests) and have wide-ranging effects on all parts of the body. They cannot, therefore, be type-cast purely in the roles shown above, but the groupings are useful nonetheless. The groupings represent trends in the relevant animal's disease response patterns and are very useful for short-listing of remedies. These and other useful remedies will be discussed later (see pp. 1088–1090), in fuller detail.

In the case of a patient affected by chronic disease, no real cure can follow treatment unless this method of prescribing is followed. The organism has learnt, in the case of chronic disease, to live in a state of uneasy harmony with the disease. The animal is therefore unable to regain health, often lost a long time previously, unless the deep, powerful and most appropriate stimulus of true holistic constitutional homoeopathy is prescribed.

Facilitative/regulatory

The facilitative level of prescribing exploits the ability of certain 'potentized' substances to facilitate metabolism with respect to those substances. Examples are the use of 'potencies' of calcium phosphoricum to facilitate metabolism with respect to calcium and phosphorus, magnesium phosphoricum to help magnesium metabolism, and cuprum metallicum to assist copper metabolism. It is well known that so-called mineral deficiencies are rarely absolute deficiencies but can be more often a malfunction of the relevant absorptive, metabolic and eliminative processes for that mineral. Cases of 'relative' excesses and deficiencies can both be helped by such methods. In the case of a hormone disturbance, a 'potency' of the hormone may help regulate and balance the body with respect to that hormone.

Detoxifying

The detoxifying method of prescribing echoes very closely the preceding remarks. Should a specific substance be causing a toxic effect, e.g. alkaloid, metal,

chemical, etc., then the body's natural ability to break down and/or eliminate such toxins will be enhanced by the administration of the specific substance, or a close relative, in 'potency' (homoeopathic dilution). Examples are the use of *plumbum* in cases of lead toxicity, *coumarin* or *melilotus* in cases of warfarin toxicity, *opium* or *nux vomica* in cases of anaesthetic toxicity or even of carbohydrate overdose in the ruminant. Such methods have often been shown to produce unexpected results, even in extreme cases of toxicity.

Historical

The historical method of prescribing utilizes the body's ability to respond to an appropriate curative homoeopathic stimulus, long after the initial disease-producing influence has subsided, should the body still be suffering from the effects of that influence. Examples are: using *arnica* long after an initial traumatic insult, should the body still be suffering disease from that injury; using *aconitum* long after a mental or physical shock, if the body is still suffering effects or fears produced by that shock; using a 'specific' remedy (see below) long after a specific infectious disease has passed its acute phase, should the body still be suffering effects from that disease.

All that is necessary, in order to utilize this method, is to detect, in a chronic disease situation, a facet of the history that leads one to believe that the current disease has its origins in a specific historic incident. One can then treat for that incident, as if it were in the herd and now, even though it may have occurred years previously.

Specific

The specific method of prescribing would usually be used in an acute infectious disease context, where a known specific infectious disease agent is involved. Generally speaking, this method of treatment would imply use of *nosodes* (remedies made from disease material). Examples are: *mastitis nosode* in cases of mastitis (see Chapter 23), *infectious bovine rhinotracheitis (IBR) nosode* in cases of IBR (see p. 286), *bovine virus diarrhoea (BVD) nosode* in cases of BVD (see p. 853) or *salmonella nosode* in cases of salmonellosis. In the acute phase of an infectious disease, it may be dangerous to use the nosode in an attempt to produce a cure. For this reason, this form of therapy is usually reserved for use during the recovery phase of the disease, in order to prevent any tendency for the disease to become chronic. During the acute phase it is always better to select an appropriate homoeopathic remedy for cure, according to the Law of Similars in the usual way. This implies that, in each case of acute spe-

cific disease, there will be no remedy specific to the disease but a whole host of possible remedies, the most suitable of which must be selected for each patient. Having said this, it is possible that *baptisia* could be specific to salmonellosis (Chapter 15), *mercurius cyanatus* to calf diphtheria (see p. 250), *mercurius corrosivus* to New Forest eye or even *borax* to foot-and-mouth disease (see Chapter 43(c)) (in those countries in which it is permitted to treat this disease).

Preventive

In herd medicine it is very important to apply preventive principles, in order to minimize or to obviate the risk of spread of a known or predicted infectious disease within the herd. This is the basis of effective veterinary involvement on the modern bovine farm unit. In an individual animal context, it is important to prevent disease occurring in the face of a predictable challenge or disease-producing event.

The greatest demands on the veterinarian using homoeopathy are on a herd basis. Where infectious disease has either entered the herd, in which case the healthy individuals must be protected, or is threatening the herd, in which case the whole herd must be protected, one would select for prevention a specific remedy. This would generally be a *nosode* (see Specific prescribing, above) although it could be any remedy from the homoeopathic *Materia Medica* that the prescriber feels specific enough to a certain disease (see Prescribing guide, p. 1091). In conventional medicine one would be reaching for a vaccine in this context, but in the case of some infectious diseases, no effective vaccine is available or no vaccine exists at all. Nosodes may be considered as if they were vaccines, if it helps the reader to understand the principle of their application in this context. However, they do not produce any antibody response in the treated animal, due to the extreme dilutions in which they are usually used (30c). Neither do nosodes carry the potential hazards that vaccination sometimes can, e.g. strain 19 *Brucella abortus* vaccine (Day, 1986, 1987b).

These preventive remedies, in order to be swiftly, effectively and easily applied to the whole group at risk, may be administered via the drinking water. Water troughs should be as clean as possible and should be large enough or well enough supplied with water, so as not to run dry on the day of dosing. The quantity of remedy used does not appear to be very critical but an easy guide is to use 5ml per drinking trough, unless the trough is unusually large or small. Frequency of dosing would depend upon the estimated properties of the challenge. In an enzootic disease situation within the herd, the frequency would be selected corresponding to the estimated violence and virulence of the disease and

according to the animals' estimated ability to withstand it. At times of high risk, when the disease agent is perhaps given the upper hand by management factors or by climate or the animal is compromised by similar factors, then one would dose more frequently. In the case of assumed risk from an epizootic disease, i.e. a disease not yet met by the herd, dosing could be more sporadic.

The second sphere of use of the preventive technique is in the case of the individual animal, which may be threatened by a predictable disease challenge. Thus with impending parturition, *caulophyllum* could be used to help prevent problems (Day, 1985, 1987b), or for an anticipated stressful journey, *aconitum* could be used in advance of the challenge. Incidentally, *aconitum* can be used on a group or herd basis, in order to prevent the production losses consequent on herd stress, such as the periodic tuberculin test.

Thus it can be seen that the application of the homoeopathic method has come a long way, since it was first devised in humans some 200 years ago. Although the rigorous and in-depth diagnostic and prescribing processes may daunt the novice, the classification into different levels at which the method can be applied in bovine medicine makes it easier to start out. They provide scope, for even the newly initiated and hesitant prescriber, to test the principles of homoeopathy and its efficacy at an easier level, without immediately being committed to long-term study or to large and therefore expensive stocks of medicines.

The challenge of herd treatment

Much has been made, in the foregoing pages, of the need to individualize therapy for best results. This high ideal is frankly not practical in a herd or group situation. If we consider, for instance, a group of calves suffering from pneumonia, treating each on an individual basis is not possible. What is needed is a modification of principles, while maintaining the essence of homoeopathic philosophy and methodology. This short section can only be a summary of the techniques involved, in order to show the options. Clearly, homoeopathy will not be a practical therapy on the farm if it is not adaptable to herd applications.

A detailed account of how this can be done is to be found in the Further reading section (Day, 1999). In essence, there are six main possibilities:

- (1) To choose a single *similimum* (a homoeopathic medicine which is similar to the signs and symptoms displayed) for the entire group. This will only be properly effective in an epizootic situation, in which all individuals are likely to be similarly affected.

- (2) To select a combination of remedies for the group. This will allow the incorporation of the spectrum of signs shown by the different individuals. A maximum of three different remedies should be incorporated.
- (3) To select a number of different remedies (maximum of three) to stimulate the individuals at different levels, as in the foregoing section. A 'constitutional' remedy, say, could work alongside a 'specific' remedy and a 'local' prescription.
- (4) A single constitutional prescription may be possible, especially if the group all come from one family or from one breeding line.
- (5) A specific or nosode prescription could be selected, as in the above section. This can be very successful in the case of a known infective disease and lessens the need for more detailed homoeopathic knowledge or skill.
- (6) The group could be 'repertorized', as if it were a single animal. The technique would be as outlined in the section describing how to match the remedy to the disease. This is an advanced technique and should not be tackled without experience.

The reference given describes how these techniques are compatible with proper homoeopathic philosophy and principles.

Materia medica

There follows a brief summary of the properties of some of the homoeopathic remedies most commonly used in a farm context and some of their possible clinical applications. This is not intended to be an exhaustive source on the subject but an introduction to these 30 useful remedies. Fuller works on this material can be found in the Further reading section. Remedies are presented in alphabetical order for simplicity, not in order of importance nor grouped according to possible application. The way in which these remedies are presented shows the emphasis placed upon the 'picture' presented by the disease rather than upon its usual *name*. Remedies are taken from the plant kingdom, animal kingdom and minerals and are available in tablet, pillule, crystal, powder, tincture, injection, cream, ointment or lotion forms. The thirtieth centesimal (30c) potency is a useful potency of most remedies, for the purposes of beginners.

Aconitum napellus: this is a remedy suitable for use in cases of sudden shock (physical or mental in nature), sudden-onset fevers, disorders from chilling and cold winds, and in cases of profuse bright red haemorrhage.

Affected animals tend to shudder in response to fear or shock, display a rapid pulse, run a fever and suffer conjunctivitis with fluid lacrimation and nasal discharge. Symptoms

tend to centre on the chest, so use in 'shipping fever' is an obvious application (see p. 286).

Antimonium tartaricum: this remedy is particularly suited to respiratory signs. Indications are mucoid, rattly breathing or coughing, frothy saliva and a tendency to cyanosis. Animals display minimal thirst and a rapid, weak pulse. Cold, damp weather aggravates the condition and affected animals are unwilling to lie on their sides. This remedy is one of several useful pneumonia remedies and should be considered in cases of fog fever (see p. 866).

Apis mellifica: it is useful in cases characterized by oedema. Urine retention, pulmonary oedema, oedematous swellings of vulva/perineum or udder, ascites, cystic ovaries, etc. may all respond if concomitant signs agree. The patient is usually thirstless and prefers cool open air. Cold bathing of affected areas produces comfort.

Arnica montana: this is a remedy of use in *all* conditions arising from trauma. Bruising, haematoma formation, pain, swelling, shock and even resultant local infection will respond to treatment. Patients often display a fear of being touched.

Arsenicum album: this remedy is a polycrest and therefore of constitutional importance. Restlessness, chilliness and thirst characterize the patient. The remedy can be useful, on a more local basis, in cases of diarrhoea, dehydration and collapse, if concomitant signs agree. Diarrhoea is usually profuse, watery and offensive-smelling.

Belladonna (genus: *Atropa*): a 'fever' remedy, this is useful in cases where there is an acute febrile or inflammatory state characterized by heat, redness, swelling, fullness and pain. The pulse may be full and bounding. There are often delirious or convulsive signs too. The animal is usually thirsty and displays a dilated pupil. Symptoms tend to centre on the chest, making a useful distinction from the usual pattern of *aconitum*.

Bryonia alba: this remedy has an affinity for serous membranes. All suitable conditions are worsened by movement, so a major sign in the affected animal is unwillingness to move. Affected animals are thirsty for long cold drinks. Guided by these three points one may prescribe confidently in cases of pneumonia, mastitis, arthritis, peritonitis, etc. The pneumonic calf will stand still, despite its fear, and will tend to lie on its affected side to prevent movement. The mastitic cow would allow herself and her hot swollen painful udder to be examined, rather than move away.

Calcarea carbonica: another polycrest, this remedy has constitutional applications. Disorders of production are an indication, e.g. fertility, lameness, mastitis. The animal has a heavy skeletal structure, large limbs, large joints and large feet. It usually has a good condition score and is generally peaceful but dominant. Movements tend to be unhurried. The appetite is very good and, if a milking cow, the milk yield is high. The animal is susceptible to chilling and usually shows catarrhal-type responses from the mucous membranes.

Calcarea phosphorica: a polycrest, this remedy is suited to similar conditions to *calcarea carbonica* and the typical animal is similar, although lighter in skeletal structure, quicker

in movement and responses, difficult to handle and more fearful.

Carbo vegetabilis: abdominal distension by gas, flatus, flatulent colic, weakness of circulation and musculature, poor resistance to infection and even collapse characterize this remedy. Its main application is in the treatment of the cold, collapsed individual, in whom its results can be spectacular. It has been dubbed the 'homoeopathic corpse reviver', on account of its prowess in such cases.

Caulophyllum thalictroides: one of the Native North Americans' so-called 'squaw-root' remedies, it has great application in all disorders of labour, at any stage (Day, 1984a, 1985). It also has an effect on shifting lamenesses, particularly if the origin is in the small joints.

Colocynthis (genus: *Cucumis* or *Citrullus*): this remedy is of particular use in colic. The abdomen is distended and the back arched. Animals will roll and kick at the belly in cramp-like paroxysms.

Hepar sulphuris: if any homoeopathic remedy could be said to fill the role of antibiotics in septic conditions, then this is the one. Suppurative processes in their early stages respond well. In suitable cases, there is always great sensitivity to pain, with relief from warm applications. Pain is aggravated by the least touch. Joint-ill and navel-ill usually respond (see pp. 249, 255).

Hypericum perforatum: injury to nerves or to areas rich in nerve endings is an indication for this remedy. It has a very rapid healing effect, both on the pain and on the physical damage. Not surprisingly (on account of modern knowledge of the physiology involved and of the symptoms) the lesions and pain of photosensitization also respond well (see p. 884).

Lycopodium clavatum: a polycrest, this remedy has an application constitutionally. With an affinity for the liver, the remedy is often used in this context. Possible digestive disturbance, dry, withered appearance to the skin, tendency to flatus, abdominal distension, liver dysfunction, dyspnoea, tachypnoea, movement of the nostrils with every breath and an overall anxiety distinguish this animal type in disease. Problems are often right-sided and the animal prefers warmer water to drink (if offered).

Mercurius cyanatus: a thirsty patient with a paradoxically wet mouth and possibly even drooling saliva may require a mercury-type remedy. *Mercurius cyanatus* patients display offensive breath, offensive-smelling ulceration of mouth and throat and swollen glands. The picture fits that of calf diphtheria.

Mercurius solubilis: as with all mercury remedies, there is a tendency to thirst, to profuse salivation, to offensive breath, to swollen glands in the throat and to ulceration of mouth, bowel or teats. Ulcers will discharge pus. If there is diarrhoea, there will also be a degree of tenesmus. Since the remedy is a polycrest, it has constitutional applications. The preceding disease tendencies in a dominant, usually heavy, animal are an indication for its use.

Nux vomica: as a polycrest, it has wide application in a constitutional context in the bovine. Patients tend to be dull and

sluggish in movements, with paradoxically rapid or violent reactions when disturbed, bad tempered and thin. They suffer digestive complaints, characterized by cessation of rumen function and a tendency to constipation, having hard knotty stools. Some cases of 'acid' or fermentative diarrhoea may respond and complaints following from overeating of concentrate will respond well. Conditions tend to be worse in the morning and worse for disturbance or chilling (Mahé, 1987).

Phosphoric acid: in common with all the 'acids', phosphoric acid is indicated in cases of general weakness. More specifically there is debility, dehydration, pale flatulent painless diarrhoea with a dry mouth, thirst and possibly a degree of jaundice.

Phosphorus: because of its extent of action, it is a polycrest and therefore of great value in a constitutional context. Phosphorus conditions are characterized by sudden onset and by their serious nature, e.g. sudden-onset pneumonia, sudden haemorrhages, hepatitis, haematogenous jaundice, etc. The phosphorus animal is also 'sudden' in temperament, being averse to separation from the rest of the herd and apt to panic. The type is of lean build and averse to handling. Conditions are worse for touch and change of weather.

Phytolacca americana: this is the remedy above all others with a reputation in mastitis. This reputation can lead to overuse in this context, as it will only produce results when used in the correct homoeopathic manner. Lymph glands and mammary glands become indurated swollen and painful. There is usually heat too. Milk becomes thickened, stringy and yellowish. Cold wet weather aggravates the symptoms.

Pulsatilla nigricans: this is a common constitutional type in the bovine, particularly in the case of heifers. The type is shy, feminine in appearance, suffers catarrhal complaints and has little thirst. Breeding problems respond well, if it is used in the correct constitutional context. Catarrhal syndromes of respiratory tract, udder, reproductive tract, etc. are typical. The animal prefers fresh, open air and symptoms are aggravated by warm, stuffy atmospheres and in the evening.

Pyrogenium: fevers, particularly those of a septic nature, respond well to this remedy, especially if pulse and temperature are not in agreement. In suitable cases, there is a tendency to toxæmia, offensive secretions, dark blood and offensive, dark-coloured, septic lesions.

Rhus toxicodendron: American poison ivy (the source of this remedy) produces, and is therefore able to help, severe pruritic conditions or conditions characterized by rheumatic or arthritic stiffness and pains with great thirst and an aggravation from cold, wet or damp conditions. Skin lesions are often vesicular in nature, resembling cowpox lesions. Musculoskeletal problems are further characterized by an aggravation when moving from rest, with a subsequent 'loosening' and easing of the stiffness and pain. Suitable diarrhoea cases display dysentery and tenesmus.

Ruta graveolens: with an affinity for fibrous structural tissues such as ligaments, tendons, joint capsules and perios-

teum, this remedy is a powerful aid in the treatment of sprains and other damage to such tissues and regions of the body.

Sabina (juniperus): sabina's main sphere of activity is the uterus, where bloody discharges and lack of tone may respond. It is not indicated where sepsis exists. Retained fetal membranes may also be expelled under its influence.

Sepia: a polycrest, sepia has great value as a bovine constitutional remedy. It is predominantly of use in a female context. Lack of tone and lack of tautness typify the conditions and the constitutional type suited by this remedy. The animal takes on a worn-out, tired, sagging appearance and so, also, do individual body regions, e.g. uterus/perineum, limbs, udder, etc. Venous congestion and tendency to prolapse are also characteristic. Fertility problems may respond, if constitutional aspects agree.

Silica: Better known for its ability to stimulate expulsion of foreign bodies from the tissues or to awaken chronic low-grade inflammatory lesions, silica is also a great constitutional remedy. Structural weakness and distortion, whether of skeleton or feet, with a poor immune response, typify the animal able to respond to the remedy.

Thuja occidentalis: The reputation of this remedy rests mostly on its action on papillomatous lesions (p. 882), especially when they occur on neck or abdomen. Ill-effects of vaccination also may respond. The constitutional and other effects of the remedy are not so important in cattle work.

Urtica urens: The lesions of nettle rash are well known to everyone, as is the pain that follows. The remedy is of value in such conditions. Apart from these properties, the remedy has the ability, in high potency, to promote milk flow and, in low potency, to induce suppression of milk. This dual regulatory power gives the remedy great value in bovine medicine. Lesions respond favourably to warm applications and negatively to cold applications, so too does the mastitis helped by urtica.

It is hoped that the foregoing brief account of 30 remedies will allow a start to be made in homoeopathic prescribing. It cannot be expected that, in so few pages, it will provide a comprehensive knowledge of the remedies. The reader must also realize that these few remedies, although forming a good nucleus of prescribing material, actually represent only a fraction of what is available. For each condition or syndrome mentioned, a great many other remedies have a potential value, should they prove to have properties 'similar' to the problem.

Prescribing guide

There follows a small vade-mecum, showing some indicated remedies that may prove effective in the named syndrome. Please be reminded that true homoeopathy does not rely upon the name of a condition for remedy selection but upon the similarity between disease

picture and remedy picture, on as many counts as possible. The following list only serves as a pointer to some commonly indicated remedies. Final selection between those remedies mentioned (and many not mentioned) rests with the prescriber. All the remedies mentioned below appear in the preceding section, so that section can act as a brief guide to help selection of the most relevant remedy. (Remedies may be given orally, by injection, topically or orally via the drinking water.)

| Navel ill (p. 249) | <i>Hepar sulphuris, silica</i> |
| Papillomatosis (p. 882) | <i>Thuja</i> |
| Placenta (retained) (Chapter 34) | <i>Caulophyllum, sabina, sepia</i> |
| Pneumonia (Chapters 17, 49) | <i>Aconitum, antimonium tart., bryonia, lycopodium, phosphorus, pyrogenium</i> |

This list is far from complete and is aimed at providing an insight and a starting platform, for deeper homoeopathic prescribing and learning.

Having read this guide to the principles of homoeopathy and having tried out some of the methods and suggestions contained in this chapter, it is hoped that the reader will go on to further study and will venture into more ambitious prescribing, from a

position of confidence. Books giving a greater depth of homoeopathic knowledge are listed in the Further reading section and accredited courses in Britain, on veterinary homoeopathy, are conducted under the auspices of the Faculty of Homoeopathy, 15 Clerkenwell Close, London EC1R 0AA. The Faculty has an examination structure, for postgraduate qualifications. On an international basis, the Faculty does help courses in other countries, and the International Association for Veterinary Homoeopathy both runs courses and sets examinations for veterinary homoeopathy.

Acupuncture

Acupuncture is a science of energy medicine, having its origins in ancient China anything up to 4000 years ago. The oldest medical textbook known, the *Huang Ti Nei Jing Su Wen* (Veith, 1972), may have originally been written as long ago as 1000 bc. Its origins are confused, since it has undergone many alterations and commentaries since it was first written. (In fact the *Su Wen* was possibly a later addition to a scaled down *Nei Jing*.) This book has formed the basis of traditional Chinese medicine theory down the centuries, but there have been myriad adaptations and variations applied since its inception, giving rise to traditional Chinese medicine as we know it today. Acupuncture is but a component of this, Chinese herbalism also forming an integral part, along with moxibustion (the application of heat). The practice of traditional Chinese medicine is truly holistic, in that it embraces an understanding of the part played by diet and lifestyle in the health of the individual and it makes a positive effort to optimize these, as an integral part of therapy.

The Chinese have long treated animals with acupuncture, so our veterinary use of this in the West is no new thing. Dogs, cats, horses, cattle and other farm animals can be treated. In countries other than Britain, working animals such as elephants, llamas, donkeys, camels and buffalo are patients. In the UK, acupuncture is much more widely used on dogs and cats than in horses, and more in horses than in cattle. This is more a function of the pattern of specialization in the veterinary profession and that more interest has been shown by those veterinarians who are in small animal practice, than a reflection of the efficacy and value of acupuncture in cattle. Cattle respond very well to the methods but chronic disease is less a feature of bovine medicine than in the other species. This means that there is less call for a specialist second opinion than in equine or pet medicine. The call for acupuncture help in cattle is reduced, compared with the other species, since the species is kept more on a financial (productivity) basis than for

emotional, competitive or recreational reasons. The reality is that there is less perceived value in the individual as a result.

Acupuncture is a system of *internal* medicine devised, in ancient times, purely from the outside of the body. In ancient China, the human body was not to be violated, either in life or in death, so post-mortem examinations and anatomical or physiological studies were not performed. The basis of the system is the relationship of points on the surface of the body to the internal organs and their integrated functions. The mechanism of the relationship is not clear to Western science and is unquestioned in the East, where such a different philosophy of life and living pertains as to be incomparable. Clearly, as far as some of the acupuncture points are concerned, there is a cutaneous-visceral reflex at work but this does not satisfactorily explain the mechanism of acupuncture, any more than does the discovery of the release of endorphins or opioids in response to treatments. Our Western way of looking at life leads to a linear thought process, trying to establish 'cause and effect', and an attempt to rationalize, classify and compartmentalize in a way that does not sit well with the oriental philosophy and method.

The Chinese discovered, empirically, a collection of points (some 700 forming the basis of the system) that related to bodily function and to disease patterns or pictures. In order to explain the indisputable facts and verifiable correlations so discovered, they wove a web of philosophical concepts, in harmony, of course, with their philosophy of life (so turning an empirical art into a science). In ancient China, and still today, medical lore, religion and their way of life are inextricably entangled and form a unity not found in any comparable form in Western culture, where it seems that all three tend to be considered as separate entities. This chapter does not argue which view may be the more correct, valid or healthy, but merely presents comparisons.

The philosophical lattice work, developed so long ago, is not there to confuse the would-be student but to explain and elucidate the empirical findings. This is not apparent to the sceptical Western observer, who will undoubtedly find the concepts not only confusing but amphibiotic. Atavism and Taoism are indigenous to the oriental way of thinking and are totally foreign to us. However, acupuncture was devised in the East and developed in the light of oriental concepts. It must be taken or left at face value, at present, until some more readily assimilable theory may be formulated that can explain the observable phenomena as well as the original. This development is not in the offing. It is hoped that by presenting a rapid overview of the theory and philosophy, it will not confuse the reader but will serve to give an introduction to the principles and methods

of traditional acupuncture and encourage the diligent student to look further into the subject.

Theory

The theory of the science of acupuncture is based upon concepts of energy and forces which are rooted in Taoist philosophy. In this there exists no linear thinking, no cause and effect. The order and pattern of life (and therefore disease, which is a part of life) and of the universe are governed by principles of inevitability. Concepts are not placed one under the other in a deductive sequence or subsumption, but side by side in a picture. Events follow each other, not by cause and effect but by a kind of inductance. Light does not cause darkness and vice versa, one becomes or leads to the other inevitably. Similarly, the concept of light cannot exist without a concept of darkness, nor the concept of good without that of evil.

It has been said of Taoism that it does not deny reason, but that it remains just beyond its grasp. It is a concept of balance, of rhythm, of sustainability, of harmony. It describes a complex web of interrelationships, in which the whole is dependent upon and affected by its parts and in which each part is dependent upon and affected by the whole and each of the other parts. There is an essential understanding of flux, of dynamism and of interconnectedness.

The two forces that maintain the universe, and the life within in it, are called *Yin* and *Yang* and represent philosophical polarities. They are the eternal opposites. They are aligned to other pairings of polarities, ranging over the whole of our existence. Examples are, respectively, dark and light, cold and hot, female and male, low and high, sluggish and fast, lower and upper, night and day, soft and hard, earth and heaven, light and heavy, passive and active, inside and outside, empty and full, water and fire, weak and strong, under- and overactivity, humble and exalted, front and back (more logical in quadruped terms than in the human biped, i.e. ventral and dorsal, in that dorsal is higher, therefore representing *Yang*) and so forth. It should be becoming clear that these two polarities act both simultaneously and antagonistically within the universe (and within its microcosm, the body). There is, however, no absolute in life and so with *Yin* and *Yang*. There is no *Yin* without *Yang*. They are forever transforming into one another, on an almost imperceptible basis. Nothing is all *Yin*, nothing is all *Yang*. All systems are composed of *Yin* and *Yang*. Within *Yin* there is *Yang* and within *Yang* there is *Yin*. Within any given *Yin/Yang* system under discussion, there is a further *yin/yang* system and, within that, another. This applies over and over, *ad infinitum*. Zou Yen, the philosopher of the third century BC, observed: '*Heaven is high, the earth is low, and thus they*

Fig. 65.2 The Taoist *Tai Chi Tu* symbol.

are fixed. As the high and low are thus made clear, the honourable and humble have their place accordingly. As activity and tranquility have their constancy, the strong and weak are thus differentiated. . . . Cold and hot season take their turn . . . and Heaven knows the great beginning, and Earth acts to bring things to completion. Heaven is Yang and Earth is Yin' (Kaptchuk, 1983). Thus are embodied the consistencies and (apparent) inconsistencies of the oriental approach and there is no way to determine the beginning or the end. The classic 'chicken and egg' situation holds, and one can only observe the continuum/perpetuum. The Taoist *Tai Chi Tu* symbol (Fig. 65.2), more correctly a sphere rather than a two-dimensional object, is the traditional and elegant attempt to represent this concept diagrammatically. In this yin-yang model, the dark area represents Yin and the light area, Yang. The dots represent yin-within-yang and yang-within-yin. As the sphere turns, so the interplay of yin and yang are illustrated.

Yin and Yang act together and antagonistically within the body and are components of the life energy – *Qi* (pronounced 'chee'). This energy is said to circulate continuously and rhythmically (to a circadian rhythm) through twelve paired (left and right) channels. These channels are often also called meridians. The correct balance and harmony of Yin and Yang within the body and the even and regular circulation of energy (*Qi*) within the channels maintain perfect health. The converse applies: an imbalance of Yin and Yang and an interrupted flow of energy will imply disease. Thus disease is considered to be more Yin or more Yang, relative to the state of health. This can occur as a relative deficiency of one or the other, or as a relative excess of one or the other. Each would produce an apparent excess of one over the other. There is unlikely to be an absolute deficiency or excess, since life could not then be supported.

Qi itself has many facets. To the Chinese, who did not distinguish between matter and energy, *Qi* could be described as *matter on the verge of becoming energy* or

Table 65.1 The paired (*tsang/fu*) organs, relating to Yin and Yang.

| Yin (<i>tsang</i> organ, ventrally/medially-routed meridian) | Yang (<i>fu</i> organ, dorsally/laterally-routed meridian) |
|---|---|
| Heart | Small intestine |
| Kidney | Bladder |
| Pericardium | Triple heater |
| Liver | Gall bladder |
| Lung | Large intestine |
| Spleen/pancreas | Stomach |

energy on the point of materializing. They did not trouble to define, merely to observe its function. It pervades the entire universe, so is not simply *life energy*. The *Qi* of the body is called *normal Qi* or *upright Qi*. This is derived in equal parts from each parent, as the *original Qi* or *conceptual Qi*. It is nourished and replenished throughout life by *grain Qi* and *air Qi*, which are combined with each other and with *normal Qi*, to permeate the entire body.

Chinese theory also gives the ultimate power of life to the kidneys, in that the kidneys store the *Jing*. This is an undifferentiated 'substance', which is most closely associated with life itself. It contains the potential for birth, maturation, decay and death. It supplies the potential for differentiation into Yin and Yang, in other words, the capability of life. Since all organs require *Jing*, the kidney bestows the gift of life on each organ. Since *Jing* also controls conception, future life is gifted by the kidneys. The anatomical relationship of the gonads to the kidney would have escaped the ancient Chinese. *Jing* gradually diminishes in quality and quantity with time, so ageing is controlled in this way. Death is inevitable when there is not enough *Jing* to maintain life. It is said '*The kidneys are the root of life, the residence of Yin and Yang, the channel of life and death*'. This makes a lot of sense in Western terms, since the kidneys, once damaged, cannot regenerate.

The channels are related to organ function, thus the twelve meridians, or channels, have names indicating these relationships. The organs, to which they relate, are each said to be either Yin or Yang in nature and, needless to say, there are six Yin and six Yang organs/channels (Table 65.1) in order to maintain balance. The Yin organs are the solid '*Tsang*' organs, the Yang organs are the hollow or '*Fu*' organs. Each *Tsang* organ is related to a *Fu* organ, e.g. (respectively) kidney is related to bladder.

The energy (*Qi*) dwells in any single channel for two hours and the flow pattern follows a '-Yin-Yang-Yang-Yin-' cycle, repeated three times. We are then able to draw a flow chart, built from the preceding lists

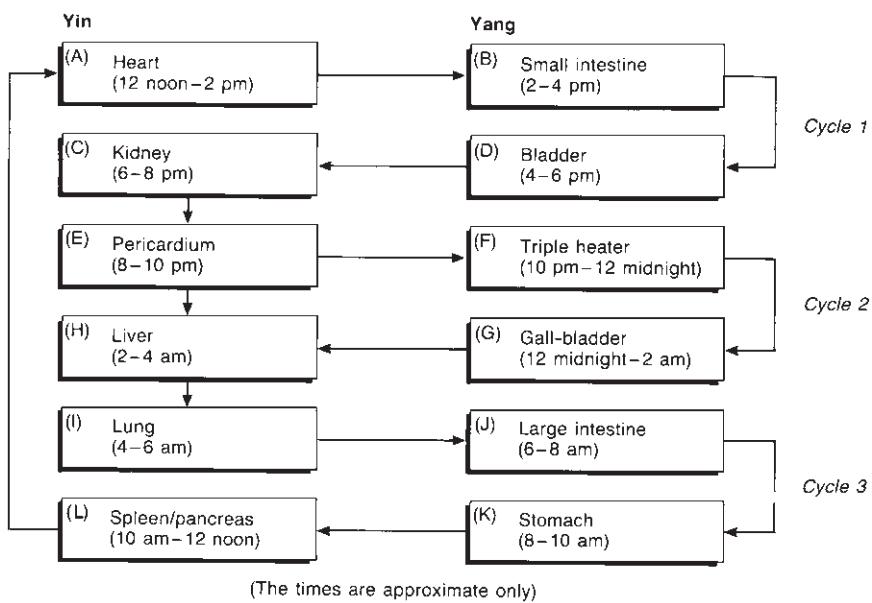

Fig. 65.3 An energy flow chart for the 'Yin-Yang-Yang-Yin' cycle.

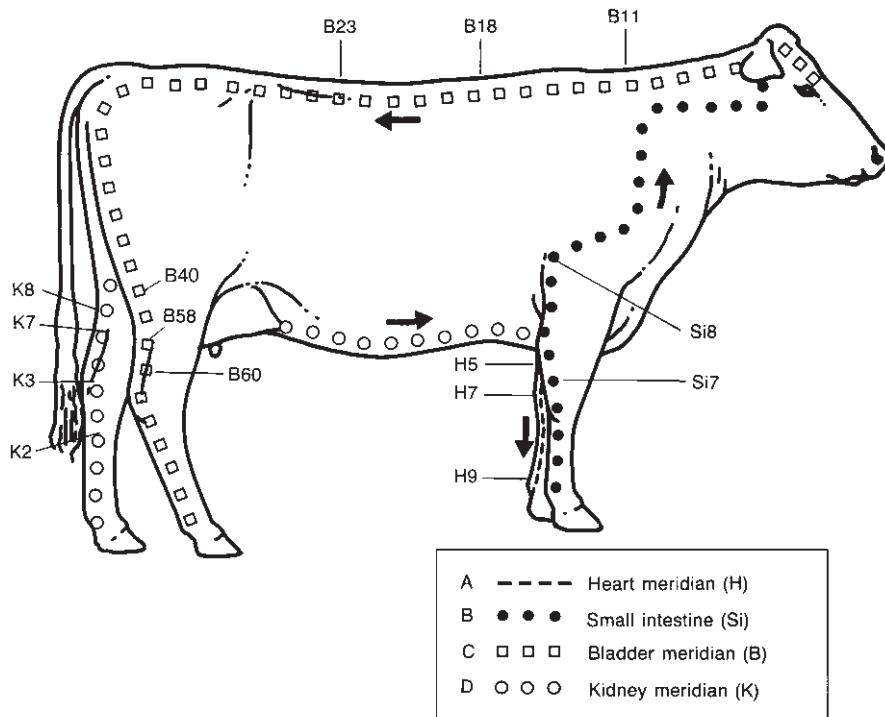

Fig. 65.4 Cycle 1 of the energy flow chart for -Yin-Yang-Yang-Yin-.

(Fig. 65.3). On the body, these are represented in diagrammatic and simplified form in Figs 65.4–65.7. Routes of meridians, and point locations thereupon, are approximate guides only. Accurate point location requires reference to more substantial works; the titles of important reference works can be found in the Further reading section. Owing to the loss of digits on the bovine limb (compared with the human five per limb) the distal sections of some meridians are open to

interpretation (Fig. 65.8) and different authors disagree in detail. Experienced practitioners, nonetheless, are able to develop their own working models and to achieve the desired results.

Having read that the channels are each related to an organ, the reader is probably wondering about the triple heater. This 'organ' represents thorax, abdomen and lower abdomen (pelvic), and therefore takes in the functions of respiration, digestion and the urogenital

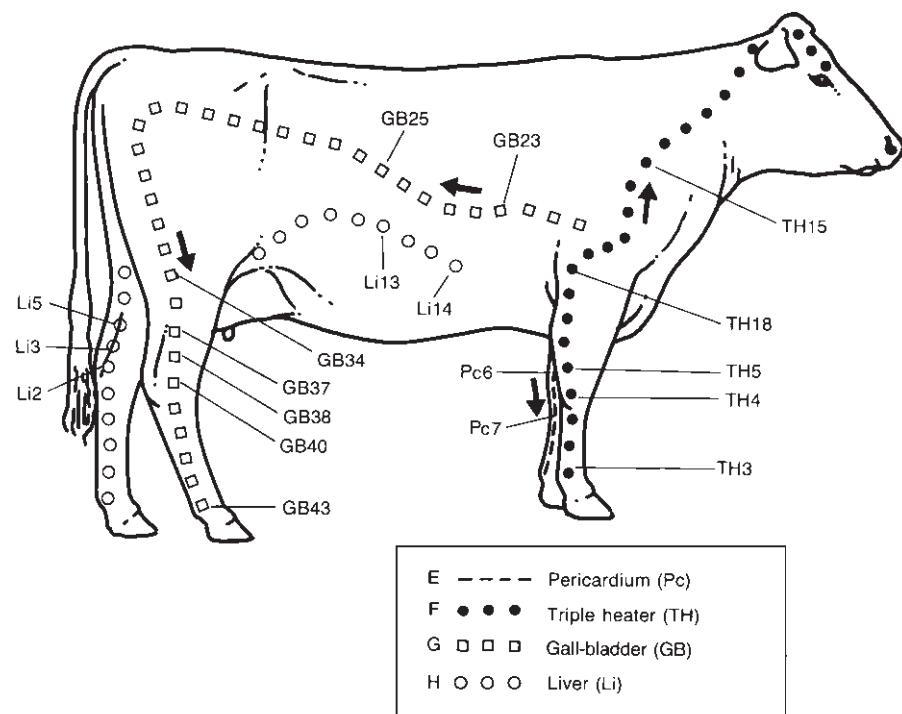

Fig. 65.5 Cycle 2 of the energy flow chart for -Yin-Yang-Yang-Yin-.

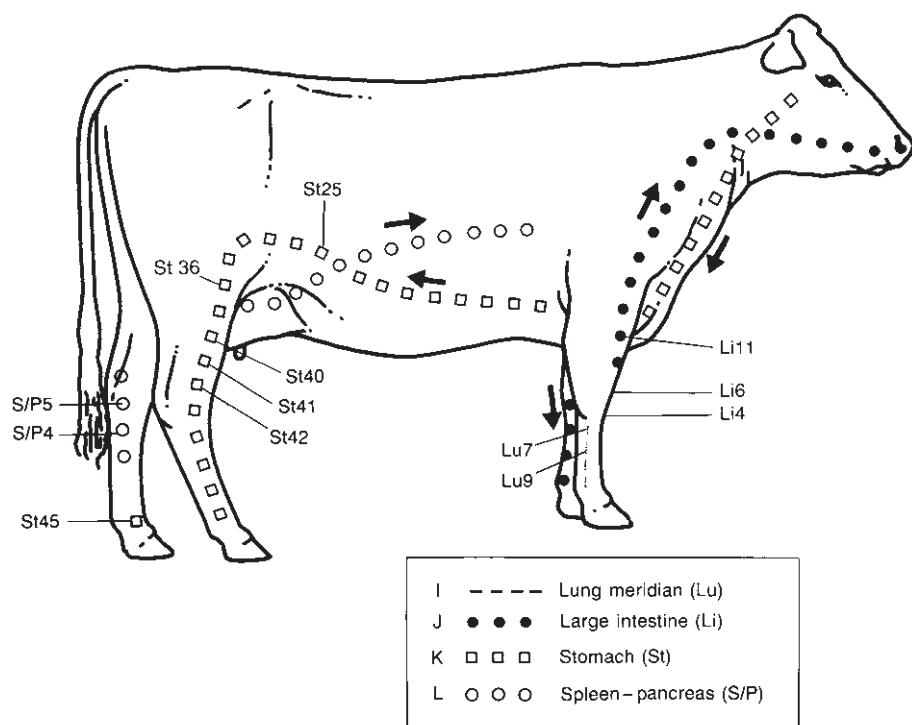

Fig. 65.6 Cycle 3 of the energy flow chart for -Yin-Yang-Yang-Yin-.

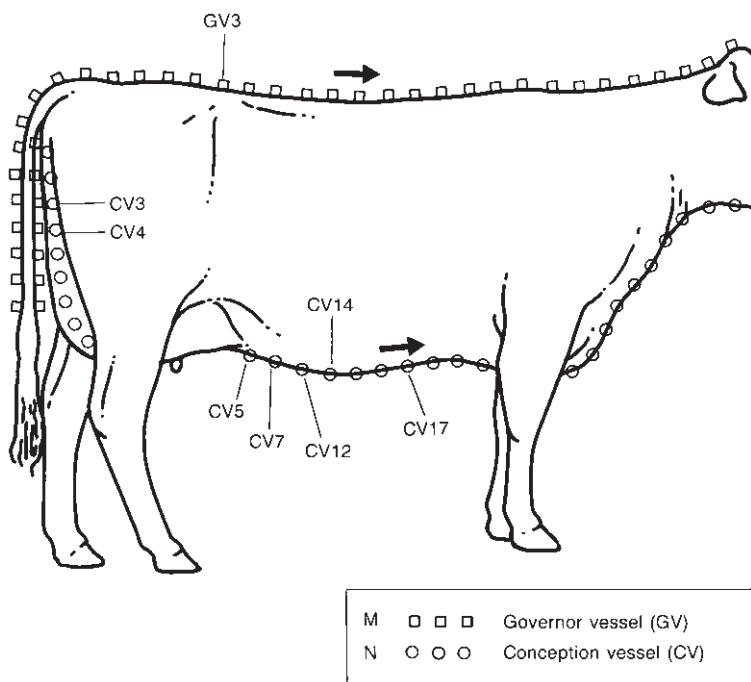

Fig. 65.7 The two extraordinary (unpaired) meridians (Governor vessel [yang] and Conception vessel [yin]).

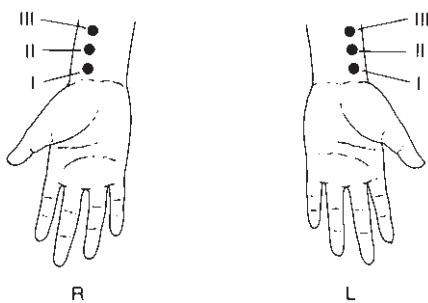

Fig. 65.8 Pulse positions on the human wrists. Each position has a deep and superficial pulse.

system. It can be considered also as the seat of humoral control and interconnections.

There are two other (extraordinary) vessels or meridians, which are of similar importance to the six pairs and these are the conception vessel and the governor vessel. These follow, respectively, the ventral and dorsal mid-lines. The energy flows from anus to mouth in both and therefore the vessels are not 'paired'. They differ from the other meridians in that they also lack special tonification and sedation points, etc. as described later for the other meridians, and are not an integral part of the circadian energy circulation system. The governor vessel is dorsal and therefore Yang, the conception vessel ventral and therefore Yin (see Fig. 65.7).

The circulation of the energy (*Qi*) is allowed to occur through the 12, seemingly-disconnected channels, with apparent open circuits at each end, by means of the

deep internal connections, creating continuity proximally and of the exterior 'secondary vessels', creating continuity at the extremities.

The opposing forces of Yin and Yang are constantly at work in the body and are supposed to be in total balance, flowing evenly through the 'channels' that the meridians represent. In fact it is better to picture a constant strife between Yin and Yang with alternating conquest and defeat but, in a state of health, with a balanced result throughout the 'championship'. It is important to note that the 'correct' balance for each individual is unique, and that a female will tend more towards Yin and a male more towards Yang.

Any stimulus that leads to an uneven 'contest', with one or other side in the ascendancy on balance, will lead to disease. The Chinese called such adverse forces the 'pernicious influences'. These are wind, cold, heat/fire, dampness, dryness and summer heat. They also believed disease could originate under the influence of emotions (joy, anger, sadness, grief, pensiveness, fear and fright), way of life (departure from Tao - 'the way'), diet, sexual activity and physical activity. Further factors were recognized, that did not fit into these categories, e.g. burns, bites, stings, trauma, etc.

Diagnosis

Diagnosis of the nature of disorders in the body in terms of the information given in the preceding pages was by pulse diagnosis in the human wrist (Fig. 65.8 and Table 65.4). Kothbauer and Meng (1983) give a method

using the midline caudal artery in the bovine (Fig. 65.9), but this is sadly a long way from the complex and refined method developed for the human (through no fault of the authors, more of anatomy and practicality). General quality of pulse can still be determined and can be very helpful. Overall impressions only can be gained by this method.

Inference can be made from the signs of disease, displayed by the body, as to the nature of pernicious influence and which meridians or organs are disturbed by this influence (Kaptchuk, 1983). This requires a great deal of further study, if the reader is to develop these skills and it is too large a subject for this small treatise. Help can, nonetheless, be derived from the following charts of relationships, which provide information on the possible route of pathology, once the disease process has gained entrance (Table 65.2).

An important and functional model for the ancient Chinese was the concept of the 'five elements'. In this abstraction there are cycles of creation and destruction/control, which can be of great help in establishing

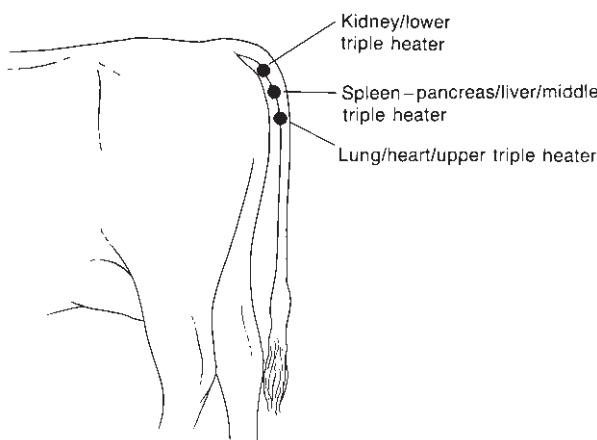

Fig. 65.9 Pulse diagnosis in the bovine (according to Kothbauer & Meng, 1983).

Table 65.2 Pernicious influences on disease.

| Yang | Yang | | Yin | Yin |
|----------------|--------------|------------------------------|--------------|------------------|
| Season | Spring | Summer | Late summer | Autumn |
| Climate | Wind | Heat | Dampness | Dryness |
| Direction | East | South | Centre | West |
| Organs (Tsang) | Liver | Heart/triple heater | Spleen | Lungs |
| Organs (Fu) | Gall-bladder | Small intestines/pericardium | Stomach | Large intestines |
| Orifices | Eyes | Ears | Nose | Mouth |
| Tissues | Ligaments | Arteries | Muscles | Skin and hair |
| Elements | Wood | Fire | Earth | Metal |
| Odour | Rancid | Scorched | Fragrant | Rotten |
| Emotions | Anger | Joy | Sympathy | Grief |
| Fluids | Tears | Perspiration | Saliva/mucus | (Mucus) |

patterns of pathology and in diagnosis. The five element theory is not respected by all practitioners of acupuncture, but holds the key to many important deductions about health and disease for those who uphold its tenets.

Water destroys Fire but creates Wood

Wood destroys Earth but creates Fire

Fire destroys Metal but creates Earth

Earth destroys Water but creates Metal

Metal destroys Wood but creates Water

The (*tsang/fu*) organs and the emotions are related to these elements. Thus, for example:

| | | | | |
|--|---|---------------|---|-------|
| Liver/gall bladder | - | Anger | - | Wood |
| Heart/small intestine, pericardium/triple heater | - | Joy | - | Fire |
| Spleen (+pancreas)/ stomach | - | Pensiveness | - | Earth |
| Lungs/large intestine | - | Sadness/grief | - | Metal |
| Kidneys/bladder | - | Fear/fright | - | Water |

In addition, the organs and functions of the body are related to each other, for example:

The kidneys are connected with (control) the bones and rule over the spleen

The heart is connected with (controls) the pulse and rules over the kidneys

The lungs are connected with (control) the skin and rule over the heart

The liver is connected with (controls) the muscles and rules over the lungs

The liver nourishes the muscles and the muscles strengthen the heart

The heart nourishes the blood and the blood strengthens the spleen, etc.

These connections are not so far-fetched, even in modern Western terms.

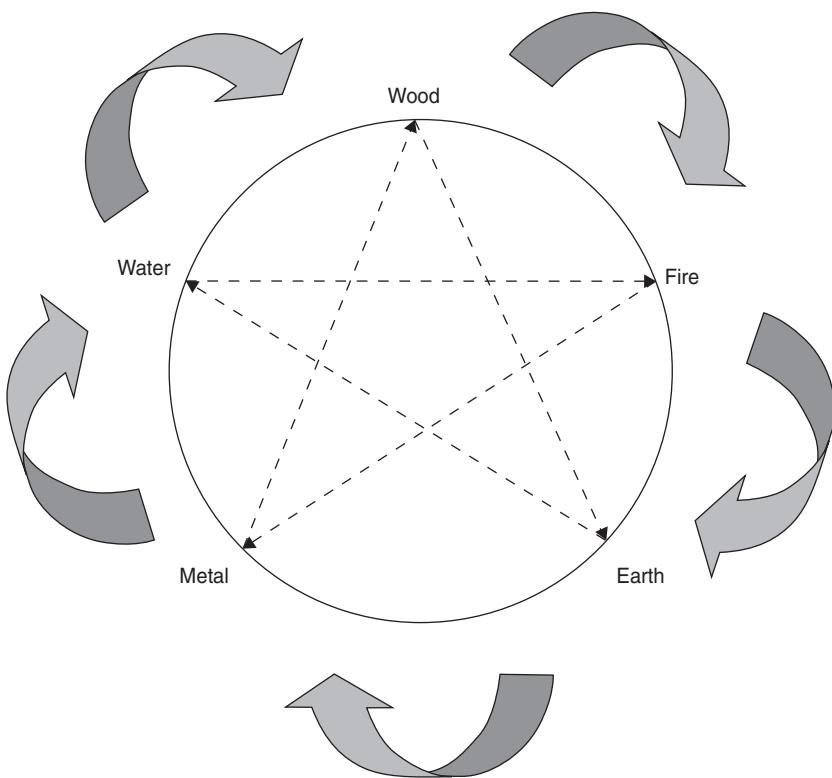

Fig 65.10 The creation (*sheng*) and destruction or control (*ko*) cycles of five element theory. The large arrows denote creation, dashed lines denote destruction/control.

What has been described, although briefly and therefore not to do it full justice, is an attempt on the part of the ancients to explain the rhythm and dynamics of life and disease, albeit often by metaphor, which can be off-putting to the Western mind. The explanation does seem to embrace the reality of the integrity of the whole body and its interconnectedness, both in anatomy and function, and its relationship to the outside world. Disease does not come in tidy parcels, affecting only one part of the body in a single way, but in complex patterns of whole body dysfunction. The philosophy behind traditional Chinese medicine embraces this essential concept very satisfactorily and provides a means of arriving at a 'diagnosis'.

From the platform of the diagnosis, in the traditional Chinese sense, a treatment rationale or treatment principle can then be devised. This will be based on the need to balance Yin and Yang, to restore harmonious flow of *Qi*, to counteract the *pernicious influences* and to support the stressed *organs*. What may be surprising, to the uninitiated, is that this allegorical methodology can provide the clinician with a valid working model for effective diagnosis and successful therapy.

Treatment (Plates 65.1 and 65.2)

The acupuncture prescription for the patient should be devised from the treatment principle, at which the pre-

scriber has arrived by following the foregoing paragraphs. Treatment of the body in traditional Chinese medicine, whether by diet, herbs, moxibustion or needles, attempts to restore the balance in the constant conflict between Yin and Yang. This treatise really only deals with treatment by insertion of needles.

Moxibustion is the application of heat to specific points of the body to supply heat energy (yang) to the system. Usually, *artemisia vulgaris* herb is used for this purpose, as a 'wool'. Heat is applied directly to the area or a few millimetres above it. Needles can also be inserted at the point and heated by burning moxa. It is not a practical method for the beginner, for general farm use. It is mentioned briefly here, merely to put it in context and to introduce the reader to the concept, which may otherwise confuse when it is encountered in other texts.

There are many different categories of points that can be utilized in acupuncture prescriptions, in an attempt to restore the desired balance. The major ones are listed below.

The points

Acupuncture points are not anatomically represented, although there are histological and physiological properties which are peculiar to them. A good account of this phenomenon is given by Kothbauer and Meng

(1983). Their exact positions are described in relation to anatomical landmarks, measurements being expressed in terms of units which relate to the dimensions of specific parts of the body. The measurement units are:

Tsun or *cun*: this is the *acupuncture inch*. In human acupuncture it is traditionally equal to the length of the second phalanx of digit 3 of the human hand.

Fen: One tenth of the above.

Finger breadth, thumb width, forearm length, pubis-nates, shin length, etc. are all as they state, and apply to human measurement, but sources vary as to their relationship to the *cun*. It is usually accepted that a thumb width is 1 *cun*, two finger breadths are 1.5 *cun*, four finger breadths are 3 *cun*, cubital crease to carpal crease is 12 *cun*, etc.

It may be thought strange to have this unique form of measurement, but it allows for measurement proportional to the size of each individual patient. In horses, some texts refer to the 'inch' as the width of the 16th rib, at the level of the tuber coxae. The provision for measurement in animals is not good, so sources can refer to precise anatomical descriptions, rather than measurement units.

The point types

Locus-Dolendi needling, using Trigger (ah-shi) points is the use of points of local pain, which are directly related to the site of injury or illness. The effect is not very long-lasting but provides relief from pain in local conditions. It requires little knowledge on the part of the prescriber, but should probably be reserved for localised locomotor pain or injury.

Master points relate to individual organs or tissues and can be used regardless of the nature of the pathology or dysfunction which that target suffers. These master points may be sensitive to stimulus when there is a dysfunction or injury in the influenced organ/tissue but are unreliable diagnostically, unless taken as part of the wider picture. Effects of using these points alone, as a method of prescribing, will lead to disappointment. There is no deep and lasting influence on disease if the prescriber sticks to this elementary process. The master point of the musculature, for instance, is gall bladder 34.

Symptomatic or influential points have an influence over certain specific functions. For instance, bladder 31 influences female hormonal function very strongly and gall bladder 39 influences the function of marrow. They can be used in a prescription when such problems predominate (Plate 65.1). The action of these points is usually fairly narrow so, again, prescriptions based on these

alone are unlikely to be far-reaching. Like master points, the symptomatic points may also be used in reverse as diagnostic tools, the reliability being questionable unless they are used as part of the whole picture.

Pilot points are used properly to redistribute or balance the Yin-Yang conflict. Main points are the *tonification points*, which increase energy in an energy deficient meridian (gold needles are often used) and *sedation points* decrease energy in overactive meridians (silver needles are often used). Each meridian has one of each of these.

The source (yuan) point on each meridian acts as an adjuvant to one or other of the two above-mentioned points. The metal used for needling is selected according to which function it is wished to augment.

The passage or connecting (luo) points, situated on each meridian, will help to 'shunt' energy from the meridian in question to its partner. Energy usually flows 'down-hill' (i.e. from 'mother' to 'son' or from the meridian earlier in the cycle to its paired neighbour).

The alarm (mu) points may or may not lie on the meridian to which they relate but may be used for diagnosis or treatment if sensitive. A sensitive point indicates stress in its related organ.

The association (shu) points, lying on the bladder meridian, are also of value diagnostically or therapeutically and relate to specific organs and meridians. For example, the association point for the spleen/pancreas is bladder 20, for the heart it is bladder 15 and for the stomach it is bladder 21.

It is helpful to list some useful points for earlier selection by the beginner; see Table 65.3 and refer to Figs 65.3–65.7.

Table 65.3 is clearly by no means comprehensive (as can be seen from the numeration), but represents a useful reference list for the main functional points. For more comprehensive point descriptions the reader is referred to much fuller works on acupuncture therapy. Their location, as shown on Figs 65.4–65.7, is a synthesis of information from personal experience and the work of Klide and Kung (1977), Lewith (1982), Kothbauer and Meng (1983), Bishchko (1983), Gilchrist (1984) and Janssens (1984). The nomenclature of the points is in accordance with the IVAS standard, in order to prevent confusion and to enable the reader to compare with all IVAS-derived texts. When reading other texts, many different conventions of nomenclature and classification will be encountered. The reader should not be confused by this, but should develop the

Table 65.3 Useful points.

| II | Stomach | Spleen/pancreas | Liver | Gall bladder |
| I | Triple heater (Yang) | Pericardium (Yin) | Kidney (Yin) | Bladder (Yang) |

ability to ‘translate’ these into the ‘standard’. In texts on TCM, another potential confusion arises from the use of the various conventions of westernization or romanization of the Chinese language (e.g. *Pinyin* or *Wade-Giles*). Again, it is important not to be daunted by this, but to compare texts in order to find the correlations.

Use of these points

The meridians are interconnected energetically in various ‘rules’ of therapy. Treatment strategies may be based on these relationships. Again the Chinese show their proclivity towards metaphorical description. The first relationship is based upon the human system of pulse diagnosis and relates to the position of pulse-taking in the human wrist (Table 65.4; see also Fig. 65.8).

- (1) The ‘husband–wife’ rule relates meridians sharing the same positions on either wrist. Tonifying one will sedate its partner and vice versa. They oppose each other.
- (2) The ‘mother–son’ rule relates to the sequence of the meridians in the circadian rhythm. A meridian preceding that in question is its mother and that succeeding it is its son. It is logical to assume that the mother is ready to give energy, the son to receive it. Tonifying the meridian in question *and* its mother will produce extra effects. Similarly, sedating both the meridian in question and its son will increase the effects of sedation. Passage points may be used instead when the meridians in question are partners.
- (3) The ‘midday–midnight’ rule relates meridians most active in a similar time period, am and pm. One will be Yin and one Yang, e.g. lung (Yin), 4 am to 6 am., bladder (Yang), 4 pm to 6 pm. Tonifying a meridian in its active time will sedate its opposite number.

These three rules should always be borne in mind because, even if it is not the intention of the prescriber,

the rule will operate upon stimulation of the relevant points with appropriate needles. Using the three rules together can achieve a rapid restoration of harmony within the body. The system of acupuncture thus used is not only complete but also quite simple to apply, providing infinite combinations of therapy. It is sad that pulse diagnosis is not so refined in animals, but the general quality of pulse can still be ascertained. The relationships of the meridians are still valid and so too is the correspondence of disease patterns with the effects from the pernicious influences and other origins of disharmony. Conclusions about meridian malfunction are inferred from the disease patterns displayed by the patient and by the demonstrable point sensitivities.

Technique of needling and treatment

Steel, gold or silver needles are selected according to the effect required. Alternatively, the different effects can be achieved by varying the needling technique or by varying the duration of insertion. The needles should be inserted confidently into the skin, as near to the centre of the point as possible. Depth of insertion is generally up to 1 cm, but varies from point to point. During a treatment the body ‘reacts’ with the needles in a way that has not been defined physiologically or anatomically. During this time, the needles are firmly held by the tissues. When a treatment is over, perhaps between 5 and 20 minutes later, the needles may be removed with ease.

After treatment there may be a ‘slump’ in the patient’s apparent energy for the next 24 hours. The author has observed this less in cattle than in other species. Treatments may be repeated at intervals of several days to several weeks, but a useful guide for an initial course of therapy is a 3 to 14-day interval for three or four treatments. If no improvement is noted in this period, it is possibly a sign of a poor prognosis. Most of the author’s successful cases have shown definite improvement within the initial three treatments. After a good initial result, in chronic conditions, treatment

may need repeating at longer intervals (say six monthly, but the patient's condition should determine this).

Up until recently, it has been very difficult to obtain meaningful training in veterinary acupuncture. At the time of writing, however, courses are available run by the combined efforts of the International Veterinary Acupuncture Society (IVAS), the Association of British Veterinary Acupuncturists (ABVA) and Exeter University.

Homoeopathy and acupuncture combined

Since both homoeopathy and acupuncture are addressing the same entity or challenge, the living and interconnected body, in disease, it stands to reason that they must overlap if they are truly effective. The different rationales and strategies merely express the fact that they represent two different windows on the same room. It is possible to combine the two therapies, only if the rationale for selection of treatments is harmonized. Failure to do this will produce disharmony and will inevitably be counterproductive. If in doubt, the best advice is not to attempt it.

It is beyond the scope of this text to go into detail on this facet of therapy, but there is a reference to further study in the Further reading section below (Day, 1993).

Herbal medicine

The use of plants and plant material in medicine is as old as human existence. Those plants which form the basis of herbal medicine are called medicinal herbs, but probably represent only a fraction of the plants which could prove to be of benefit, if researched. They are classified according to origin (whether ayurvedic, traditional Chinese, Western, Australasian, etc.), or according to effect. This latter would be a different classification system, depending upon the culture which devises it. Broadly speaking, in the West, we classify according to the perceived pharmacological effect.

A large proportion of modern conventional drugs owe their existence or their origins to herbal medicine. The rationale of the use of herbs is to exploit their primary effect, rather similarly to the rationale of modern drug medicine and unlike homeopathy, which exploits the secondary effect (the body's reaction), although it uses many of the same plants that are used in herbal medicine. Although there are similarities between drug medicine and herbal medicine, the tradition of herbal medicine is very holistic in the truest sense. The more modern fashion for establishing a supposed active ingredient of a medicinal herb, purifying it

and using it in isolation is not at all in accordance with the holistic principles of herbal medicine. The obvious danger of this practice, leading to potential side-effects, is that the synergistic effect of the other constituents of the plant is lost.

Western herbs are classified according to their perceived actions, as per the following examples.

Alterative, anodyne, anthelmintic, antibacterial, antacarrhal, antiemetic, anti-inflammatory, antifungal, antilithic, antispasmodic, aperient/laxative, aromatic, astringent, bitter, cardiac, carminative, cathartic/purgative, cholagogue and anticholagogue, demulcent, diaphoretic, diuretic, ecbolic, emetic, emollient, expectorant, febrifuge, galactagogue, hepatic, hypnotic, nervine, rubefacient, sedative, sialogogue, soporific, stimulant, styptic, tonic, vesicant and vulnerary.

Chinese herbs are classified according to their ability to modify the course of action of the pernicious influences. The usual oriental pictorial language prevails. Examples, with an approximate Western equivalent where appropriate, are:

Release externally (diaphoretic?), purge down (purgative?), clear heat, transform moisture (damp), facilitate urine (diuretic?), expel wind-damp, dispel cold, etc.

Because material doses of herbs are utilized, there is the inevitability of tissue or milk residues. Some of these will be totally harmless or even beneficial to the consumer. Some may be harmful. Because the residue side of the use of herbs is so poorly researched and so beyond our control, it is wiser not to use herbs in food-producing animals unless absolutely sure of the consequences. A fuller account of veterinary herbal medicine is to be found in the Further reading section (Day, 1998).

Essential oils

The use of essential oils in medicine (aromatherapy) is also a very ancient tradition around the world. Further reading is recommended (Grosjean, 1994). The application and rationale are not dissimilar to those for herbal medicine. The active principles are distilled aromatic compounds derived from plants and represent very powerful and effective medicines. The classification of the oils is as for Western herbs.

Since the same caveats apply to aromatherapy for food-producing cattle, as have been detailed for herbs, with the additional worry of powerful taints of meat or milk, the use of aromatherapy in production cattle is not advised.

Other therapies

Two other therapies lend themselves to specialized use in cattle and bring with them no risk of meat or milk residues, they are *Schüssler's Tissue Salts* and *Bach's Flower Remedies*.

Tissue Salts: In the latter part of the nineteenth century, Schüssler, who was a homoeopath, devised a system of medicine based upon the mineral nutrition of cells. His 12 mineral remedies were prepared to the sixth centesimal potency, according to homoeopathic methodology. The 12 remedies are:

Calcarea fluorata, calcarea phosphorica, calcarea sulphurica, ferrum phosphoricum, kali muriaticum, kali phosphoricum, kali sulphuricum, magnesia phosphorica, natrum muriaticum, natrum phosphoricum, natrum sulphuricum, silica.

These remedies, according to the founder, are able to correct cellular chemistry in order to achieve health (Goodwin, 1980). The rationale appears to work in part, and the practice persists in modern times. The author believes that these remedies act as facilitators, regulators or modulators of those cellular processes which involve those minerals. A more detailed description of this action of potentized substances is found in the section on homoeopathy, presented earlier in the chapter. Knowing what we now know about enzymes and their cofactors, this is easily comprehensible in modern terms.

In view of modern knowledge and understanding, and recognizing the adverse effect of artificial nitrogenous fertilizers on the soil mineral content in modern times, it is logical to extend the range of 'tissue salts' to include *chromium, cobalt, copper, iodine, manganese, selenium, zinc*, etc. The potential for helping cattle back to balance, in terms of mineral metabolism, particularly in those situations of relative or marginal insufficiency as can be encountered on farms, is an interesting development. No one could pretend that such dilutions amount to material supplementation, but the aid to absorption and metabolism, which they can offer, can amount to a significant benefit. The use of these potentized salts, in place of some of the mineral supplementation now required by most farm livestock, should be particularly attractive in the case of organic farm units, where outside inputs need to be minimized (Day, pers. comm.).

Bach Flowers: In the 1930s, another homoeopath, Edward Bach, devised a system of medicine which would treat disease more via the psychology and personality of the patient than via the obvious physical signs. This system can be applied well to animals, but it

is best used on those animals with which we develop close emotional ties. This is because we are then better able to discern the necessary prescribing clues. There is not much application in farmed cattle, for this reason. Further reading is recommended, for a deeper understanding (Chancellor, 1971; Ball & Howard, 1999).

Bach's 39 remedies include *agrimony, beech, centaury, clematis, elm, holly, oak, olive, rock rose, scleranthus, vine and willow*. The system is included in this chapter, esoteric though it may seem, for two reasons. It introduces the reader to the medical modality and it presents the opportunity to use of one of Bach's medicines, which can be of great value in cattle medicine: *Rescue Remedy*.

Rescue Remedy is composed of Bach's *cherry plum, clematis, impatiens, rock rose* and *star of bethlehem*. It is of great virtue in the treatment of stress, fear and shock situations, and can be used just as well in cattle as in other species. Situations demanding its use are post surgical trauma, disbudding, herding of unhandled cattle, injuries, entrapments or 'casting', bereavement or distress on handling for procedures such as foot trimming. It can be given by mouth or to a group via the drinking water and can represent a very positive welfare input.

Conclusion

It is to be hoped that the reader, having studied this chapter or one or other part of it, will have experienced adequate stimulation to take a deeper look into alternative medicine (see Further reading section). It is also hoped that he or she will have gleaned sufficient information to take the first steps in applying one or both of the main therapies described therein. What should be clear is that either of those systems of medicine is a very large and complex subject. Should the reader wish to go further, it must be said that a great deal of motivation and dedication will be required. If this chapter has provided the motivation, that is good. If not, then it should at least serve to dispel some of the mists of ignorance and suspicion that enshroud the art and science of both homoeopathy and acupuncture. This should allow for more productive cooperation between conventional veterinarians and those who have diverged into 'alternative medicine'. Those who choose to apply themselves to diligent study and to professional application of these methods will be able to enjoy a life full of surprises and rewards commensurate with effort, but will not have chosen an easy option.

Introduction

The following chapter deals with those surgical situations which most commonly arise in dairy practice. There are always several ways to achieve the same end and there are probably as many variations in the techniques described here as there are surgeons. The methods detailed in this account are only one variation. However, they are based on many years of experience in practice and in the more rarified environment of the university teaching hospital and every attempt has been made to keep the contents practicable and pragmatic. Although each individual technique is dealt with comprehensively, there are some general points which relate to them all and are most sensibly made at the outset.

Anaesthesia

Most procedures described here will be done under local anaesthesia or regional ‘blocks’. The author’s guide to success with these is based on several points. Firstly, for most ‘blocks’ in cattle use 3 per cent lignocaine with adrenaline. The rate of development of the block is faster and it persists for much longer than when a 2 per cent solution is used. However, use the latter alone without adrenaline for subcutaneous infiltration as occasionally the vasoconstrictive effects of adrenaline can lead to local skin ischaemia, necrosis and death.

Secondly, use plenty of anaesthetic solution. It is cheap and the added expense of using 50 per cent more is easily outweighed by better results. For example, most descriptions of paravertebral anaesthesia advocate 15–20ml spread between the upper and lower branches of each nerve. Increasing the amount to 25 or 30ml greatly increases the percentage of successful blocks, especially in relatively inexperienced hands. Thirdly, despite the refinement of the techniques nerve blocks are still relatively imprecise methods of inducing analgesia. To offset this, spread the anaesthetic solution more widely to create a larger block of saturated tissue and to increase the chances of affecting the target nerve. Finally, do not ‘line-block’ at the site of the incision if at all possible as this creates a sodden, jelly-like tissue which is difficult to dissect and which has reduced initial healing properties. Use either a regional block or a field block.

Preparation of the surgical site

Whenever we operate on large or small animals we have to accept that we cannot create a sterile field. At best we can hope to make it ‘surgically clean’ and reduce bacterial contamination to a level where it can effectively be controlled by antibiotics and body defences. The weakest link in sterility is always the patient itself and this is where most attention should be directed. Physical removal of hair and dirt is important; use proper clippers whenever possible and clip a big enough area to give a good margin around the incision site. Initially wash the area with copious amounts of water and antibacterial soap, although elbow grease is probably more important than antisepsis at this stage. Finish with an antibacterial agent which will persist on the skin; although pure surgical or methylated spirits poured onto the skin is comforting it does not, in fact, achieve very much.

Drape as extensively as possible. For abdominal surgery prepare several large drapes that will hang over the animal’s back, each with holes appropriate for a certain technique. Only two variations are really needed, one with two holes for abomasal and rumen

approaches and one for caesarean sections. The synthetic material used for tent making is now widely available and is ideal, being impervious to fluids, mouldable and capable of being sterilized. The use of drapes makes the maintenance of a clean site so much easier and imparts a professional air to the operation.

The choice of suitable dress for the surgeon is difficult. Abdominal surgery requires extensive intra-abdominal palpation or manipulation. A long-sleeved gown is inconvenient in that the material abrades the wound edges and rapidly becomes sodden and uncomfortable; in a rumenotomy it also becomes severely contaminated. For the same reasons the use of gloves for these procedures is often impractical too. A good compromise which should be encouraged is a short-sleeved gown worn over a disposable plastic apron. Even if only freshly laundered and not sterilized they are still infinitely preferable to the calving gowns which many practitioners use. If these are the same garments which are used for routine obstetrics they will inevitably be grossly contaminated and will impregnate the wound edges with a good variety of pathogenic organisms.

Having eschewed gloves for abdominal surgery, there are some occasions when they should be used. The hands of a dairy veterinary surgeon are, of necessity, frequently in contact with faecal or septic material and even with a full surgical scrub they are unlikely ever to be surgically clean. For those surgeries where maximum cleanliness is essential, e.g. in an umbilical hernia repair where non-absorbable sutures are to be buried, the practitioner should overcome his prejudices, accept the limitations and wear gloves!

Surgery

The old adage ‘time is trauma’ still holds true; for large animal clinicians it could be supplemented by ‘time is infection’, ‘time is tiredness’ and practically ‘time is money’. An inexperienced surgeon cannot be expected to be rapid but there are some things which help. Most novices spend more time nerving themselves for the next action than actually doing it and then more time contemplating what they have done. If these delays are omitted then the duration of a procedure can be sharply reduced without spending less time on the actual surgery. In addition, if gratuitous and unnecessary tissue handling is abolished, tissue trauma will be greatly reduced to the benefit of healing.

Another area where a great deal of time can be wasted is that of haemostasis. The concept of a blood-free field is dear to the heart of many surgical teachers and newcomers often devote a great deal of time and effort to stopping every bleeder.

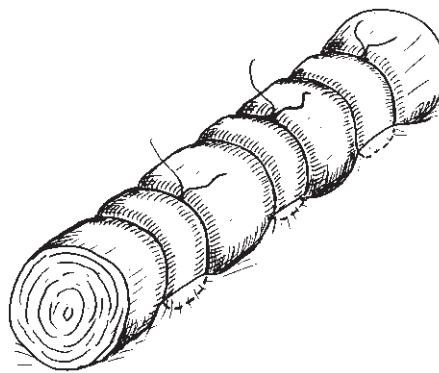

Fig. 66.1 A Stent bandage. The cylinder is made of rolled up gauze swabs; it should be sutured firmly, tenting the surrounding skin at the suture attachment points. It can be left in place for about 48 hours, although it must be removed earlier if it becomes sodden. It protects the wound and exerts inward pressure which prevents fluid accumulation.

Cows can afford to lose a great deal of blood before showing any ill-effects, but even if no haemostasis is done they will never lose more than a few hundred millilitres during a routine procedure. Consequently only those vessels which are a persistent nuisance should have time spent on them. The others will dry up very rapidly. The most efficient method of dealing with them is to clamp them in the tip of a pair of artery forceps then to twist them about eight to ten revolutions. Although this advice may sound heretical to some, it is sound, and surgery which is done rapidly but deftly without unnecessary frills will result in less tissue trauma, less contamination from the environment and substantially better healing.

For suturing, plain catgut is entirely adequate and cheap. Despite purist objections the variety obtainable in long lengths in plastic cassettes is perfectly acceptable. In its thickest size it is suitable for closing even the largest abdominal wounds and should there be infection, its rapid lysis is beneficial in that the sutures do not form a persistent nidus of sepsis. The suture wound can be protected effectively by means of a stent bandage (Fig. 66.1). This will help absorb wound seepage following umbilical hernia repair or eye enucleation, and will effectively reduce post-operative swelling.

Rumenotomy (see p. 837)

The indications for rumenotomy are: confirmation and treatment of traumatic reticulitis ('wire', 'hardware disease') and examination of the cardia, oesophageal groove, reticulo-omasal orifice, reticulum and rumen. The abdominal wall incision is also suitably placed for exploration of the left and caudal abdominal cavity.

Anaesthesia

This procedure must be done with the animal standing. Fractious patients must not be given too much sedation otherwise there is a risk of them going down during surgery with disastrous results. In most cases, local anaesthesia of T13, L1 and L2 spinal nerves using the paravertebral technique is satisfactory without need for sedatives.

Technique

No specialized instrumentation is needed for the technique described here. However, the surgeon should wear a short sleeved gown to avoid gross contamination of the sleeves and, for exploration of the rumen, gloves should not be worn as they promptly fill up with rumen liquor! Surgeons with short arms must recognize that they may not be able to reach the reticulum in a large cow. Under these circumstances there is a definite need for a long-armed assistant.

The site for the incision is high up on the left flank just caudal to the last rib (Fig. 66.2). This is so that the rumen can be entered above the likely level of ingesta and to minimize the distance from the incision to the reticulum. Following routine preparation of the area, start the incision some 6–7 cm ventral to the transverse process and some 5–6 cm behind the last rib and continue ventrally for some 15 cm parallel to it. Remember that the aperture must be large enough to accommodate easily the upper part of the surgeon's arm without traumatizing the tissue. Once through the skin there is no great muscle thickness, though it is important that the three mainly aponeurotic abdominal muscle layers be identified so that the peritoneum can be recognized and dealt with carefully. During this stage, haemorrhage is not usually a problem and only the occasional spurting vessel needs attention.

The peritoneum must be cut carefully to avoid possible damage to the rumen wall, which is often tightly applied to its underside because of the concurrent rumen tympany. The safest method is to pick up a fold of peritoneum in tissue forceps and to incise with a scissor tip. Once a hole is created, air will rush *into* the abdomen with a characteristic sound and the rumen should fall away. Insert two fingers into the hole and, with one each side of the scissor blade acting as tissue guards, lengthen the incision to its full extent.

Prior to entering the rumen it is worthwhile exploring the left cranial abdomen. Pass the right or left arm coated with some sterile lubricant e.g. KY jelly, into the incision and then forward between the rumen and inner left abdominal wall. The ribs can be felt laterally and on the dorsal cranial rumen the free 'tongue' of the spleen can be palpated. In the case of a recent wire penetration the cow will begin to show signs of resentment at this point and the first adhesions may be encountered. In early cases, this feels as if the hand is separating two freshly buttered pieces of bread and their extent is surprising! With time, they become organized and more difficult to disrupt.

If no adhesions are present then the reticulum can be reached and palpated. If this engenders no obvious pain response then it is unlikely that the animal is suffering from traumatic reticulitis and another cause for the symptoms must be sought.

The problem of contamination of the peritoneal cavity during rumenotomy has long worried surgeons and many methods, some extremely complex, have been devised to avoid this. However the bovine peritoneum is remarkably tolerant to the presence of the rumen contents in small amounts and, while excessive contamination is obviously to be avoided, these laborious methods are time-consuming and unnecessary.

In preparation for entering the rumen, place a small folded cloth in the ventral commissure of the abdomi-

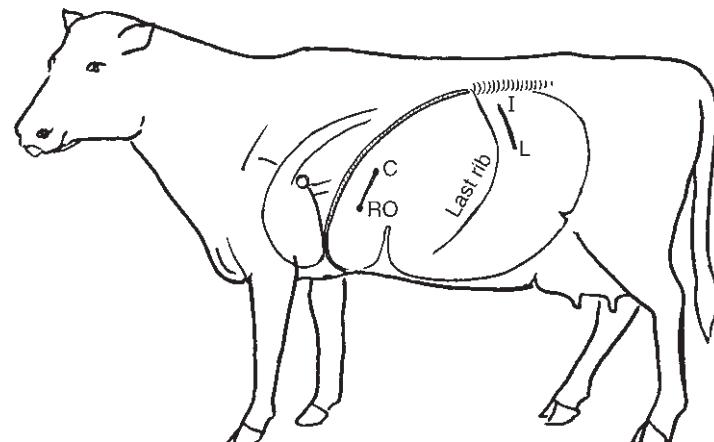

Fig. 66.2 This shows the position of the incision line (IL) for a rumenotomy. Note that the reticulum and heart apex are separated only by the thickness of the diaphragm. C, cardia; RO, reticular-omasal orifice.

nal incision so that half lies between the rumen and peritoneum and half outside on the skin. This will mop up most of the inevitable spillage of rumen contents. Pick up a fold of rumen wall from approximately 5–6cm caudal to the abdominal incision and exteriorize it. Retain this vertical fold of rumen by clamping it firmly with two pairs of strong Vulcellum or other tissue forceps, some 15cm apart. The upper pair is held by an assistant who stands on the right side of the cow and who is instructed to maintain a gentle upwards and outwards traction.

Incise the rumen fold between the two forceps and expose the lumen. There is some haemorrhage from the cut wall but haemostasis is rarely needed. Apply a third tissue forceps to the mid point of the caudal cut edge and ask the assistant to maintain a mild degree of caudal traction to open up the rumen incision. Hold the lower pair of forceps in the left hand and insert the right hand and arm into the rumen. Follow the dorsal wall of the rumen downwards and forwards *over* the mass of contents. The reticulum is identifiable by being at arms length, being full of fluid and having a distinct honeycomb pattern to its mucosa.

Sometimes the wire is immediately palpable, protruding from the reticular wall; if so, grasp it firmly and withdraw it. Note the angle and depth of penetration as these factors can influence the prognosis; e.g. a cranial penetration of even 1 or 2cm could have impinged on the pericardium; a medial penetration could well result in the localized peritonitis affecting the vagus nerve and inducing ‘vagus indigestion’. Bring out the offending wire, holding it firmly all the way, rinse the arm and explore the reticulum again. Further foreign bodies may be found within the silt that invariably lies on the reticulum floor as may all kinds of other, harmless items such as bolts, pebbles etc. Take the opportunity to examine all aspects of the reticulum, cardia, oesophageal groove, etc., for abnormalities and try to assess where the bulk of the adhesions lie. This is best done by attempting to pick up folds of reticular wall. In the normal state this can be done fairly easily, but where induration of the wall and peritonitis exist it is impossible and attempts will be met by evidence of severe discomfort from the patient. The disposition of the inflammatory process also has implication for the prognosis; major involvement of the medial reticulo-rumen wall could well lead to damage to the stretch receptors located there.

If no foreign body or penetrating wire is discovered at the first examination, the reticulum wall must be searched carefully, honeycomb by honeycomb. If no trace of a wire is then found (and fresh adhesions are present) it must be assumed that either the wire has dropped back into the lumen and has been swept into the rumen food mass or, more commonly, the wire has

completely penetrated and has begun a migration through the abdominal or thoracic structures. While this is likely to have further grave repercussions, with chronic peritonitis, liver abscesses, pleurisy or pericarditis all being possible, the occasional wire can migrate out through the body wall or become encapsulated in omental tissue and be rendered harmless.

At this point, terminate the search, withdraw the arm carefully from the rumen and scrub up again while the assistant maintains traction on the rumen incision, holding it clear of the abdominal wall.

Clean the surface of the rumen by gentle wiping with a moistened swab. Close the incision in the rumen with a continuous inverting pattern of absorbable suture material (Fig. 66.3). Catgut is ideal. Start the inversion several centimetres dorsal to the dorsal commissure and be sure to include the areas traumatized by the forceps in the inversion. Invert at least 2cm of each margin and continue the inversion pattern for several centimetres ventral to the ventral commissure. Pull the suture material tight as each suture is laid to ensure a watertight seal. One layer is usually sufficient but there is always enough slack rumen for a second inverting layer to be inserted for maximum security of closure.

The rumen is now allowed to fall back within the abdominal cavity. Because the initial fold was taken from caudal to the abdominal incision the rumen suture line now lies several centimeters caudal to its abdomi-

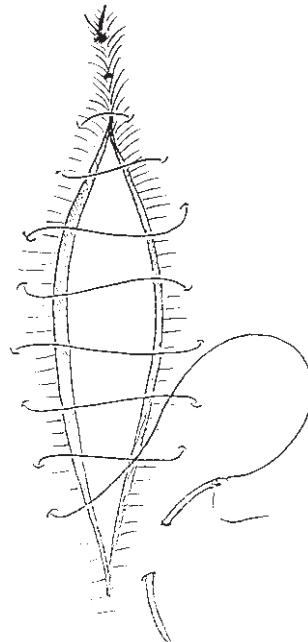

Fig. 66.3 An inverting ('Cushings') type suture pattern which may be used for closing an incision in the rumen, abomasum or uterus.

nal wall counterpart and the risks of adhesions and fistula formation are diminished.

It is the author's practice to close the abdominal incision in three layers: an evert continuous pattern of absorbable material in the peritoneum and transversus, a series of large simple interrupted sutures, again of absorbable material, to close the remaining subcutaneous layers and, finally, horizontal mattress sutures of non-absorbable material for the skin. If the margins of the abdominal wound appear somewhat traumatized, discoloured or contaminated, debridement by slicing a thin sliver of tissue off each incision edge will create fresh bleeding surfaces for apposition and virtually eliminate the potential for major infection and dehiscence.

In the normal course of events, removal of a penetrating foreign body should result in a dramatic clinical improvement over two to three days, recovery being hastened by the use of broad-spectrum, systemic antibiotics. Occasionally the penetrating portion of the wire will have instilled infected material into important sites such as the pericardium and despite foreign body removal the symptoms of pericarditis will progress. Similarly induration of the medial reticulum/rumen can result in the development of 'vagus indigestion' even if surgery was successful (see p. 835).

Locally, the most likely complication is the development of an abscess or abscesses at the incision line. This will show 10–15 days post surgery as a small lump or lumps which can eventually rupture and discharge pus. These abscesses are almost invariably located around the nidus of a buried suture and, for rapid treatment, the abscess is incised, the suture located and removed. This is facilitated by having used interrupted sutures for closure of the bulk of the abdominal wall. Sometimes the sutures are difficult to locate and in this eventuality, if absorbable material such as catgut was used, the suture will lyse and disappear of its own accord, following which the abscess will dry up. If non-absorbable material was used the suture will have to be removed otherwise the infection will persist indefinitely. After two to three weeks there is no risk involved in either searching for or removing these sutures. There will be enough thickening and induration at the site to prevent accidental penetration into the abdomen, and enough healing to prevent dehiscence.

Dilatation and displacement of the abomasum (see also pp. 839–842)

This is a 'production' disease. It is seen primarily in dairy cattle within the first three to four months after calving. The aetiology of condition is still not completely elucidated but is certain to be multifactorial. Any set of circumstances which creates a complete or

partial atony of the abomasum will lead to gas accumulation and instability of the organ. Normally the abomasum lies within the right, ventral aspect of the cranial abdomen; when it fills with gas it acts much as a hollow ball pushed down into a swimming pool: it wants to rise and it can do so with some force! Whether the abomasum rises to the right or the left of the rumen probably depends on factors not yet fully understood, but an important one is likely to be the physical size of the rumen relative to the abdominal cavity. In diets deficient in roughage, as are many fed to the modern dairy cow, the bulk of the rumen diminishes; its mesenteric attachments force it to contract dorsally thus creating a potential space ventral to it. Nature and a closed cavity such as the abdomen abhors a vacuum and the nearest mobile organ, the abomasum, becomes drawn down and across to occupy a more ventral mid line position. If distension occurs now, the greater curvature of the abomasum is able to rise on the left hand side. In countries such as the UK, left side displacement seems to predominate while in some European studies, right side dilatation, displacement and associated torsion are much more common.

Factors which have been implicated in the aetiology of atony include a high concentrate, high fat diet, chronic hypocalcaemia, stress of parturition, abomasal ulcers, accumulation of silt within the abomasum and vagus nerve damage. Of these the most important are likely to be the high concentrate, high fat diets commonly fed to parturient dairy cows. Others, such as abomasal ulcers and silt impaction, are probably due to the same aetiological factors or they are a mechanical consequence of the atony.

Left displacement of the abomasum (LDA)

Diagnosis is based on the presence of a non-pyrexic, sudden onset 50–75 per cent drop in milk yield within the first few months after calving, coupled with a very characteristic selective appetite where the cow is reluctant or refuses to eat concentrate food. The heart rate is normal, except when there is severe distension of the displaced abomasum. The faeces are characteristically firm and may be mucus covered, although occasionally and confusingly there may be diarrhoea. A ketonaemia may be present but the condition is distinguished from simple ketosis by the local symptoms related to a distended, abnormally positioned abomasum.

Auscultation over the last two or three ribs on the left side will, when the abomasum is distended, often reveal the characteristic splashing and pinging noises associated with a gas/fluid interface. However, if the cow is immobile these may have to be instigated by firm ballotment. This is best done by placing the right ear over the mid point of the last-but-one rib and using one's

knee or fist to rhythmically indent or ballot the left lower abdomen. A second method is to tap the upper last two ribs sharply while listening at the same point as before. If there is a gas distended viscus, i.e. abomasum deep to the ribs, the tapping noise will have a clear resonant quality not heard in the normal cow.

Both tests are easy to perform, take only a few seconds and should be part of a routine examination of any anorexic cow. If positive, they are virtually pathognomonic for a displaced abomasum. Although both 'vagus indigestion' and the much rarer pararumenal abscess can under some circumstances produce similar noises, these will extend much further caudally in the flank and be associated with other symptoms.

The absence of these characteristic sounds does not mean that an LDA is not the cause of the problem, only that the abomasum is not distended with gas at the time of the examination. Any previous vigorous movement, e.g. being brought in from the collecting yard, can result in the escape of gas and fluid from the abomasum, either back to the reticulum or forward to the duodenum. If possible, re-examine the animal in about half-an-hour or come back the next day. Sometimes several examinations are necessary.

Treatment: All the techniques described, and there are many, are directed towards returning the abomasum to the right and anchoring it there. The most commonly used techniques will be described here, although the author does recognize that others or variations may be used successfully. The 'toggle' method is described on page 842.

The bilateral flank technique: Of those techniques done in the standing animal, this is probably the most consistently successful. Its great advantage is the ease with which in most cases the abomasum can be returned to the right. This is especially important when the organ is tightly distended and apparently immobile. Its only real disadvantage is that it does need two people, though one can be a lay assistant.

Anaesthesia: Bilateral paravertebral anaesthesia of T13, L1 and L2 spinal nerves. Sedation is usually not required, but if needed it should be used sparingly to avoid the possibility of the animal going down.

Technique: No special instrumentation is needed. Make the left side incision as for a rumenotomy. Incise the peritoneum carefully as the distended abomasum may be lying up against its deep face and an accidental incision in the organ would result in its collapse with serious contamination of the abdomen with acidic and irritant abomasal contents. Through the incision the abomasum is seen lying between the abdominal wall

and the rumen and pushing the latter medially. (This accounts for the hollow looking sublumbar fossa of many LDA patients.) If one surgeon is operating on both sides, open the left flank first, protect the wound with a towel laid across it and then open the right side.

The position of the right incision is critical to the success of the operation. Make a vertical incision about 15 cm long with its centre point about half-way up the flank and some 6–7 cm caudal to the last rib. Higher, and there could be difficulty reaching the abomasum. Lower, and the small intestine will persist in prolapsing through the incision. The internal abdominal oblique muscle is the thickest at this point and its fibres, cut obliquely, hide some large vessels. Only the largest of these need to be dealt with and they can be stopped quickly by clamping with artery forceps. Do not leave these hanging on the wound as they will inevitably fall off or be carried accidentally into the abdomen. Cut the peritoneum carefully with guarded scissors. Visible through the incision will be a curtain of fat-filled mesentery and omentum, with the descending duodenum running horizontally across the middle of the incision and separating them.

Lubricate the right arm and pass it into the incision downwards and slightly forwards between the abdominal wall and the omental sheet. Advance across the mid line and as far over to the left as possible. Simultaneously the assistant on the left starts to deflate the abomasum by rhythmic downwards ballotment using the flat of the hand or a fist. Even if at first the abomasum seems reluctant to empty, persistent intermittent pressure will usually cause release of gas and fluid through the pylorus or cardia with a characteristic burbling sound. As the body of the abomasum becomes slacker it is pushed further and further down the left flank to meet the surgeon's awaiting hand. Grasp a large handful of the tissue which is being pushed ventrally and attempt to draw it across the mid line. Establish a push-pull sequence and continue until the abomasum has completely disappeared from the left flank. Sometimes the tissue being pulled can be felt to tear; this is almost certain to be omental tissue and not abomasal wall. If this happens grasp a fresh handful and try again.

If the abomasum does not collapse with ballotment, relieve the initial tension by puncturing the gas cap with a 14 g needle. Further rhythmic bouncing should then cause it to deflate. If the organ still remains fixed in position it is worthwhile checking for adhesions between it and the peritoneum or rumen. They can form as a consequence of the abomasal ulceration that is present in many cases.

In the majority of cases the abomasum and its abomasal attachments come over easily. Pull a handful of the displaced tissue up into the right incision. First to appear will be folds of fat-filled omentum. Search then

for an area where the fat deposits are thickest and firmest. In this region lies the pylorus which is instantly recognizable as an obvious, shiny, serosa-covered blind-ending sac. Occasionally some degree of upwards traction on the omentum is needed before the pylorus comes into view. Palpate the pylorus, the pyloric antrum and the body of the abomasum to determine whether there is any abnormality such as gravel impaction. If all is well proceed with the omentopexy.

The earliest techniques sutured the pylorus to the inner face of the abdominal wound. However, this put too great a tension on the abomasum and animals would take many days to accommodate. Current practice is to allow the pylorus to sink back to a more anatomically correct position and anchor it via its omental attachments.

Grasp a fold of thick omentum some 12–15 cm from the pylorus and fix it with Vulcellum or similar forceps. Start the abdominal incision closure with a continuous simple suture pattern picking up peritoneum and transversus, but with every deep needle pass pick up a deep bite of the omental fold. Do this for the *whole* length of the incision in order to ensure a strong adhesion. Then close both wounds in the routine manner as described for the rumenotomy.

With this technique there is usually a good strong adhesion formed and the recurrence rate is low. However, some do tear away and the owner should be instructed to lessen these chances by feeding a high roughage, low concentrate diet for 7–10 days and keeping the animal quiet, in a loose box if possible.

An alternative technique is performed through a paramedian incision. It has the advantage of needing only one surgeon, though the animal must be heavily sedated or under general anaesthesia. This in itself carries some risk in the cow and the animal *must* be starved of food and water for 24 hours prior to surgery to minimize the risk of regurgitation. Also heavy faecal matting of the ventral abdomen in some cows can make asepsis of the surgical site impossible to achieve.

Position the animal on its back (wedge-shaped supports can be made if this operation is done frequently) and support her firmly. Prepare the area that lies in the triangle between the costal arches, then if necessary carry out a ‘field block’ to anaesthetize the incision site. This lies some 5 cm from the mid line with its cranial margin some 20–25 cm behind the xiphisternum. Be sure to identify the course of the mammary vein before cutting as this runs within 10 cm of the mid line in places. The ‘milk-well’ or foramen through which the vein enters the abdomen can usually be easily palpated and this gives a guide to the course of the vein which, as the animal lies in dorsal recumbency, is completely collapsed.

Incise the skin parallel to the mid line; below, the abdominal wall at this point is almost entirely fibrous,

being composed of rectus sheath and aponeurotic rectus abdominis muscle. On entering the abdomen, identify the abomasum which is likely to have risen to lie at, or near the incision line. Push the organ, probably in a collapsed state, over onto the right side, identifying the attachment of the greater omentum to the greater curvature. Grasp a fold of the greater omentum some 7–10 cm from, and parallel to the insertion of the omentum to the abomasum and incorporate it in the closure of the peritoneal incision. This is done with a continuous simple suture of catgut or similar. This has the effect of interposing a barrier between the abomasum and the left side, preventing displacement in that direction or upwards on the right.

Close the fibrous aponeurosis with strong non-absorbable sutures laid in simple interrupted fashion (absorbable material is unlikely to remain strong enough for long enough in this high stress, poor healing site). Coapt the skin with horizontal mattress sutures and protect the wound with a Stent bandage (Fig. 66.1) sewn firmly in place.

Other techniques: A non-surgical method for correction of LDA is the ‘rolling technique’. Although quite effective at correcting the displacement, its major drawback is the very high rate of recurrence. It was popular in the early days following the discovery of the condition, but it does have a place in modern therapy as a means of returning the abomasum to its correct position prior to surgical omentopexy by a surgeon working through a single, right sided incision.

Cast the cow onto her right side and hobble her. Pull her gently onto her back (dorsal recumbency). Rock her gently over this 90° arc for two to three minutes to allow time for the gas-filled abomasum to move from the right to a higher position, i.e. into the ventral abdomen. Finally, allow her to roll into left side recumbency when the buoyant abomasum should slide around to her, now uppermost right side. If this is done as a prelude to surgery, the operation should commence immediately as redisplacement can occur within a very short time.

Another technique used by single-handed surgeons is to deflate the distended abomasum using a 14 g needle attached to a length of giving-set tubing. The needle is taken into the abdomen guarded by the left hand, passed between the abdominal wall and the omentum, lateral to the rumen and up to the abomasal gas-cap. The wall is punctured, as much gas as possible released and the partially deflated organ manhandled into its correct position. The drawback of this method is that the needle often becomes blocked and it is sometimes impossible to deflate the abomasum sufficiently to reposition it. A larger needle gauge would help avoid this, but would increase the risk of subsequent leakage.

Some techniques have been developed which involve operating through the left flank alone. One such method attempts to create a barrier to redisplacement by suturing either the omentum or the actual rumen wall to the peritoneum and musculature of the left mid flank. The abomasum is first repositioned and a series of sutures is laid to create the adhesions. This is a rather imprecise method and the results are distinctly variable. The rumen can occasionally be penetrated resulting in abscess formation. Another method involves placing long, 100 cm (3–4 feet), heavy synthetic sutures through the cranio-ventral fundic area of the abomasum. After deflation, the organ is repositioned whilst keeping the free ends of the sutures outside the incision. These are threaded, one at a time, on to a large straight needle which is then taken into the abdomen and used to penetrate the ventral abdominal wall immediately caudal to the xiphoid process. The sutures are tensioned to bring the abomasal wall into firm contact with the peritoneum and then tied outside. Again, the aim is to create adhesions which, this time, it is hoped will bind the abomasum into its correct position. The sutures are left in place for three to four days before being removed. It is suggested that because of the risk of leakage of abomasal contents, both intraperitoneal and systemic antibiotics are used. Although the author has no personal experience of these techniques, both have their advocates, with the latter method especially being popular in some countries.

A final technique, which is occasionally described is known as the 'ventral abdominal blind approach'. It has few adherents because of its imprecision and the very high risks of serious complications. The cow is cast in dorsal recumbency and an area behind the xiphoid is surgically prepared. The animal is rocked from right to left until the abomasum is auscultated in its normal position. A large, full-curved needle threaded with 6 mm ($\frac{1}{4}$ inch) cotton or synthetic tape is passed blindly through the abdominal wall, hopefully through the abomasal wall and out again. The sutures are pulled tight and tied off. They are left in place for several days to allow adhesions to form before being removed.

Abomasal dilatation and right sided displacement (RDA) (see p. 842)

In the UK this variation is seen much less frequently than left side dilation and displacement. As with LDA the symptoms are usually manifest within the first few weeks after parturition. Insidious in onset, with inappetance, reduction in milk yield and a variable ketosis, the animal's condition soon deteriorates with signs of abdominal pain shown by lifting of the hind legs towards the belly and looking around at the flank. There is elevation of the heart rate to about 100 bpm

and, frequently, diarrhoea and melaena. A marked difference between this condition and LDA is that right side dilatation and displacement frequently progresses to a complete torsion of the organ around either a caudo-cranial, vertical or transverse axis. This leads to compromised blood supply to the organ, sequestration of fluid and gas within the lumen, further distension and a marked increase in the severity of the symptoms. The animal becomes profoundly depressed, totally anorexic and the heart rate increases to between 120–140 bpm.

The aetiology of the condition is probably similar to LDA. However, in many cases of RDA large amounts of sand or silt are found, often impacted into the pyloric antrum. There is still dispute as to whether this is cause or effect, although it does suggest either a high intake of mineral matter, e.g. through the feeding of root crops, or possibly a chronic, low-grade atony which leads to the reduced passage and hence accumulation of this solid material. Other suggested aetiologies are mechanical strictures, or pyloric dysfunction consequent to abomasal ulceration or maybe pyloric nerve damage.

Diagnosis is by detection of a distended viscus on the right side. Auscultation and ballotment of both flanks take little time and should be a routine part of any clinical examination. The sounds are identical to those heard in a case of LDA and they occur in a mirror-image position, i.e. over the last two ribs. If dilatation is severe or torsion has occurred, the distended viscus can often be seen distending the cranial, right sublumbar fossa just behind the last rib. The organ can also be felt per rectum as a spherical, taut structure at arm's reach on the right side of the abdomen. The animal's general demeanour, and especially the heart rate, will indicate whether torsion has occurred.

Anaesthesia: A right side paravertebral block of T13, L1, and L2 spinal nerves or a field block.

Technique: The only special item of equipment needed is a stiff plastic tube, about 1.5 m long and with a bore of some 1 cm. This will be used to syphon off the fluid sequestered within the abomasum prior to correction of the displacement or torsion. If available, a stirrup type pump is also useful to speed up the evacuation.

Make an incision in the right flank as if for an LDA correction. Palpate the swollen abomasum and try to assess visually the condition of its wall. In general terms, the larger the organ and the darker its colouration, the less favourable is the prognosis; where torsion has been present for some hours it can be enormous, contain many gallons of fluid and, when its blood supply has been compromised, it will be a dull, dark reddish-blue in colour.

The first step in the management of this formidable looking organ is to reduce the tension in its gas-cap.

Pierce the most dorsal accessible point with a 14g needle attached to a length of plastic giving-set tube. When the wall is reasonably slack, insert a purse-string suture in the serosa and muscularis layers in a position above the fluid line. Make a small incision within the purse-string and thrust the plastic tube through into the lumen, drawing the suture tightly around it. Foul-smelling, coffee-coloured and often blood-stained fluid will run out of the tube and can be collected for disposal. The stirrup pump will speed up the process and can be reversed to blow out the tube if it becomes blocked.

The next step is to reposition the abomasum, a relatively simple procedure if only dilatation is present. However, in a case of torsion the direction of the twist must first be established.

After removing the evacuation tube and tightening the purse-string suture, try and feel at the extremities of the organ, i.e. the omaso-abomasal junction and the pyloric end, to see if the twisted tissue there gives some indication of the torsion axis. If not, a process of trial and error repositionings often proves successful. In the author's experience most torsions occur along a caudo-cranial axis with the direction of twist being anticlockwise when viewed from behind, so it seems logical to try correcting that version first. Using the flat of the left hand on the most dorsal part of the partly distended abomasum, push downwards and obliquely forwards; if this is the correct direction, the twist unravels itself and the area reverts to a relatively normal anatomical state. If not, the organ will resume its previous abnormal position, begin to distend and another direction must be tried. Fortunately, gentle perseverance usually pays. Once repositioned, the abomasum can be anchored by the standard omentopexy technique.

Unfortunately, there is a high rate of recurrence of this condition. Many authors, believing that pyloric dysfunction contributes greatly to the development and persistence of the syndrome, advocate either a pyloroplasty or a pyloromyotomy with or without evacuation of silt.

Although there is not enough information available to decide which combination is the correct one, it seems illogical not to carry out the relatively simple pyloric surgery and to remove any silt which seems to be forming an obstructive mass. This author has had encouraging results with the simpler pyloromyotomy coupled with silt removal.

To evacuate the sand, exteriorize a portion of the flaccid abomasum, make a 10cm incision in the wall and, having protected the abdominal wound margins with a sterile towel, manually remove the contents. Close the wound in two layers; firstly the mucosa with a simple continuous pattern and then the muscularis and serosa with a continuous inverting suture, both of catgut. To perform the myotomy, identify the thick muscular sphincter (see

the section on LDA), grasp it firmly between the thumb and forefinger and incise parallel to the lumen axis through the serosa, circular muscle and submucosal layers until the mucosa bulges from the inside. (If the mucosa is accidentally punctured it can be repaired with a catgut suture.) An alternative method is to carry out the procedure while the abomasal evacuation incision is still open, inserting an index finger into the sphincter lumen and cutting down *very carefully* on to the site indicated. When these procedures are complete the abomasum is anchored in the usual manner.

Some idea of prognosis can be gained by studying the abomasum after its deflation and repositioning. If the discoloured wall assumes a more normal healthy colour and acquires a degree of tone, the outlook is reasonable. If it stays discoloured and flaccid the prognosis is not good. Pre- and postoperative fluid replacement therapy will be of course very beneficial and the choice of fluid should take into account the massive sequestration of sodium and chloride ions that has occurred. Intravenous normal saline or Ringer's (not bicarbonate-containing Hartmann's) solution at 5l/h to a 450kg cow has been recommended. This can be 'spiked' with potassium (up to 40mmol/l).

In the first days after surgery the patient should receive routine antibiotics and be fed small quantities of hay only, though with unlimited access to water. During this period, foul smelling diarrhoea is inevitable but temporary.

Intestinal obstruction (see p. 847)

The theoretical causes of intestinal obstruction include volvulus, gut tie, strangulation in scrotal or umbilical hernias, caecal torsion and others. However, intussusception would seem to be the one most commonly encountered in practice situations. It may be seen in any age of animal, but most often is encountered in young stock.

Acute intestinal obstruction differs from most of the other abdominal conditions in that it causes abdominal pain which manifests as a colic-like syndrome. The bovine reaction to this is much more subdued than the more excitable horse, but it does show in restlessness, with frequent getting up and down, looking around at the flanks and lifting of the hind legs to kick forward at the belly. Some people describe a 'trestle'-like stance which affected animals adopt with a dipped back and spread legs. Rectal temperature can vary and is no guide but as the condition progresses the heart rate will cross the 100bpm barrier and reach a high of 120–130bpm. Faeces are passed at first but on the second day only scant, tarry material is seen. The colic phase may only last 12 hours or so and the animal often looks brighter for a time before becoming dull and depressed

as the obstruction leads to gut necrosis, peritonitis, toxæmia and shock.

This set of signs presented to the clinician fairly obviously indicates an abdominal problem and in theory there are a number of conditions to consider. However, the absence of a distended single viscus rules out LDA, RDA or torsion. Hernias can be examined externally for signs of strangulation and traumatic reticulitis can be virtually eliminated by, amongst other differences, a failure to elicit pain by ballotment of the xiphoid region and by the fact that it rarely causes such an elevated heart rate or signs of colic.

A rectal examination is important both for elimination and possible positive findings. Where an obstruction is present, some distended small intestinal loops may be palpable in the right abdomen and occasionally, in small cows, an intussusception can be felt as a sausage-shaped mass about 6cm in diameter and of variable length. However, distended gut loops alone or the presence of taut bands of mesentery are a strong indication of an abdominal catastrophe and the need for an exploratory laparotomy.

Bearing in mind the simplicity and straightforward nature of the procedure, a laparotomy should be regarded as a diagnostic tool; there is an immense amount of diagnostic and prognostic information to be gained and there is the opportunity for immediate corrective surgery; it is therefore surprising how often it is shunned by both veterinary surgeon and owner.

Surgical correction of intussusception: Make the laparotomy incision in the mid point of the right flank,

preferably under paravertebral anaesthesia of T13, L1 and L2 spinal nerves. Avoid making the incision too low in the flank otherwise small intestinal loops will persist in prolapsing out of the wound. The small intestinal mass is reached by first going caudally between duodenum and the flank, then medially and finally cranially into the omental sling, or recess in which the bowel loops lie (Fig. 66.4). The intussusception is usually easy to feel and once located it should be exteriorized. Sometimes the mass will not come to the incision. In these cases surgery cannot be performed and the procedure must be abandoned. Most, however, can be exposed although the mesentery is short and access to the affected area and to the surrounding normal bowel is always limited. This fact makes the help of an assistant essential since a constant traction has to be maintained to keep the mass in view of the surgeon.

Several additional problems now have to be overcome. In other species it is usual to remove the intussusception along with a reasonable length of normal bowel each side so as to ensure viability of the anastomosis. In the cow, however, the mesenteric frill is so short that only the intussusception itself and a minimal margin of normal gut can be removed otherwise the two cut ends might not come together.

Before attempting resection, it is worthwhile seeing if the invaginated length (the intussusceptum) can be pulled clear of the enveloping bowel (intussuscipiens). If this can be done easily and the wall looks pink and healthy then there is no need for resection. Usually though, adhesions have fixed the two parts together or

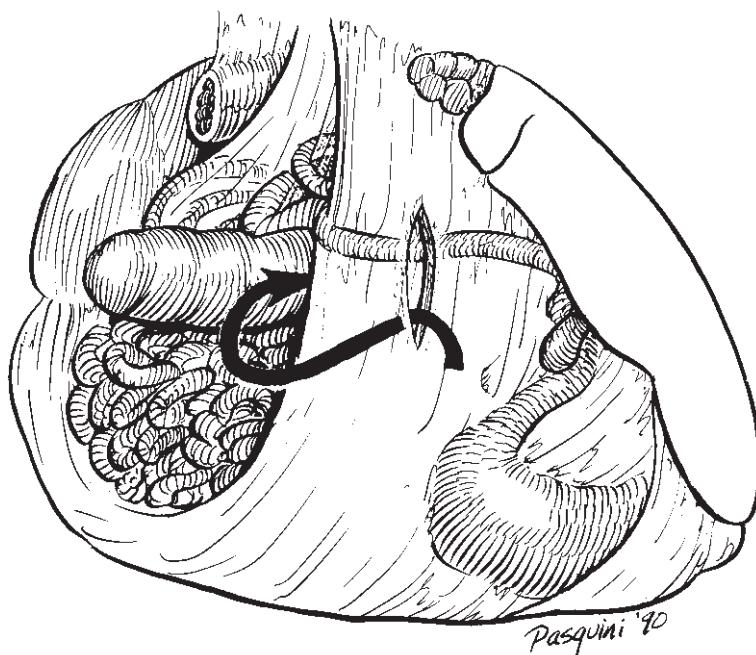

Fig. 66.4 This illustrates the route taken to gain access to the small intestine from a right flank laparotomy incision. (Courtesy of Chris Pasquini.)

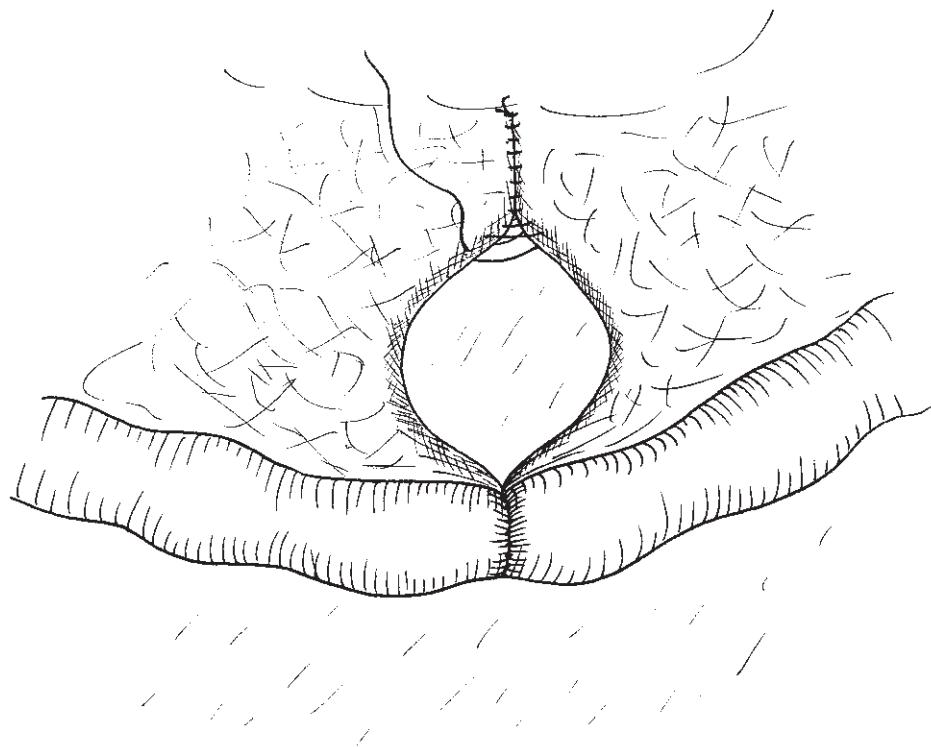

Fig. 66.5 This illustrates the problem in closing the defect in the mesentery following a small bowel resection.

if they are separable the intussusceptum is discoloured and friable and must be removed.

Use bowel clamps to isolate the intussusception. (Use the minimum compression needed to avoid trauma to the remaining gut.) Place each pair about 5 cm apart and try to ensure that the bowel between them has a good blood supply. Again, unlike other species the cow provides unique problems, as the blood vessels to the small intestine, although large, are completely obscured under a thick layer of mesenteric fat; ligating individual vessels supplying the intussusception is therefore difficult. To ensure that all are sealed start the ligation procedure at the level of one of the inner clamps. Take bites of the mesentery and fat with strong absorbable suture material and lay down an arc of overlapping blind ligatures from one end of the intussusception to the other. Occasionally large lymph nodes will get in the way and the ligature line must deviate around these. When all the ligatures have been laid, resect the affected length, cutting the bowel close to the inner set of clamps. This leaves a good length of free bowel protruding from the remaining forceps and makes the subsequent surgery easier.

Either an evert or inverting suture pattern can be used to join the two ends, although the latter gives a more secure union with better healing. Whichever is

chosen, insert the first four sutures at the poles of the lumen, the first being inserted at the mesenteric border. There is likely to be a disparity in size of the lumen of the proximal and distal segments and if this disparity is large then apposition may be difficult. If there is enough slack, the distal stump can be cut at an angle to try and equate the circumferences (see Fig. 66.5). An alternative is to take longer bites of the proximal end to try and pull it down to the size of its opposing partner.

When completed, test the seal by removing the clamps and massaging gut contents at pressure through the anastomosis. If it holds, the next step is to close the hole in the mesentery. Use an absorbable material (catgut) and a continuous simple pattern, starting from the inner aspect of the defect and working outwards. Because of its short length that part of the mesentery adjacent to the bowel may not come together (Fig. 66.5) and the hole so formed will have to remain.

Clean the anastomosis, return the bowel to its correct position and close the abdominal incision routinely as described elsewhere in this chapter.

Caesarean section

This is probably the commonest major surgical procedure in cattle practice. It is carried out in all sorts of cir-

cumstances; from the ordered serenity of a teaching school clinic to the murky depths of small hill-farm barns at 3 am by torch or car headlight. It is therefore a procedure performed in sometimes difficult and adverse conditions, often by a surgeon tired by the attempt to calve the animal, and frequently under pressure of other calls to attend. It therefore, more than most, requires the establishment of a routine which can be carried out in all foreseeable circumstances. The technique described here is a routine which the author has developed over the years and which has worked successfully and consistently.

Indications: These are dealt with exhaustively elsewhere. However, one point needs to be stressed: the decision to carry out a caesarean section is one that should be made at the earliest stage possible. Far too many of these procedures are carried out after heroic attempts at normal delivery and avoiding surgery have failed, with a bone weary clinician operating reluctantly on an exhausted and traumatized patient.

Anaesthesia: A decision must be made early whether to operate on a standing or recumbent animal. The standing position is infinitely preferable so if the cow is tractable, use little or no sedation, merely manual restraint. If the animal is wild enough to require heavy sedation then the author recommends that the animal be cast at the outset and hobbled to keep her down. Nothing is more chaotic than operating on an ataxic cow struggling to keep her feet and collapsing, inevitably on the wrong side during surgery.

Anaesthesia of the flank is best achieved by paravertebral block of T13, L1, L2 and L3 spinal nerves, the latter included because the top 2cm or so of the incision often intrudes into this dermatome. In addition the author strongly recommends epidural anaesthesia for all caesareans other than early elective cases. If not done, any cervical stimulation, for example by the calf moving against it, will trigger abdominal contractions even in exhausted cows. At best these are disconcerting, at worst they can cause massive prolapse of the rumen through the abdominal incision. However, the epidural injection must be done with care since too much volume will cause the cow to start knuckling on her hind legs (usually the right one first) and to become unsteady on her feet. Only the barest minimum, sufficient to stop straining should be given and this is usually the same as that required to produce vulval anaesthesia. A small cow should require no more than 1.5–2ml of 3 per cent lignocaine (2–3ml of 2 per cent). Also be sure to carry out the injection with the cow standing or, if already down, with the animal's hindquarters in a horizontal position. If the animal's pelvis is tipped to one side or other to any degree, the block will probably

Fig. 66.6 A Charles Roberts embryotomy knife.

not work. This is presumably because gravity causes the anaesthetic solution to affect only the dependent side and the straining reflex is an 'all-or-nothing' phenomenon!

Technique: This technique requires the use of a Charles Roberts embryotomy knife (Fig. 66.6), but no other special instruments.

If the surgery is to be carried out in the standing position, put the patient's right side up against a barrier of some sort to prevent her swinging away. Mild restraint can be achieved with a nose twitch or 'bull-dog' but, if at all possible, always have someone standing at her head to exert control if necessary. If the cow is down, or cast, position her in sternal recumbency with her hind-quarters tipped towards the right. Hobble both fore and the right hind legs together but pull the left hind gently backwards to stretch the left flank. Take care not to put too much traction on the leg as this can cause peripheral nerve injury. Again it is sensible to have someone at the cow's head to restrain her if she attempts to get up. Some surgeons operate with the animal in full lateral recumbency. This provides for good restraint, but lifting a calf out of the abdomen at arms' length with bent back is extremely difficult and uncomfortable, not to say dangerous and the author does not recommend it for this reason alone. In addition there is the distinct impression that abdominal wound closure is more difficult with more tension being required, probably because of the increased upward intra-abdominal pressure and the convexity of the upper flank.

The only technique to be described here will be the sloping, left flank incision principally because the author has had no indication to do any other. Right side 'caesareans' should be avoided because of the propensity of the small intestine to prolapse profusely out of the abdominal incision for the duration of the surgery. Occasionally though, old left side lesions may make this necessary and the surgeon should be aware of this complication of operating on the right side.

Begin the abdominal incision about 12–15 cm ventral to the tuber coxae ('pin-bone') and, at an angle of about 30–35° to the vertical, extend it downwards and forwards. Make the incision long enough to remove the anticipated size of calf at the outset. Extending it later, when the calf is stuck half way out, is difficult; an adequate size makes for easier delivery and much less

trauma to the wound edges. Cut through the fatty subcutaneous fascia and the external abdominal oblique muscle whose fibres cross the incision at right angles and which, at about this level, merge with the relatively avascular aponeurosis. Deep to this lies the principal muscle layer, the thick internal abdominal oblique with its fibres running approximately parallel to the incision. Reverse the scalpel and with its blunt handle separate a small gap in these fibres at mid incision level. Insert the index finger of each hand into this gap and pull apart. The muscle then splits easily and bloodlessly along the incision line to the required length.

Below lies the transversus muscle whose fibres run, like the external oblique, across the incision. At the mid point there is usually a fairly large segmental nerve and accompanying blood vessels and it pays to ligate this bundle before cutting. For some reason this nerve branch often seems to retain sensation, so it is wise to stand away from the hind leg whilst it is quickly cut. Take care cutting through the peritoneum as the rumen is usually tightly applied to its deep face.

Pass the right hand and arm behind the rumen and then medially to feel the uterus lying in the mid and right caudal abdomen. Palpate it thoroughly to feel the lie of the calf within. If the calf is in anterior presentation relative to the cervix, feel for the distinctive outline of the hocks and, if in posterior presentation, locate the head and nose. Once these are found the uterine incision can be made without delay.

The principles are: begin the incision over the extremity of the calf which is furthest away from the cervix (i.e. over the hocks or nose of the calf) but not too close to the fallopian tubes or ovaries; continue the incision over the dorsum or back of the calf, along the greater curvature of the uterine horn, making the aperture big enough to extract the calf without tearing the uterus in the process. However, the incision must not be so large that it extends too far towards the cervix and therefore to a position which will be difficult or even impossible to reach and suture. As a general rule this means an incision length of between 30–50 cm depending on the size of the calf. Also the more friable the uterus (e.g. after a torsion), the longer it should be to help prevent tearing. If these lengths sound excessive, remember that following removal of the calf, uterine contraction will substantially reduce them within minutes.

Many texts refer to exteriorizing the uterus or visualizing it before making the incision. However, few people are strong enough to manipulate, let alone lift this huge and heavy organ (often 75 kg or more) at arm's length, and in trying to do so, accidental damage is often done. It is far better to learn to use a Robert's knife which has a protected blade and is used to incise the uterus *in situ*. The prospect of using a knife blindly in a site surrounded by small intestinal loops is daunting.

At first; however, the novice should take heart from the fact that the author has never experienced or heard of any damage being done with this instrument. Hold the knife in the palm of the left hand with the blunt, probe-headed blade away from the palm and pointing forwards. Push this blunt point vigorously through the uterus wall over the extremity of the calf, then push the knife along the greater curvature of the uterus for the required distance, preventing loops of bowel from possibly straying into the cutting area by using the first two fingers of the same hand extended alongside the knife guard. If the knife is sharp it cuts effortlessly, pushing cotyledons aside with its blunt probe tip and thus minimizing haemorrhage.

To remove the calf grasp a leg, through the fetal membranes if they are not cut, and bring it to the abdominal incision. This may necessitate careful manipulation and flexion of the joints, especially in the case of the hind limbs. Deal with each leg separately, and the head too if the calf is in posterior presentation. Break through the fetal membranes and extract the calf by lifting it as gently as possible from the incision. Remember that some part of the calf may be within the pelvis and traction downwards and cranially may be needed. If the calf is alive, try not to let it fall and snap the umbilical cord precipitously; rather move the calf away from the cow slowly, breaking the cord in a controlled movement. If possible, let someone else deal with resuscitation of the calf and return to the cow.

Even in this short time, the uterus will have contracted considerably, but in the majority of cases it is perfectly feasible now to exteriorize the incised horn to make closure easier. This has to be done carefully to avoid damage to the uterine wall and is best done with flattened cupped palms and a scooping motion. Where the placenta has separated, the membranes can be peeled away easily, but when the calf is delivered alive this is not feasible and attempts to separate the fetal and maternal parts of the cotyledonary attachments will result in severe damage and bleeding. However, if the placenta remains in its entirety, it will make closure very difficult. A simple remedy is to grasp the mass of membranes close to the uterine incision and to cut the bulk away with a scalpel keeping about 10–15 cm away from the cotyledons. Some of the large placental vessels bleed transiently but this is not a problem. By this method, suturing the uterus is simplified and expulsion of the remaining membranes is not affected.

Begin the uterine closure at the cervical end of the incision some 3 cm away from the wound commissure and invert 2–3 cm of the wound edges to bring serosa in contact with serosa. Any continuous inverting suture pattern will suffice but a Cushing's pattern (Fig. 66.3) provides for the most rapid closure. Use an absorbable material such as catgut and penetrate only the serosa

and muscular layer. Pull each suture bite snugly as it is laid and be careful not to trap strands of placenta in the closure. If a 'T' or 'Y' tear has occurred suture the branch tear(s) first then treat the remainder as a single incision. If there is any doubt as to the seal achieved, oversew the whole incision with a second inverting layer. Clean the uterus of blood and fibrin tags and replace it in the abdomen.

Close the peritoneum and transversus together with a continuous evertting suture to appose peritoneum to peritoneum. This is not a weight-bearing layer so the closure can be rapidly attained with large tissue bites. Oppose the remaining layers of muscle and fascia with a row of large, simple interrupted sutures. As there is tension on this part of the closure the knots can be difficult to tie, with the first throw slackening before the second throw is laid to lock it. If the first throw is made a triple or even quadruple slippage does not usually occur and tissue opposition can be maintained. The skin is closed with horizontal mattress sutures of non-absorbable material.

The choice of suture materials for the deep layers of the abdominal wound is the subject of controversy. However, the author has no doubt that an absorbable material such as catgut is indicated. The thickest gauge is easily strong enough and, in the event of infection, these sutures will not act as persistent, individual foreign bodies, will lyse rapidly and will not have to be painstakingly removed before healing can take place.

As soon as the surgery is over, release the cow and, if it is alive, allow her access to the calf. In an uncomplicated caesarean section there is no indication to use any drugs other than the routine pre and post operative antibiotics. However, if the uterus seemed slow to contract down, as often happens when a dead calf is removed, oxytocin can be given and, of course, if there is any suspicion of hypocalcaemia, appropriate therapy is indicated.

Special cases

Caesarean section in cases of torsion of the uterus: The operation proceeds routinely until the stage of incising the uterus. If this is done without first correcting the twist, suturing will be extremely difficult because in the, by then, untwisted uterus, the incision will lie on the deep face of the horn. It is therefore the author's practice to try and correct the torsion at this stage if at all possible. Use the flat of each hand to start the heavy uterine body swinging in the copious peritoneal fluid that invariably is present in these cases. Be very careful not to allow stray fingers to penetrate the oedematous, friable uterine wall and if this seems likely, or the twist is resistant to correction, abandon the attempt and proceed to incise the twisted horn. Uterine wall tears

are far more likely in torsion cases so make sure that the uterine incision is made long enough to extract the calf easily. Also sutures tend to pull through the soft wall and it is invaluable to have an assistant scrub up to help oppose the edges of the incision. Always oversew in these cases and check that the torsion is completely relieved before closing the abdomen.

Removal of a dead, contaminated calf: The bovine abdominal cavity is, by and large, a tolerant organ, but the gross contamination by infected fluids, membranes, hair, etc. that occurs in a caesarean delivery of long dead fetuses leads to a high incidence of maternal endotoxaemia, peritonitis and abdominal wound dehiscence. However, with suitable modification to the basic technique the level of post operative morbidity and mortality drops to such a low level that surgery becomes a viable alternative to sending the animal for slaughter. These modifications were adopted successfully by the author and others at the Liverpool University Veterinary Field Station.

In anticipation of the massive abdominal contamination give the animal 10 million units of crystalline penicillin G intravenously just prior to surgery. Open the abdomen in the conventional way but then attempt, if at all possible, to bring the gravid horn up to the incision. (Take care not to damage the friable uterine wall in the process.) Incise the horn over an extremity and try to extract the calf and membranes with the minimum of spillage into the abdomen. To make this easier, make sure that both the abdominal and uterine incisions are of adequate length to prevent sticking or tearing. Close the uterus carefully as described for uterine torsion and oversew the first closure. Clean the uterus, reposition it and then begin the task of cleaning out the abdominal cavity. This is achieved by repeated lavage. Use 2 litres of saline each time, warmed and poured through the incision. Use the saline to literally wash the viscera before scooping as much as possible with cupped hands. Repeat this process twice. Instill 10 million units of crystalline penicillin G into the peritoneal cavity and begin the closure.

The margins of the abdominal wound will be severely contaminated so remove a 4–5 mm strip of the incision margin of each muscle layer by sharp dissection. The bleeding edges are then sutured in the usual way using plain catgut. Strip the contaminated fascia from below the skin margins and close the skin with horizontal mattress sutures of a non-absorbable material. Use high levels of penicillin and streptomycin to supplement the initial intravenous therapy for about 5 days and to ensure the maintenance of high concentrations in the peritoneal cavity inject 10 million units of penicillin G directly through the abdominal wall in the right sublumbar fossa on the first and second post operative day.

Despite these precautions, wound infection can occur and can be recognized by a swelling of increasing size at the ventral aspect of the wound which is painful on palpation. Needle puncture will confirm the presence of pus. In these cases remove the sutures from the lower third of the incision and open the wound to allow drainage. Penetration of infection into the abdomen is not likely at this stage and the only treatment needed is daily wound irrigation. It is in these circumstances that the use of catgut sutures is vindicated. The material lyses rapidly in the infected tissue and does not form a series of permanent niduses of infection which would have to be removed before healing could take place. Whilst these open wounds look extremely serious, provided drainage and irrigation are maintained they heal well with minimal long term scarring.

Caesarean section for treatment of Hydrops allantois: Hydrolantois in the cow develops within the last three months of pregnancy. It results in a massive fluid accumulation within the allantoic cavity and caesarean section is the treatment of choice. Initially a two stage operation was devised in an attempt to avoid the splanchnic pooling and vascular embarrassment which might occur if the fluid was allowed to escape too quickly. On the first day, a drainage tube was inserted into the uterus and fluid was evacuated slowly overnight; on day two a routine caesarean section was carried out. A development of this technique was to drain fluid through a larger bore tube over an hour or so before completing the caesarean procedure.

The author has modified this technique further so that delay is minimized.

Begin the abdominal incision in the usual way but open only the top or dorsal 50 per cent of the wound. The fluid-filled uterus invariably bulges out of the aperture. Make a small 2cm stab incision into this bulging portion and slowly release some of the fluid. As the intra-uterine pressure drops, slowly at first, then faster and faster, the abdominal and uterine incisions can be progressively enlarged. If the evacuation of fluid is controlled to take place over 15–20 minutes the animals show no sign of discomfort or vascular embarrassment and the caesarean section can proceed as normal. Bear in mind, however, that the calf is likely to be small, so the incision does not need to be as large as normal, and that the vastness of the uterus and prolificacy of the membranes can occasionally make locating that calf rather difficult!

Amputation of a digit or claw (see p. 430)

The main indications for this procedure are severe trauma to the hoof and associated internal structures and intractable infection of the foot. It is a procedure

whose success rate and ease of execution improves considerably, the earlier it is done. Too often the clinician and owner delay the decision to amputate, just in case the animal improves, and are only persuaded that it is necessary when the infection has extended above the hoof and the distal limb is swollen and excruciatingly painful. By this time, the unfortunate patient has lost a great deal of condition and most of her milk, has taken up a great deal of time and money and is a prime candidate for humane slaughter, not surgery.

Probably the commonest instigating condition for this type of deep infection is solar ulceration. Typically the lesion remains unnoticed because of its bilateral nature and only when infection penetrates through the keratogenic layer into the deeper structures does the lameness worsen sufficiently for the farmer to notice and bring the case to the attention of his veterinary surgeon. By this time involvement of the deep flexor tendon (DFT) at its insertion into the pedal bone has usually occurred. This extension of infection to the level of the DFT is easily established by probing down through the granuloma which is always present by this stage at the ulceration site. If the probe tip strikes bone or penetrates to a depth of 2.5–3 cm, then DFT involvement is certain. In these cases it is the author's practice to excise the granuloma and the infected deep tissue once only. If, on a repeat examination some 5–7 days later, the granuloma and sinus have reappeared, then, as the chances of success a second time are minimal, amputation is recommended. At this stage, infection is usually localized within the hoof and has not spread to the soft tissue of the pastern region or, worse, to the flexor tendon sheath.

Done at this relatively early stage, the operation is easy to perform and is usually successful in its aims. The animal heals rapidly and begins to improve in condition almost immediately after surgery. However, a warning note must be sounded: the remaining digit will now be carrying all of the animal's weight. It will therefore be subjected to a great deal of extra wear and tear and is likely to support the cow for only one or two more lactations; in small cows, with a good clean management system it can be much longer.

Anaesthesia: For the technique to be described here, the animal must be sedated and cast to lie in lateral recumbency. For sedation use xylazine or chloral hydrate. The latter drug, now sadly out of fashion, is in many ways superior to modern sedatives for this type of work and is also unlicensed in the UK. Onset of sedation is quiet and unmarred by bellowing or salivation and the depth of sedation can be profound if so desired. Its analgesic effect is good and its duration of action, after oral dosing and a 10–15 minute induction period, is 45 minutes or longer; this allows plenty of

time for surgery by even the most inexperienced. The recovery phase is calm and uneventful and it is cheap!

The oral dose is between 60 and 90g, depending on the size of the animal, and it can be given through a stomach tube, dissolved in about 1 litre of warm water, or as a drench. If using the latter method allow the animal plenty of time to swallow and to avoid inhalation of the liquid. Make sure that the solution does not contact the eyes as it is extremely irritant.

Chloral hydrate can also be given intravenously, virtually to effect, although again its irritant nature means that care must be taken to avoid perivascular injection.

Whatever sedative is used, local analgesia of the foot is essential. The method of choice is, without doubt, intravenous regional anaesthesia (IVRA).

The secret of successful IVRA is the application of an effective tourniquet. Use thick (2cm diameter) rubber tubing of the type used in milking machine pipelines, applying it just proximal to the carpus or the hock. To improve compression in the latter case, place 15cm (6 inch) bandage rolls into the lateral and medial depressions which lie just anterior to the Achilles tendon. Wind the tubing around the leg at least 4 times applying *maximum* effort to ensure a high degree of tension and compression; if necessary, use two people. Whilst doing this do not lift the leg above the horizontal or the limb veins will collapse and be difficult to inject. Clip a strip over one of the superficial veins and clean it thoroughly. Using a wide bore (16g) needle inject about 30ml of 2 per cent lignocaine or 20ml of 3 per cent, rapidly into the vein; withdraw the needle and syringe and apply pressure to the injection site immediately. (If the injection is done slowly the animal often kicks after about 50 per cent of the solution is injected and frequently the needle pulls out of the vein.)

Once injection is completed, full analgesia will usually develop in about 10 minutes or so. However, before starting the incision, this must be checked. Within a volume of tissue subjected to IVRA the initial effects are random, with blocks of anaesthetized tissue lying adjacent or deep to other tissue blocks which are fully sensitive. It is therefore essential to check, not just by skin pricking, but by driving a needle down to the bone all the way around the claw. (It needs little imagination to picture the consequences of completing half the operation only to find the deep layers of tissue are entirely sensitive!) The interdigital cleft and especially its caudal aspects seem to be the last tissue to be affected and these areas should be carefully checked. If anaesthesia has only been partially achieved after 10–15 minutes, repeat the intravenous injection using the same amount of local anaesthetic solution. If it is still not fully effective then it is likely to be the tourniquet which is at fault.

Technique: No special instruments are necessary, although a proper curette is a great help.

With the cow in lateral recumbency, and the affected claw uppermost, prepare the foot for surgery. The claws can be difficult to clean and a combination of paring and scrubbing with a stiff brush is often needed. To clean the interdigital area use three or four lengths of cotton bandage soaked in surgical scrub and see-sawed briskly backwards and forwards in the cleft.

Make the incision about 5mm proximal and parallel to the coronary band–skin junction. Extend the incision through the thick skin all the way around the outer hemicircumference of the pastern and into the interdigital cleft. Here, cut the skin 2–3mm axially to the horn–skin junction, carrying the incision through the cleft to rejoin the skin wound. Always take care to cut towards (or into) the affected claw. Some force is needed to penetrate the thick skin of this region and one inadvertent slip of the scalpel blade into the sound claw can ruin the animal. Once through the skin, angle the incision proximally to aim for the proximal interphalangeal joint. This lies in the dorsal (anterior) half of the pastern thickness and some 20mm proximal to the coronary band (Fig. 66.7). Careful dissection is not necessary and the fascia, ligaments, tendons and sheaths can be cut rapidly with fairly bold strokes.

Finding the proximal interphalangal (pastern) joint can be difficult at times, especially if chronic infection has resulted in extensive fibrous reaction or the deposition of periarticular new bone. The easiest way is to put an axial (inwards) force on the claw and then to make a series of cuts parallel to where the joint is believed to be. When one of these cuts is made in the

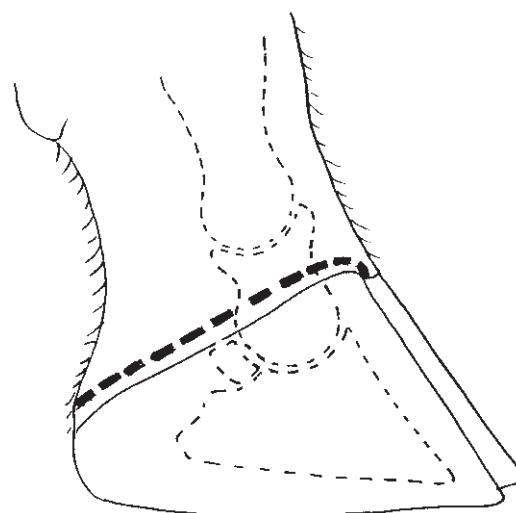

Fig. 66.7 The heavy dotted line shows the course of the initial skin incision when amputating a digit. Note the position of the proximal interphalangeal joint relative to this incision.

correct place the tautly stretched collateral ligaments and joint capsule part easily with the release of some synovial fluid and an increase in joint laxity. Carry this incision on and around the articulation, bearing in mind its deeply curved profile. Take care when cutting its deep attachments not to penetrate too far towards the sound digit. During this phase twisting and turning the partially amputated claw can help to expose and tense the tissues for cutting. At this point, scalpel blades are often broken and it is a good idea to have a few spares available. Complete the removal of the claw by severing any remaining attachments.

During surgery, haemorrhage is not a problem because of the tourniquet; however, if some pre-emptive action is not taken it can be quite considerable once the latter is removed. The only vessel of real significance is the dorsal digital artery and its cut end is usually fairly easily found in the dorso-medial quadrant of the wound axial to the stump of the first phalanx (Fig. 66.8). Ligatures should not be used as the wound is to heal by second intention. Instead, grasp the severed end of the artery in forceps and twist it some 8 to 10 times to seal its lumen. Debride the wound if necessary, cutting off any obviously infected or necrotic tissue. Do not remove any of the large interdigital fat pad which prolapses into the wound unless this too is infected. Check the flexor tendon sheath: if the fluid that can be milked out of it is turbid or flocculant it should be repeatedly irrigated with saline and antibiotic solution. Although not disastrous, this finding is a poor prognos-

tic sign as the sheath usually remains infected; it also occasionally communicates with the sheath of the sound claw at the level of the fetlock. The final step is to curette the articular cartilage. This must be done thoroughly to expose the subchondral bone over the entire surface of the articulation. If it is not done carefully, granulation tissue will not grow from the bone end, or adhere to it, and a persistent sinus will develop in the healing tissue. The use of a proper curette greatly simplifies this part of the surgery, but if one is not available a scalpel can be used as a substitute.

Careful bandaging of the wound is vital, not only for its protection but as the only means of post operative haemostasis. Place a layer of non-adhesive dressing on the exposed tissues then overfill the wound cavity with gauze, swabs or cotton wool. Wrap the stump and the entire pastern region with a layer of cotton wool and use a cotton elastic bandage to keep it in place. Finally, apply a 10cm (4 inch) elastic adhesive bandage. Starting from the tip of the remaining claw, progress upwards, increasing the tension over the stump and continuing up to and above the fetlock. The latter is necessary to anchor the bandage securely; if it were to come off the consequences would be disastrous! Take care not to crush the accessory digits; the bandage can be laid over them, but its tension should be slackened and they should be packed around with liberal wedges of cotton wool prior to wrapping. This will prevent the skin necrosis that can occur deep to them if they are subjected to too great an inward pressure.

Once the bandage is secure, the tourniquet can be removed. By this stage it will probably have been on for at least a half to three-quarters of an hour. This does not seem to be harmful in any way and the author has often seen tourniquets *in situ* for an hour or more without deleterious effect. Remove the hobbles and assist the patient onto her sternum. Do not force her to her feet, rather let her get up in her own time. As soon as she puts weight on the foot blood is frequently forced through the weave of the bandage – if this is minor it can be ignored, but if it persists for 10–15 minutes or is excessive in amount, apply a second elastic adhesive bandage over the first and, if necessary a third. *Do not*, under any circumstances, remove the existing bandage.

Leave the bandage in place for four to five days. If it is taken off before that time the fragile clot is easily disturbed and haemorrhage can be severe. Thereafter, change it every five to seven days depending on the amount of exudate produced by the healing wound.

The wound cavity will begin to contract about seven to ten days after surgery rather like a flower closing and the wound area diminishes rapidly. Concurrently, granulation tissue grows from the cut surfaces and at five to six weeks is usually flush with the skin edge. Skin contraction continues and when the wound is about 30mm

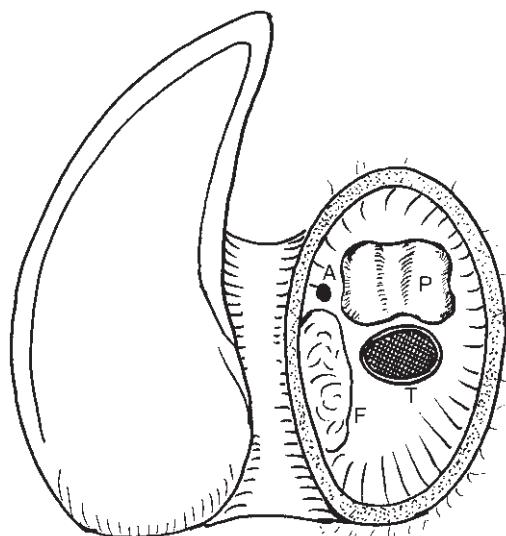

Fig. 66.8 This shows the anatomic relationships of the structures remaining after amputation. A is the arterial stump; F is the fat pad; T is the transected flexor tendon bundle and P is the distal end of the first phalanx.

across the bandage can be left off. Exuberant granulation tissue is not a problem at this site.

Occasionally a cleft persists in the granulation tissue bed and wound closure stops. This usually shows three to four weeks after surgery and the likely cause is incomplete stripping of the articular cartilage. If there is no progress over one week, reanaesthetize the site, cut out the granulation tissue and recurette the bone end.

If surgery has been delayed, infection may have established itself proximal to the amputation site. In these circumstances, and especially where tendon sheath is involved, the lameness and swelling will persist despite some wound closure. No hard and fast rules can be given as to when to give up hope of healing but, if there is no improvement in the condition of the distal limb or the lameness within two weeks of surgery, then resolution is very unlikely and the animal should be slaughtered on humane grounds.

Other techniques: The disarticulation technique described here is somewhat more complicated than those which use an embryotomy wire, either to cut through the phalanges or to carry out the entire amputation. Its use is justified because transection of either the second or first phalanx opens up their medullary cavity to an infected environment, resulting in a fairly high incidence of osteomyelitis following such procedures. In addition the nutrient foramen of the bone may also be destroyed leading to necrosis of the remaining fragment. A second distinct advantage of the disarticulation method is that it produces a cup-shaped wound cavity which maximizes the potential for healing by skin contraction. In contrast, the use of an embryotomy wire for the entire amputation produces a flat wound surface. This does not favour skin contraction and wound closure is often considerably delayed.

However, there is no doubt that this technique takes much less time than disarticulation and it can be performed without casting the cow; for these reasons alone many busy practitioners prefer it. With the foot anaesthetized, locate the wire loop in the interdigital space, checking that it begins to bite above the coronary band. The aim is to amputate through the distal third of P1 (i.e. distal to the nutrient foramen) so initially angle the direction of cut proximally. When the wire is at the correct level, change the plane of incision to lie at right angles to the long axis of the phalanx and complete the amputation. It is worth checking carefully to ensure that it is indeed P1 that has been cut and not P2, otherwise ischaemic necrosis of the remaining fragment of the second phalanx is very likely. Otherwise postoperative management is the same as for disarticulation.

Avoid techniques which call for sutured flaps of skin over the stump. This operation at best can only be

regarded as clean and never sterile. Sutured wounds in this environment always succumb to infection and to post operative haemorrhage and swelling and always dehisce.

Surgical correction of an umbilical hernia

The reasons why umbilical hernias develop in some animals are not fully understood. It is presumed that in some there is a failure of the normal closure mechanism (see p. 182), although there is no doubt that many previously normal calves are found to have hernias following a bout of 'navel-ill' or umbilical infection. This also accounts for the incidence of navel abscesses which can mimic hernias and for the fact that hernias and abscesses can co-exist.

Hernias are broadly classified into those where the contents are easily returned to the abdomen, i.e. 'reducible', and those where the contents are not, the 'non-reducible'. The former, which are in the majority, are easily diagnosable and cannot be confused with an abscess. The latter, however, present as a firm swelling which could be either an abscess or a combination of both abscess and hernia. In these suspect cases, use needle puncture and aspiration to determine which is what. Puncture the swelling from both its caudal and cranial aspects, using a separate needle for each puncture to prevent possible transmission of infection. Use a large gauge needle and much suction as the pus in these abscesses is often quite thick.

Small hernias, i.e. those with rings which are two fingers' width or less, do not usually need repair. The animal grows around the hernia and it is insignificant. Some surgeons recommend closure because of the risk of strangulation of herniated viscera; this risk is very small and the author has seen only one case in over 20 years. In addition, the hernial content is almost always omentum rather than the vulnerable small intestine. However, hernias which are 3 fingers' width or more are often quite pendulous and can become traumatized. They can also become significant cosmetic blemishes in later life. Occasionally, the abomasum can become lodged in large hernial sacs although this does not seem to create any clinical problems for the animal.

Technique: No special instruments are needed.

The calf should be prepared by being starved of all food for 24 hours. As well as being a routine preparation for anaesthesia this creates a slack abdomen during surgery which helps with ring closure. The surgery should be performed under general anaesthesia, or under heavy sedation, with the surgical site anaesthetized by a field block. With the patient in dorsal recumbency, excise a fusiform (Fig. 66.9) shaped area of skin centred on the cicatrix at the hernial apex. Try and

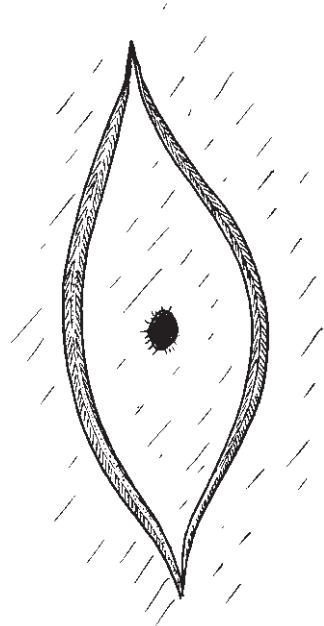

Fig. 66.9 A fusiform incision around the cicatrix.

estimate how much surplus skin is to be removed and adjust the width of the excised portion accordingly; err on the cautious side as more can be removed later. Separate the skin of this area from the underlying fascia by blunt dissection, though at the cicatrix it is firmly attached and may need to be cut. Next, using blunt dissection with a scissors tip, and beginning at the cicatrix, dissect back the multiple layers of fascia in a radial fashion to expose the discrete, thick, peritoneal hernial sac which lies deep to them. This is facilitated by grasping the cicatrix with an Allis or similar forceps and applying upwards traction to tense the tissues. As the fascial layers peel back, the sac becomes more obvious and eventually becomes completely exposed, along with the now easily discernible edge of the hernial ring. Clear the fascia back from the edges of the ring for at least 1.5 cm all the way round so that there is a clear shelf of aponeurosis into which the closure sutures can be laid.

Invert the sac and contents into the abdomen; if they go easily, as most do, there is no need to open the sac. If the contents are irreducible, the ring will need to be enlarged. Carefully, so as not damage the hernial contents, make a small opening in the sac at the caudal or cranial ring margin. Using a grooved blade director if available, or any blunt instrument which can be inserted between the contents and the ring as a shield, enlarge the ring by cutting caudally or cranially as appropriate. In most cases the ring only needs to be enlarged to a small extent before the contents and subsequently the

sac can be inverted into the abdomen. There is no need to suture the sac, only to close the now enlarged ring in the usual way.

For closure, use strong, non absorbable suture material which forms a secure knot. Monofilaments are not ideal and the author prefers a sheathed multifilament type of suture. There is no need to use any complicated suture patterns to overlap the ring margins, e.g. the so-called 'vest-over-pants' technique, as a simple apposition with simple interrupted sutures is entirely sufficient. The former creates a bulky mass of tissue which in turn creates a poor cosmetic effect. Also there is no need to 'freshen' the ring edges.

Insert the first suture some 1 cm beyond the caudal or cranial ring edge, then progress along the ring laying sutures every centimetre or so to finish one centimetre beyond the ring edge at the opposite pole (Fig. 66.10). Use the finger of the 'spare' hand to protect the abdominal viscera from the point of the needle. Lay all the sutures before tying and clamp each pair of free ends with artery forceps to prevent them from pulling out or becoming tangled. Tie the sutures one by one, starting with the outer ones and progressing towards the middle. Pull each suture tightly enough to appose the ring margins and then a little more to create a mild compression effect. If tied in the conventional way the first throw often slips as tension comes on it; to prevent this either use a stitch holder while the second throw is being applied or, alternatively, make the first throw a triple rather than a double. This will usually resist the applied tension sufficiently for the locking throws to be completed.

Close the fascial layers over the ring sutures with a simple continuous pattern using absorbable suture, having first trimmed off any excess tissue that may prevent a flat closure. If the skin edges are still apart, put in a subcuticular layer to bring them together. More likely there will be some surplus skin and this too can be trimmed away, being careful to maintain the fusiform shape of the final deficit. Close the skin with either a simple interrupted or interrupted horizontal mattress suture pattern. Finally, to apply pressure to this ventral and dependent wound, and to protect it, sew on a Stent bandage (Fig. 66.1).

The repair of large hernias: To repair hernias which have large rings over four to five fingers in width, most surgery texts advocate the use of stainless steel or synthetic mesh to fill the defect. The author has had little success with these as, no matter how tightly they are sutured in place, they invariably sag under the weight of the viscera so that the final result is little better than the original hernia!

An alternative and effective method is to create a slack abdomen by depriving the animal of roughage for

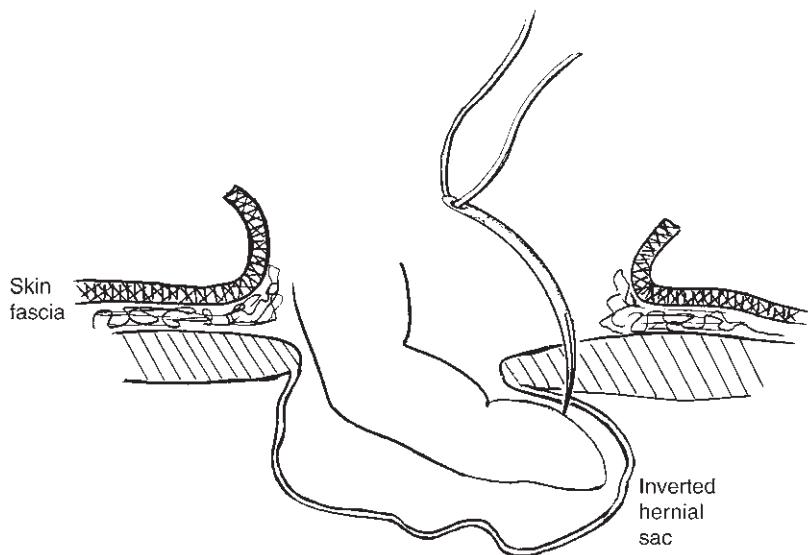

Fig. 66.10 Illustration of how the index finger is used to guard the advancing needle tip when laying sutures to close a hernial ring.

some 48 hours prior to surgery and then to carry out the repair as described above. Be sure to use strong suture material and to take good solid bites of the fibrous aponeurotic tissue surrounding the ring. One modification which helps a great deal is to have an assistant apply upwards traction equally and simultaneously on all the laid suture ends to bring the ring edges together before the row is tied off, one suture at a time. Using this technique and preoperative fasting, even the largest hernias can be repaired satisfactorily.

Dehorning of an adult

In the past this procedure was commonplace; nowadays it is done less and less since most cattle are debudded as calves. As a consequence, many students may not see the procedure performed at all.

Dehorning should be done in the winter months when the risk of fly-strike is at its lowest.

Anaesthesia: This is a technique which relies heavily on good restraint of the animal and the use of a 'crush' and the help of a strong and competent assistant are essential if a rodeo is to be avoided.

For most routine cases the standard cornual nerve block is sufficient. A common mistake is to use too little anaesthetic solution: at least 10ml should be infiltrated across the path of the cornual nerve. Redirect the needle several times during the injection to saturate a large volume of tissue and increase the chances of a successful block. Bleeding from the injection site is normal and a good indication that the needle was in the correct place. Another error which can lead to problems is to attempt surgery too soon after the injection was made. Wait for at least 10 minutes before beginning to cut and,

if several animals are to be done, anaesthetize and operate on them a batch at a time. Be sure to use an anaesthetic solution containing adrenaline which has a long duration of effect, and be sure that there is enough help available to persuade the animals to enter the crush a second time!

Animals with very large horns and therefore a broad diameter at the skin–horn junction often require an additional ring block for full analgesia. If in doubt carry out this procedure at the outset to avoid undue pain and the consequent non cooperation of the patient. The skin at the base of the horn is tightly applied to the skull and infiltration can be difficult. Slide a long, relatively narrow gauge needle (e.g. 19G) under the skin and inject the solution as the needle is withdrawn. Concentrate on the caudal aspect of the horn base as the 1st and 2nd cervical nerves can innervate this area of skin–horn junction and they will not have been affected by the cornual block.

Surgical technique: There are many methods for removing the horns; the commonest are shears, embryotomy wire and the butcher's saw. Shears can be used for young stock where the horn and cornual process is soft, but they are well nigh impossible to use if the horn is mature or the horn base is very wide, as in the Welsh Black breed. They allow very rapid removal of horns, though if used carelessly they may not cut the horn low enough and therefore not amputate a complete circle of the keratogenic tissue which lies at the skin–horn junction. In addition to the long term complication of horn regrowth which may result, there is the more immediate problem that a cut made too high amputates the cornual vessels after they have entered the bone of the cornual process, making haemostasis extremely difficult.

Embryotomy wire is silent in operation, resulting in better patient cooperation; it allows for the direction of cut to be changed and provides good intrinsic haemostasis. However, the push/pull action needed is very tiring, the wire often jams in the cut, especially if it is used too fiercely, and it is very prone to break.

The author's preference is for a heavy butcher's saw which cuts with its own weight and whose use involves a more congenial action than the embryotomy wire.

With the animal in the crush, the assistant should, using a 'nose lead' ('nose grip', 'bulldog'), bend the animal's neck sharply to one side to move one horn away from the crush door. This often causes the head to tilt to one side and it should be straightened as much as possible before cutting begins. At this stage check that the anaesthetic has worked and that the whole of the horn base is desensitized. If it has not been done already, clip the hair from around the base of the horn then position the saw blade some 2.5cm from the medial horn base. Angle the blade towards the point where the ear meets the head and begin sawing. Occasional animals object violently even when the horn is apparently completely desensitized and the blocks have been repeated or supplemented with a ring block. In these cases it is likely that they are reacting to the noise of the saw in their heads and a change to an embryotomy wire will solve the problem.

Saw swiftly through skin and bone to emerge just above the ear. Take care not to lift the skin from the ear and, if this seems likely, cut the remaining skin tag with scissors.

Haemostasis: When the horn is finally detached from the head, haemorrhage can be impressive. However, it is not life-threatening and can easily be temporarily stopped by finger pressure. Many techniques of haemostasis have been described and advocated but the simplest and most effective is torsion or twisting of the bleeding vessels.

With a robust pair of artery forceps, grasp the vessel ends firmly, apply gentle traction and spin them about six or so revolutions or until they break off. This will, in most cases, completely stop the bleeding or at worst reduce it to a small point of seepage. The largest vessels are always to be found at the ventral, rostral edge of the skin wound and, if the cut is made low enough, will be exposed for several centimetres of their length. If they are not, grasp the bleeding, severed end of the artery and, using gentle leverage over a finger, expose a sufficient length to be twisted. Do not attempt occlusion by snapping off the vessel end, as is occasionally recommended; a high proportion break way below skin level and continue to bleed from inaccessible depths. If these large vessels are occluded in the manner described most

of the remaining bleeding points stop or slow to a level where they can be ignored.

In those cases where the horn and cornual process have been sectioned too high the vessels will continue to bleed from the vascular canals within the bone. They cannot be picked up in artery forceps and are a nuisance. The time-honoured way of dealing with these is to insert a sharpened matchstick point into the hole to plug it. Although seemingly crude in these days of modern technology, it works, and the presence of the wood fragment does not appear materially to affect healing in any way.

Post operative course: Treatment of the resultant wounds with antibacterial powders and aerosols is widely practised. However, its effects are likely to be cosmetic only and the author uses no wound dressing without apparently affecting the speed or course of healing.

Post operative care must involve examining the animals every few hours for the first day or so in case there is secondary haemorrhage; thereafter daily monitoring will be sufficient. Advise the farmer to feed hay off the ground and not from overhead racks as this diminishes the amount of seed and dust contamination of the exposed frontal sinus. In the normal course of events the hole will scab over within one or two weeks, with complete healing by skin contraction and epithelialization taking several months.

Complications: Secondary haemorrhage is not common provided the largest vessels have been dealt with properly. However, fighting or rubbing of the wounds can occur as the analgesia wears off and bleeding can be severe. Identification of the source of the haemorrhage is almost always impossible as the side of the head and the surgical site are covered with a mass of blood clot which effectively hides the bleeding point. The area is now completely sensitive again and the animal usually vigorously resents its handling. The quickest and least painful remedy is to apply pressure. Place a large pad of cotton wool directly over the horn stump and bind it down tightly with several rolls of 10cm (3 inch) adhesive elastic tape wound around the head. Leave the ears protruding, as they help to prevent the bandage slipping, and take care not to constrict the larynx or trachea. Although apparently crude, it is a very effective method and avoids the need to reanaesthetize and explore the site in an often fractious animal. Some individuals may be extremely anaemic after such haemorrhage and a small number may require blood transfusion. As a rough guide, if the animal is able to stand and move around without being too ataxic it is not likely to require such measures. However, if in doubt, transfuse.

Long term complications are sinus empyema and fly-strike. Farmers must be instructed to call for veterinary attention if a recently dehorned animal becomes dull or anorexic. In these cases the sinus should be examined, if necessary by lifting the scab. If infected, or affected by fly strike, give systemic antibiotics and treat locally by irrigation with copious amounts of water to remove the pus or larvae. Repeat the irrigation daily until the sinus is clean and healing is progressing well.

Eye enucleation (see p. 922)

The common indications for eye enucleation in cattle are panophthalmitis and conjunctival or scleral squamous cell carcinoma. The presence of infected or tumour material within the conjunctival sacs in these cases precludes a subconjunctival approach through the palpebral fissure and so most large animal enucleations are done by a transpalpebral technique. With this method, the eyelids are sewn tightly together to trap infection or neoplastic material with the conjunctival sacs and the globe is removed intact to maintain a sterile wound.

Anaesthesia: In tropical countries where ocular squamous cell carcinoma is rife, enucleation is a common procedure and is usually done under retrobulbar block. This is a relatively simple technique which is described in many textbooks but, if only the occasional enucleation is done, and facilities are available, then the lack of movement and relaxation of general anaesthesia makes for much easier surgery!

Technique: Prepare the eye by fine clipping of the eyelashes, lids and periorbital region, followed by removal of debris and discharge from the conjunctival sac. Sew the shorn eyelids together *tightly* with an O or I non-absorbable suture, laying the sutures close to the eyelid margins. The lids and surrounding area can now be prepared for surgery.

Incise the skin of the upper lid in a line parallel to the lid margins and some 4mm outside the suture line. Deepen the incision carefully to expose the subcutaneous fascia. Using Metzenbaum or other similar scissors blunt dissect under the skin of the eyelid, through the circular muscle of the eye (*orbicularis oculi*), until a probing finger shows that the dissection plane has reached the boney rim of the orbit. Extend the skin incision the length of the upper lid and the dissection plane to the remainder of the dorsal orbital rim. Repeat the process on the lower eyelid so that the incisions above and below the suture line meet beyond the medial and lateral canthi in a fusiform shape. Make sure that the dissection planes within the lids remain superficial until the orbital rim is reached; this will help prevent acci-

dental rupture of the conjunctival sac and contamination of the wound.

To penetrate into the orbital cavity, retract the upper eyelid skin and use a finger tip to locate the boney edge of the mid upper orbit. With a scalpel cut just below the bone edge and parallel to it. Once an access hole has been created, use a curved-on-flat scissors to extend the aperture laterally and medially, keeping close to the orbit rim all the way round. Leave the medial canthus until last as the largest vessels lie here and their bleeding can be difficult to control. Up to this point haemorrhage is not usually a problem and it can be controlled by conventional means. When the medial attachments are severed the globe becomes free and relatively mobile. If bleeding from the medial vessels is severe then hard finger pressure for a minute or so should reduce it to manageable proportions. These vessels are often difficult to identify and even more difficult to grasp with artery forceps so if first attempts fail, apply pressure to the area for a little longer and then proceed with freeing the globe from its deep attachments. This is done by putting outward traction on the globe, inserting a heavy pair of curved-on-flat scissors into the gap between globe and orbit and cutting the taut tissue. As the globe becomes progressively looser it can be pulled further from the cavity and access improves. Ideally the muscles should be detached close to their insertion on the capsule so that as much tissue as possible is left within the orbit to minimize dead space. Practically, poor access, retrobulbar fat and the inevitable haemorrhage mean that cutting is usually done blind and the muscles, fat and optic nerve are sectioned randomly. As soon as the globe is free lift it away and attend to any haemorrhage. Unlike the dog and cat, bleeding from the optic artery is not dramatic, there is no need for ligation, and at worst blood wells up slowly within the cavity and can be contained by firm finger pressure maintained for four to five minutes. It is not necessary to stop haemorrhage completely so as soon as it has slowed to manageable proportions suture the remaining skin of the eyelids together with horizontal mattress sutures of non-absorbable material. With the suturing completed, squeeze out excess blood from the socket through the incision line and sew a stent bandage (Fig. 66.1) firmly in place over the wound so as to exert a firm inward pressure. This controls residual haemorrhage and protects the wound.

If the conjunctival sacs and globe were removed intact, healing is likely to be uncomplicated. Remove the 'Stent' at two to three days and the sutures at about 10 days. Some authorities recommend instilling antibiotics into the orbital cavity before wound closure, but this is probably not indicated unless there is some contamination and routine prophylactic and post operative antibiotics normally suffice.

Where there is known contamination of the wound, first intention healing may still occur with vigorous antibiotic therapy, but an alternative method is to pack the cavity with sterile cotton bandage coated with anti-bacterial cream and layered concertina fashion. The free end is laid in the medial commissure of the wound which is sutured in the usual way apart from its medial 1–2 cm. The bandage is removed through this gap after two to three days and the socket eventually fills with granulation tissue. There is a persistent discharge from the drainage hole and routine management involves maintaining the patency of the aperture and clearing up the discharge. Irrigation of the cavity does not seem to materially affect the healing process. When the socket is full the discharge dries up and the medial sinus closes. This process can take several weeks.

Teat surgery (see Chapter 27)

Milk production is the *raison d'être* of the modern dairy cow. Inefficiency in any of the factors involved leads to her becoming unprofitable. The care of teats and the surgery that is frequently involved therefore deserve more attention than they often receive.

There are three enemies of successful teat surgery: the 3 Ms! Milk, milking machines and mastitis must always be taken into account by the surgeon.

A simple way to avoid these problems in the small proportion of surgery which is elective is to delay until the cow's next dry period. Often this option is not open as the majority of surgical procedures are emergencies. In these cases the surgeon must take steps to ensure that milk pressure does not build up within the teat, that the teat and surgical site do not have to bear the trauma of being milked, either by machine or by hand, and that adequate antibiotic cover is given.

In practice the former two requirements are met by using plastic indwelling cannulae, of which there are many designs. Use them liberally; they are relatively cheap and work well. However, bear in mind that as well as being a boon, they can also act as very efficient introducers of infection if used incorrectly. If they drop out, they must never be reintroduced, but must be replaced by a new one from the packet. Supply them in quantity with careful instructions as to their handling and the cleansing of the teat before insertion.

To protect against infection be scrupulously clean when introducing anything into a teat and use intramammary antibiotic preparations routinely after any form of teat surgery or while a cannula is in place. Systemic antibiotics too, although not often used, are indicated in cases of trauma and surgery to aid successful healing.

Restraint: It is impossible to be clean and deft when the patient's hind legs are flying around the surgeon's head! Use restraint and lots of it! For simple examinations, tail restraint, i.e. forcing the root of the tail vertically, is often adequate; it discourages kicking, although it will not stop a reaction if there is a sufficiently painful stimulus. A second level of restraint is a 'nose lead' or 'bulldog' clamp; again its effect is of discouragement rather than prevention of reaction. A more effective method is the 'udder cinch'. This is a length of rope with a loop in one end which is passed around the cow's abdomen just in front of her udder. The free end is threaded through the loop and pulled against it to tighten the cinch around the belly. Pull it tight enough to cause the cow to sway slightly then secure the free end by tucking it partially under the taut portion to form a quick release (Fig. 66.11); do not pull too tightly or the animal may go down! Used in combination these

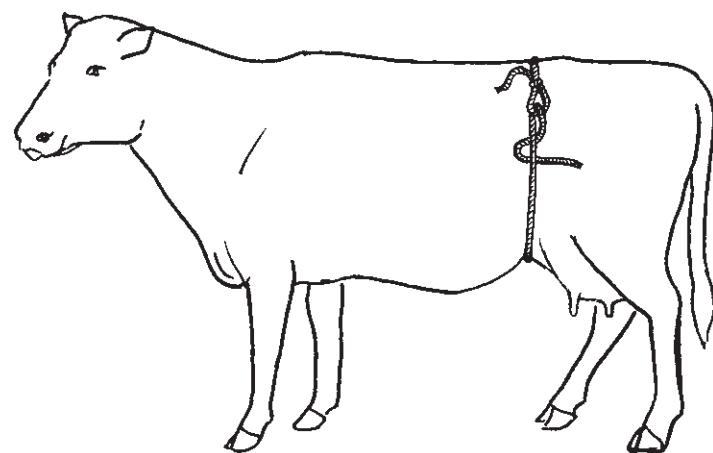

Fig. 66.11 An udder cinch.

three techniques of restraint will dissuade the cow from kicking even in the face of a considerable pain stimulus. Use them routinely as a cow's kick is quite capable of causing major injury!

When there is a need to perform fine surgery, e.g. the closure of a lacerated wound, the success rate will be much better if the cow is first cast, restrained and positioned to allow good access to the wound, better lighting and a more comfortable position for the surgeon.

Local anaesthesia: The usual method is a ring block at the base of the teat or an inverted V block (Fig. 66.12). In the former technique, the cow need only feel one needle prick, as the subsequent injections are made through the area of skin already desensitized. For streak canal and teat sinus surgery, more localized analgesia can be obtained by putting a tourniquet around the base of the teat and infusing local anaesthetic solution up through the streak canal.

Crush injuries: In days gone by when cows were shippen-housed, crush injuries were commonly caused by one cow swinging round to tread on her lying stall-partner's teat. Nowadays most cases are in older cows who tread on the hind teats of their own pendulous udders whilst getting up. These self-inflicted injuries usually consist of gross contusion to the teat walls with much haemorrhage into the substance of the teat, swelling, pain and acute stenosis of the streak canal.

If no major laceration has occurred, the treatment is one of systemic antibiotics for several days and insertion of an indwelling cannula to ensure that milk can be released from the quarter and that milking is avoided. Leave the cannula in place until the swelling and pain have subsided and the streak canal is functioning again; this can take up to 14 days.

Inserting the cannula into the painful and swollen teat can be difficult. After gentle cleansing of the teat and the canal area, locate the latter with a blunt ended probe. Insert theatraumatic end of a tube of intramammary antibiotic and lubricate the canal with the

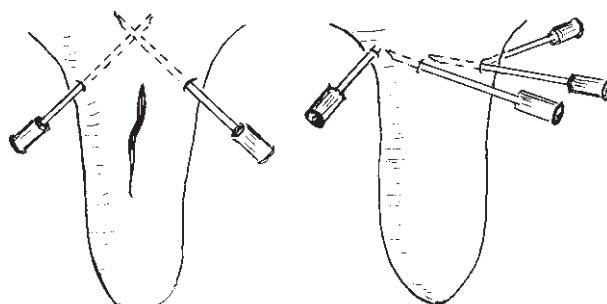

Fig. 66.12 Ring block and field block techniques.

cerate. Also use the cerate to lubricate the cannula before inserting it gently into the canal and spiralling it up into the teat. Once in place remove the cap and, after a pause whilst the lubricant with which the cannula is filled dissolves, the milk and some of the antibiotic will run out.

Streak canal stenosis: This long-term sequel to teat trauma is caused by fibrosis of the sphincter region. It results in an increase in time needed to milk the quarter and is a nuisance in a parlour system which does not tolerate delays.

In the first instance, dilatation of the canal can be tried, using a plastic teat cannula; this is inserted and left in place for 7 to 10 days. If this is ineffective use a teat dilater. This device has two arms which, when the instrument is in a closed position, form a probe-like shape. After insertion into the canal a knurled knob is turned at the end of the instrument and the two arms separate, stretching the lumen of the canal. These two methods are relativelyatraumatic and should be used if possible; however, their effects are usually temporary.

A more permanent result is obtained by incising the canal walls with a McLean's knife or similar. This is flat, double-edged (Fig. 66.13) and is used with a push/pull action. The teat is grasped firmly as if for hand milking, tensed and the probe end of the knife inserted into the canal. A sharp push causes the leading edges to cut as the blades pass through the canal. Once inside the blades are rotated through 90° and pulled sharply out, creating a cruciate incision. Use the narrowest blade size first and if after its single use the milk flow is good, insert a plastic cannula and allow the healing phase to take place around it. If the milk still does not run out easily, repeat the procedure with a larger diameter knife.

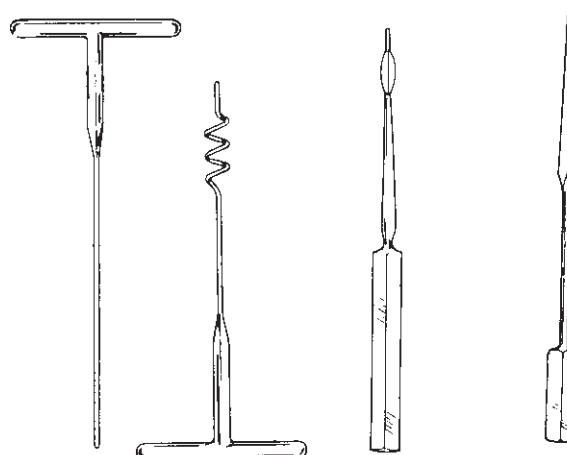

Fig. 66.13 Some common teat instruments; from left to right: a probe, a Hudson's spiral, a McLean's knife and a Hall's knife.

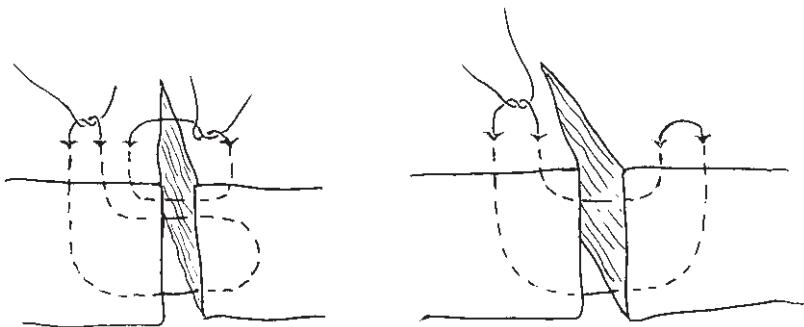

Fig. 66.14 Two suture patterns which provide apposition of both the deep and superficial layers of the teat wall.

Although effective in the short term this is also traumatic to the canal and sphincter, and post operative fibrosis will usually result in a sphincter of varying competence, with contraction of the scar tissue almost always causing a recurrence of the problem at some later date.

Lacerations: For the purpose of deciding on the appropriate treatment, teat lacerations should be divided into 'penetrating', i.e. those where the wound penetrates into the lumen of the teat or canal, and 'non-penetrating', where the deep layer(s) are intact.

Non-penetrating wounds: Teats heal extremely well if given the opportunity. If it is certain that there is no penetration and no leakage of milk through the wound, then allowing the wound to heal by second intention or granulation is less risky than attempting to suture and possibly entrapping ischaemic tissue and infection. There is then the distinct possibility that enclosed sepsis will erode through the deep layers of the wound and create a fistula into the lumen. Only if a non-penetrating wound is very fresh and exceptionally clean should suturing be considered. If there is doubt, treat by physical cleansing of the wound and by inserting a cannula to remove the trauma of milking. Systemic and intramammary antibiotics are indicated and usually healing is rapid with minimal scarring.

Penetrating wounds: Where the lacerations penetrate into the lumen there is not the luxury of deciding whether to suture or not. The wound must be closed to prevent the development of a fistula and inevitable mastitis and, because the surgery involved is delicate and must be done carefully, there is every reason to cast the patient and conduct the operation in a controlled and comfortable manner.

In cases where the cut is recent and is minimally contaminated, simple cleansing and suturing may be all that is needed. However, most wounds are much older when seen and are often badly contaminated. In these circumstances a much better rate of healing is achieved if the cleansing of the wound is supplemented by surgical

debridement of the wound margin. To achieve this, trim a thin (0.5mm) sliver of tissue off each wound edge along the whole of its length, extending the wound commissures slightly at each end. This results in fresh bleeding tissue being apposed and a consequent rise in the chances of primary union.

Use the suture patterns shown (Fig. 66.14) if possible as these compress both the superficial and deep layers, yet can be removed later. Sometimes the teat wall is exceptionally thin and these more complicated patterns are difficult to use; in these cases use simple interrupted sutures. Using fine, non-absorbable material, lay sutures fairly close to each other and do not penetrate the teat lumen.

On completion, allow the cow to rise then apply a bandage to the teat. Degrease its surface carefully with alcohol and allow it to dry. Place a small patch of non-adhesive wound dressing over the incision line and, using a 2.5cm wide adhesive bandage, start at the sphincter end and layer it directly on to the teat skin. Overlap each winding by about 30 per cent and secure the upper, free end of the bandage to the skin with a single superficially placed suture. Insert a cannula into the streak canal and remove the cap; this will prevent any build-up of milk pressure within the teat. Give systemic, broad-spectrum antibiotics. The use of intramammary cerates within the first few hours is questionable as their base is very pervasive and may penetrate the suture line if they contact it before there is some adhesion between the wound edges. After the first 12–24 hours they are definitely indicated as a barrier to any infection entering the teat.

Special cases: Sometimes the teat is lacerated horizontally near its end so that the cut lies close to or enters the streak canal. To discover whether there has been penetration, hand milk the teat and look for milk emerging from the cut.

Where the streak canal has been spared, the decision to suture or not will be based on the criteria already laid out. In these cases the laceration rarely extends even 180° around the teat circumference and so it usually does not gape too much. With a teat cannula in place

to minimize milking trauma, but otherwise left to their own devices, teat lacerations usually heal extremely well, being barely visible in a few months. This makes the possible repercussions of suturing and the trapping of infection much less acceptable.

On the other hand, when the streak canal has been cut its early closure is essential. However, before suturing begins, try to make some estimate of whether the distal tissue flap has an adequate blood supply for survival and healing; there is no point in trying to repair the defect if it has not! Sometimes it is obvious that the attachment of the flap is too small for a good supply to be present and in these it is best to cut it off immediately in the sure knowledge that it is not viable. With a cannula inserted in the remaining streak canal while healing takes place, the resulting slightly truncated teat is likely to be completely functional, although more liable to bacterial ingress and mastitis.

In other instances it is obvious that a good blood supply exists and repair can proceed; in yet others it is not so obvious and in these cases it is wise to give the tissues the benefit of the doubt.

Before beginning to suture, debride the cut surfaces carefully, if necessary cutting a thin sliver off both surfaces of the entire wound. Also, and most importantly, insert a teat cannula through both parts of the streak canal so that they will be aligned during suturing and in subsequent healing. In the post operative period, examine the wound often and remove the sutures from any part that looks as if it may dehisce. In this way pus pressure is not allowed to build up and disrupt healing further.

Transection of the teat: Milking machines need very little length of teat to hold on to, so if after the acci-

dental amputation an inch or so remains it is worthwhile attempting some reconstruction. Trim the end of the stump so that it lies roughly at right angles to the long axis of the teat, then insert a purse-string suture around its circumference close to the cut end. Draw the purse-string tight to compress the sinus opening snugly around a plastic cannula. Fashion two or three stay sutures to anchor the cannula in place and remove its cap or plug. With heavy antibiotic cover the teat end will heal around the cannula into a semblance of a streak canal. There will, of course, be no sphincter and milk leakage and bacterial ingress are major hazards. However, as a salvage operation it will often allow completion of the lactation and even a subsequent one.

Repair of congenital and acquired teat fistulae: Congenital fistulae are usually first noticed when a heifer calves and comes into milk. The most likely explanation for their presence is that they are the streak canals of otherwise vestigial, supernumerary teats. Acquired fistulae are the result of wounds to the teat and failed repair of penetrating lacerations. They are a nuisance in that they leak milk, which causes bacterial multiplication on the teat surface and hence milking machine contamination. They also allow ingress of infection into the quarter and attract flies. To avoid the complications associated with open teat surgery, delay if possible until the next dry period. Then with a cast, restrained cow and the maximum cleanliness available, excise the fistula through all the wall layers by means of a fusiform incision. This shape causes the minimum of distortion on closure of the wound. Use the suturing techniques described above, apply a bandage post operatively and give systemic antibiotic cover for several days.

Introduction

It is generally believed – and frequently repeated in the literature – that ‘stress’ is the major challenge to the welfare, health and productivity of animals in intensive commercial cattle enterprises. However, when it comes to drawing practical conclusions from the literature it becomes clear that scientists have been working with paradigms of animal stress that have done little to help the industry to cope with the biological imperatives that it must address as it seeks to manage intensive units with the minimum of animal distress. There is a lack of unanimity and clarity about which stimuli are so stressful that, on occasion, they can undermine the dynamic equilibrium established and maintained by a battery of homeostatic responses. Any stimulus that challenges homeostasis can be described as a stressor. It is a condition of life that homeostasis is under constant challenge by a multitude of stressors. Most of those encountered by cattle in a well-managed enterprise are amenable to the routine coping strategies of the animals; however, there are occasions when particular stressors seem to overwhelm the homeostatic responses, to the detriment of welfare, health and production. Apparently, the amount of stress an animal perceives depends on the intensity and duration of challenging stimuli and on the animal’s physiological and psychological state when challenged; as a consequence, the effects of a particular stressor may differ between one animal and another or, indeed, the same stressor may have different effects on an individual animal on

different occasions. Hence, when stress has adverse effects on health, different patterns of disease may emerge amongst animals exposed to the same stressors.

Historically, biologists have formulated paradigms of stress based on the concept of an integrated stress response jointly regulated by the sympathetic–adrenal medulla axis (Cannon’s fight/flight response to threat) and by the hypothalamic–pituitary–adrenal cortex axis (the general adaptation syndrome described by Selye). The two neuroendocrine axes have the capacity to alter metabolism and to redistribute metabolites to help the animal maintain homeostasis as it responds to stressors. While these feedback systems are capable of coping with the many uncomplicated and discrete stressors that animals encounter every day, it has been realized that the operating characteristics of typical feedback-controlled homeostatic systems are too narrow to account fully for the complexity of the interactive responses that culminate in stress-related pathology. By definition, homeostatic responses serve to maintain the constancy of the internal environment; each strives to return a regulated parameter to a set point that represents the central tendency of that activity. For instance, a fall in serum calcium concentration elicits an immediate increase in the secretion of parathyroid hormone, which should promptly bring the calcium concentration back to set point, its ‘normal value’.

Many stress disorders may not be amenable to such a straightforward resolution. Stressors may create perturbations within several interacting organ systems and they may require compensatory responses that elicit changes in the activities of other body systems that are governed by other regulatory actions. In those circumstances, the regulatory systems must have sufficient flexibility to enable them to recalibrate operating set points and to adjust the dynamic ranges of compensatory processes so that the interactions between the brain, the autonomic nervous system and the endocrine system are geared to defend welfare, health and productivity in the face of ongoing and evolving challenges. That type of construct is exemplified by the physiological adaptations of a mother during pregnancy: as gestation progresses the set points and operating ranges of

a plethora of homeostatic systems continually readjust in such a manner that the organ systems remain a harmonious team.

In this chapter we provide a synoptic overview of the homeostatic components of the ‘integrated stress response’ before proceeding to introduce a relatively new paradigm of stress that recognizes that stressors may activate multiple interactive mechanisms, that functional set points are subject to change, that disturbances in one body system may elicit compensatory changes in another and that compensatory changes come at a biological cost which may make the animal vulnerable to other unrelated stressors – which cost is a determinant of the clinical consequences of environmental stressors. We shall then examine the paradigm in relation to aspects of the more common problems encountered in intensive cattle enterprises: lameness, mastitis, infertility, metabolic disorders, welfare, behavioural problems and levels of production.

The stress system

For didactic purposes, it is convenient to refer to the neuroendocrine responses evoked by stressors as the work of the ‘stress system’ (Fig. 67.1). As mentioned,

the core of the stress system consists of two axes that serve to integrate neural and neuroendocrine activities: in one, a neural pathway links the sympathetic division of the autonomic nervous system with the adrenal medulla (the SA or sympathoadrenal axis); in the other, hormones link the hypothalamus with the adrenal cortex (the HPA or hypothalamic–pituitary–adrenal axis). The stress system is on continuous service: in the absence of significant challenge it has a baseline, circadian pattern of activity that delivers homeostasis at rest; when challenged by perceived stressors it makes the appropriate adaptive changes to maintain physiological equilibrium, delivering what might be described as stress-related homeostasis.

Anatomically, three elements of the nervous system interact to provide the regulatory core of the stress system (Fig. 67.2):

- Groups of noradrenergic neurones in the brainstem (the locus coeruleus–noradrenaline system; LC/NA);
- Peptidergic neurones in the hypothalamus, mainly in the paraventricular nuclei (PVN), that release corticotrophin-releasing hormone (CRH) and arginine vasopressin (AVP);
- Central neural projections that enable the LC/NA neurones and the PVN neurones to innervate and activate each other.

Mutual interactions between the two axes are not restricted to local neurocircuits. They are regulated in parallel by an extensive battery of humoral messengers: hormones, opioid peptides, cytokines, growth factors, metabolites – some stimulatory, some inhibitory and almost all counter-regulated by glucocorticoids (Chrousos, 2000). For instance, the secretion of ACTH (which can be stimulated by hypoglycaemia, social stress, fear, physical stress, exercise, acute illness or inflammatory cytokines) is inhibited by oxytocin, somatostatin and opiates, and is modulated by negative feedback by glucocorticoids. We shall have occasion to return to the importance of counter-regulation again, and again.

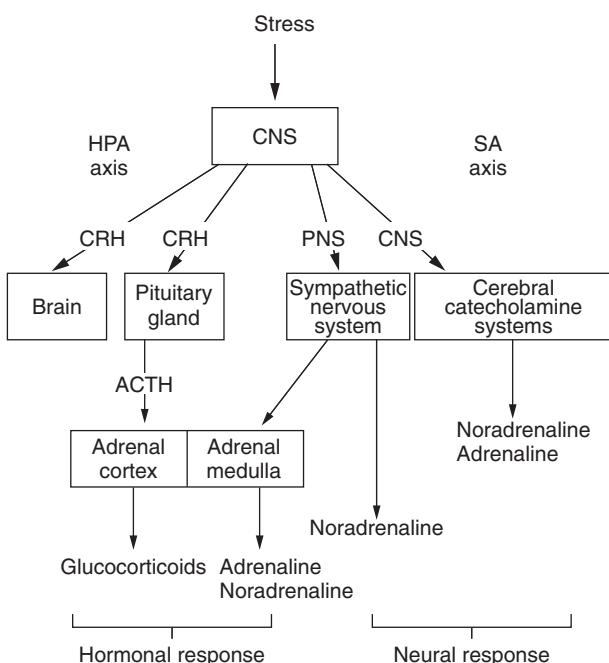

Fig. 67.1 Schematic overview of the stress system. CRH, corticotrophin-releasing hormone; HPA axis, hypothalamic–pituitary–adrenal axis; PNS, peripheral nervous system; SA axis, sympathoadrenal axis; ACTH, adrenocorticotrophic hormone.

The stress response

The principal function of the stress system is to release appropriate amounts of glucocorticoids and catecholamines from the adrenal glands and of noradrenaline at peripheral nerve terminals, specifically to assist the animal to cope with the demands of metabolic, physical, social or psychological stressors. The SA axis elicits responses much more rapidly than does the HPA axis; that is largely because it releases catecholamines

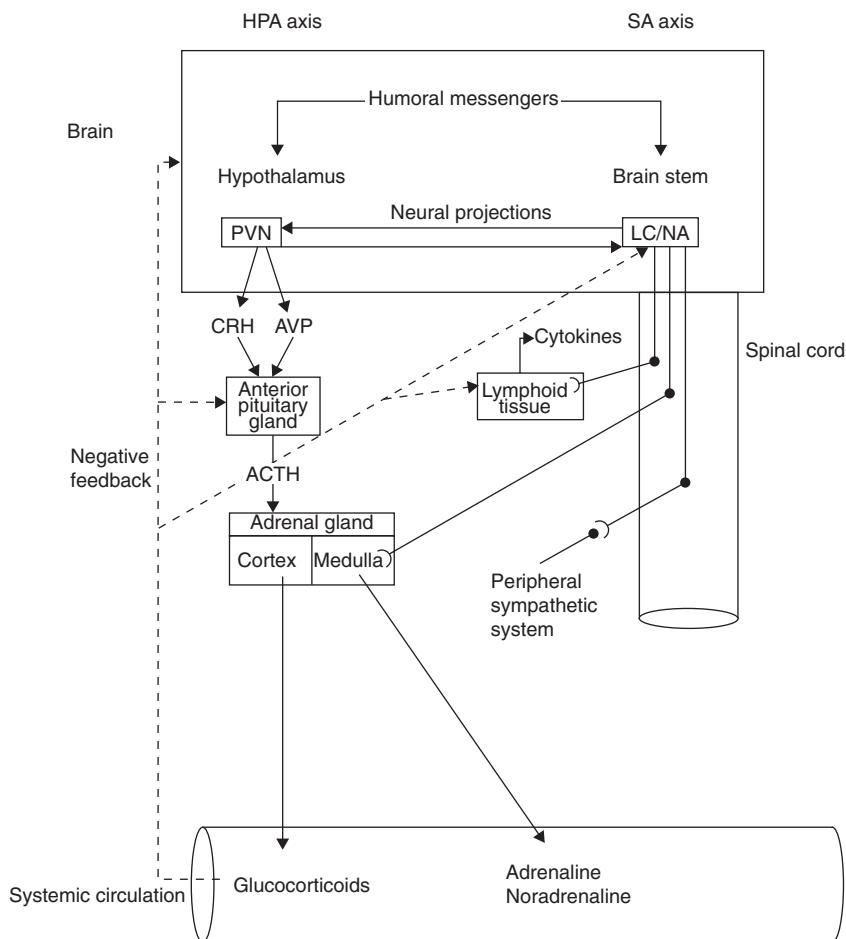

Fig. 67.2 A schematic representation of cross-talk between the neural, endocrine, and immune systems when challenged by stressors. The cell bodies of the peptidergic neurones that govern the hypothalamic-pituitary-adrenal (HPA) axis are located principally in the paired paraventricular nuclei (PVN) within the hypothalamus. They secrete corticotrophin-releasing hormone (CRH) and arginine vasopressin (AVP; also known as ADH), both of which stimulate the release of adrenocorticotrophic hormone (ACTH) from the anterior pituitary gland. ACTH stimulates the adrenal cortex to release glucocorticoids (principally cortisol). The glucocorticoids exert negative feedback at hypothalamic and pituitary levels of the HPA axis and they counter-regulate the activities of both the sympathoadrenal (SA) neurones in the brain stem (locus coeruleus-noradrenaline: LC/NA) and (but not shown) the central humoral messengers that modulate the stress response. Neurones in the PVN and in LC/NA mutually innervate and activate each other. The SA axis releases noradrenaline within the brain (not shown), adrenaline and noradrenaline from the adrenal medulla and noradrenaline from peripheral sympathetic nerves. The cells of the lymphoid tissues release various cytokines that interact extensively with the neural and endocrine systems (see Fig. 67.6). Solid lines represent activation; dashed lines represent inhibition.

that can achieve their objectives by modifying pre-existing substrates within their target cells, whereas the HPA axis releases steroids – hormones that direct the synthesis of new proteins that the target cells must manufacture before they can proceed to do the business. When the stress system is being aroused, the peptidergic neurones at the PVN and the noradrenergic neurones of the LC/NA activate each other and both contribute to the adaptive behavioural and physiological changes that ensue.

Response of the SA axis

When activated by stressors, the SA axis releases noradrenaline from neurones within the brain and from peripheral sympathetic nerve endings; in addition, it releases both adrenaline and noradrenaline from the adrenal medulla. The noradrenaline released centrally results in greater mental acuity ('arousal'), whilst the catecholamines released peripherally promote changes in metabolism and in the activities of

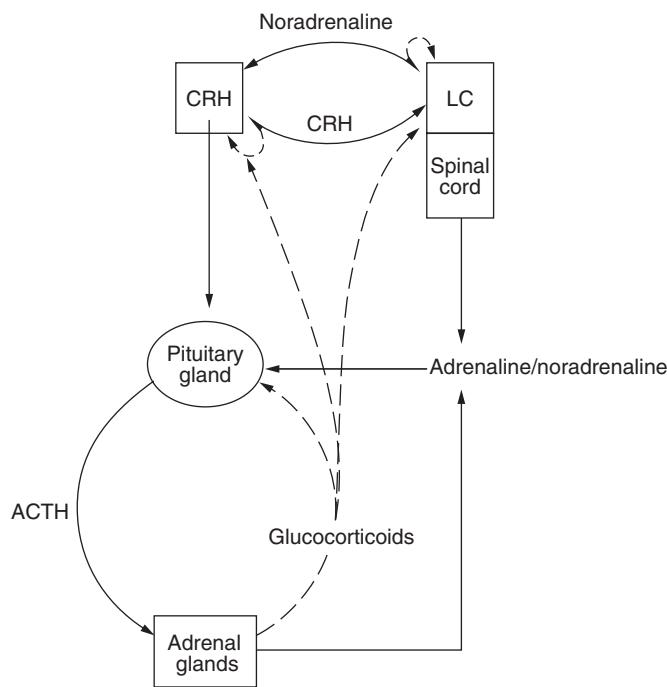

Fig. 67.3 Schematic diagram of the functional inter-relations between corticotrophin-releasing hormone (CRH) and the locus coeruleus–noradrenaline (LC/NA) system. ACTH, adrenocorticotrophic hormone. Adapted from E.O. Johnson *et al.* (1992). Solid lines represent stimulatory effects; dashed lines represent inhibitory effects.

the cardiovascular and respiratory systems to increase cardiac output, to facilitate oxygenation of blood, to raise blood glucose concentration and to deliver the enriched blood selectively to the tissues upon which the stressors are making the greatest demands.

Response of the HPA axis

The paraventricular nuclei secrete CRH and AVP in response to stressors. In cattle, the two peptides appear to be equipotent in stimulating the pituitary gland to secrete adrenocorticotrophic hormone (ACTH) which, in turn, stimulates the adrenal cortex to secrete glucocorticoids. As the final effectors of the HPA axis, glucocorticoids (chiefly, cortisol) participate in a multitude of activities that maintain whole-body homeostasis, including feedback regulation of both axes of the stress system (Fig. 67.3) and the metabolic readjustments (Box 67.1) required to sustain the physiological adaptations invoked to cope with stressors.

Counter-regulation

The stress response can increase the concentrations of adrenaline and/or glucocorticoids in the circulation.

Box 67.1 Metabolic responses to stress.

- Initially, insulin secretion is suppressed
 - decreased uptake of glucose by cells: hyperglycaemia
 - breakdown of stored triglycerides: increased fatty acids in blood
- Raised concentration of plasma catecholamines
 - breakdown of stored glycogen:
 - in liver → increased blood glucose
 - in skeletal muscle → increased blood lactate
 - breakdown of stored triglycerides → increased fatty acids in blood
 - increased secretion of glucagon
 - decreased secretion of insulin
 - increased gluconeogenesis (from glycerol, lactate, amino acids)
- Increased secretion of glucagon
 - breakdown of stored glycogen
 - breakdown of stored triglycerides
 - increased gluconeogenesis
- Rapid rise in secretion of glucocorticoids
 - breakdown of skeletal muscle
 - breakdown of stored triglycerides
 - inhibition of uptake of glucose by tissues (other than brain)
 - increased gluconeogenesis
- Increased release of arginine vasopressin (AVP, ADH)
 - retention of water
- Increased release of renin
 - activation of angiotensin–aldosterone system
 - retention of water and sodium ions, loss of potassium ions

The secretion of adrenaline is the more rapid response that underpins the flight/fight reaction, whereas the glucocorticoids give a slower response that helps to reallocate resources to meet the challenges to homeostasis and, equally important, to curtail the potentially harmful effects on health and welfare that could be exercised by exaggerated or unregulated autonomic responses. The importance of counter-regulation of the autonomic component of the stress response is brought into sharp focus by the conviction of our medical colleagues that the risk of myocardial infarction is significantly increased in individuals in whom sustained high catecholamine levels cause hypertension by sustained contraction of arterial smooth muscle and at the same time induce metabolic changes (insulin resistance, hypercholesterolaemia, hyperlipidaemia) that predispose to arterial damage and the formation of atherosomatous plaques in the coronary arteries.

Counter-regulation of the SA response is a key element in an animal's ability to cope with environmental stressors without incurring a residual physiological toll of inordinate proportions.

Coping with stressors

Animals may employ active coping strategies to reduce the aversive effects of stressors or they may use passive coping strategies to minimize the biological cost of the stress response evoked by the stressors. Moberg (2000) identified four general types of biological responses available to an animal to cope with stress: behavioural, autonomic, neuroendocrine and immunological (Fig. 67.4). Although all four biological defence systems are available to respond to a stressor, an animal does not always call on each of them to deal with each stressor: different stressors elicit very different types of biological responses. Nevertheless, in the vast majority of instances the response will contain some element of all four.

Behavioural responses

Behaviour offers the animal choices: to confront the stressor aggressively, to remove itself from the stressor or to engage in displacement activity that ameliorates the impact of the stressor. In many instances a behavioural response is the simplest and most biologically economic reaction to a stressor; for instance, simply walking away. However, some displacement activities (e.g. stereotypies such as compulsive walking) may expend an enormous amount of energy to no productive purpose.

Autonomic (LC/NA) responses

When the situation is not immediately resolved by a behavioural response, the reaction is directed by a generalized activation of the sympathetic nervous system including the release of adrenaline from the adrenal medulla. The preparation for 'fight or flight' is manifest by a heightened state of arousal, by increases in blood pressure, heart rate, respiratory rate, blood flow to skeletal muscles and consumption of energy and by decreased blood flow to skin, kidneys and digestive

tract. Another consequence of general activation of the sympathetic system is the release of renin, leading to activation of the angiotensin–aldosterone system, and consequent conservation of sodium and water, accompanied by excretion of potassium ions.

Neuroendocrine responses

Within minutes of the LC/NA response, the HPA axis is called to arms but, because steroids take longer than amines to elicit responses, there is a time lag before the glucocorticoids begin to exercise dominant control – with adrenaline, growth hormone and thyroid hormones in supporting roles. The combined activities of these hormones result in metabolic adjustments (Box 1) while the animal continues to resist the stressor(s) or until its reserves of energy have been exhausted. The first priority is to maintain blood glucose concentration and to conserve the glucose for utilization by the neural system. The liver can liberate glucose from stored glycogen. Skeletal muscles do not possess the full complement of enzymes necessary to do this; there glycogenolysis yields lactate, which the liver can use to produce new glucose (gluconeogenesis). Metabolic processes are altered so that peripheral tissues use lipids rather than glucose as the prime source of energy; glucocorticoids and growth hormone (GH) act in consort to facilitate that switch by inducing the breakdown of triglycerides stored in adipose tissues to yield the required fatty acids plus glycerol. These glucose-sparing actions are augmented by the synthesis of new glucose from endogenous substrates: the glycerol released from adipose tissues is made available for the synthesis of glucose in the liver (gluconeogenesis), as is the lactate released from muscle glycogen. Concurrently, the same hormones induce proteolysis in skeletal muscle, releasing amino acids that the liver also uses to manufacture glucose. The process of gluconeogenesis is regulated by glucocorticoids (HPA axis), by glucagon and by adrenaline from the adrenal medulla (SA axis).

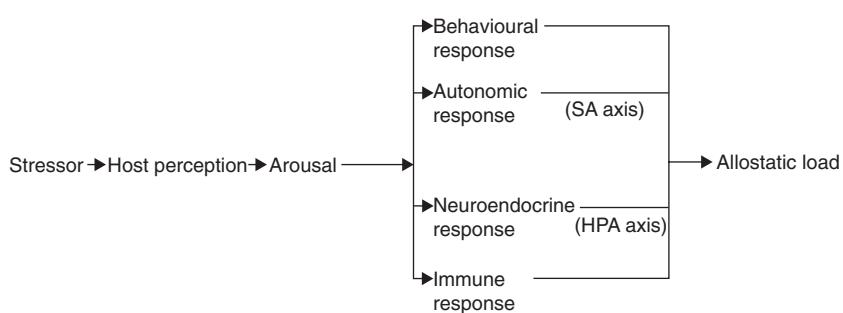

Fig. 67.4 Coping with stressors. SA axis, sympathoadrenal axis; HPA axis, hypothalamic–pituitary–adrenal axis.

Immunological responses

The two axes of the stress system are at all times engaged in bidirectional communication between the central nervous system and the immune system. The cross-talk is intensified during the stress response. The brain issues messages through the SA and HPA axes that affect the activities of the cells of the immune system, while products elaborated by various immunocytes affect the functions of the neurones at the centre of both axes. In brief, the corticosteroids and the catecholamines down-regulate the activities of the immune system: they inhibit many of the functions of leucocytes, macrophages and lymphocytes, and they decrease the production of many cytokines and mediators of inflammation. Also, it is believed that the endogenous opiates released in response to stress are, in general, immunosuppressive. Early in the response to stress there is increased release of growth hormone and prolactin, both of which enhance the immune response; however, the circulating levels of both hormones are decreased later in the stress response and, also, when there is recurrent or chronic stress. Thus, the net effect of stress is immunosuppression and increased susceptibility to some infectious diseases, particularly those that target the respiratory system or the digestive system. There is convincing circumstantial evidence that some bacterial, viral and parasitic pathogens themselves act as stressors that attenuate the immune response.

Physiological toll

If stress is intense and prolonged, the coping strategies may become part of the problem. Rapid production of glucocorticoids in response to a stressor is beneficial, provided an efficient shut-off can occur; chronic elevation of glucocorticoids persisting after the stressor has gone indicates poor adjustment and is detrimental to health. Prolonged elevation of glucocorticoids in the circulation can cause excessive breakdown of muscle protein, depletion of energy reserves, hyperglycaemia, immune suppression, attenuation of the inflammatory reaction, increased susceptibility to infection and delayed healing of wounds. The principal mechanism by which the body is protected from these deleterious effects is feedback inhibition of the HPA axis by the corticosteroids themselves.

The biological costs of stress

All stressors, no matter how innocuous, have some biological costs. There is a price to pay, even when the homeostatic balance is restored promptly. The real questions are: to what extent does the challenge dimin-

ish the body's metabolic reserves and how does this impact on health and welfare?

In the first instance, the biological cost of stress is met from the body's reserves of energy. For many short-lived stressors that cost is negligible: it is met from reserves without any impact on other biological functions. As an example, catecholamines secreted during stress stimulate the conversion of stored glycogen into glucose; once the stress has been alleviated, the glycogen stores are quickly replenished by gluconeogenesis; there is no lasting deficit. On the other hand, when there are insufficient biological reserves to meet the costs, resources must be diverted from other biological functions: for example, if a young heifer reared under very stressful conditions has to divert a significant fraction of the energy normally expended on growth and reproduction it is likely that her growth will be retarded and puberty will be delayed. In other words, for some persistent or intense stressors the cost is high, a significant burden on the body that places the animal 'at risk of developing pathologies' (Moberg, 2000). The gap between those two extremes is filled by examples in which the hidden costs of coping strategies so deplete biological reserves that the animals develop 'pathologies' when challenged by what might otherwise be considered to be rather minor, inconsequential factors. Such are the cases that raise the questions that need to be addressed by the clinician in the field: how does stress influence the pathogenesis of disease and what accounts for the variation in susceptibility to stress-related diseases amongst animals in the same, or similar, environmental circumstances?

The transition to pathology

There are several routes by which coping strategies can progress into pathology.

- If stress is intense and long-lived, the coping strategies may become part of the problem. The potential pathological consequences of prolonged elevation of glucocorticoid concentrations have been mentioned above. Persistent activation of the SA axis, which stimulates the renin–angiotensin–aldosterone system, may also translate into pathology: initially, by progressively increasing blood volume and raising blood pressure; later, as a consequence of the alterations in neuromuscular excitability due to hypokalaemia.
- Obviously, whenever coping strategies have exhausted the biological reserves of the animal it is to be expected that further challenge(s), even by inconsequential stressors, may translate into pathology.

- A coping strategy may increase the animal's exposure to environmental factors that damage its health (e.g. the housed subordinate cow that copes with dominant cows by standing and lying at a distance in damp, dirty, unsheltered locations) or it may deny the animal the opportunity to participate in activities that promote its health and welfare (e.g. limit its access to feed or, in the extreme, an animal exposed to chronic, unavoidable stress may develop 'learned helplessness', become recumbent and stop eating).
- A coping strategy may involve a physiological response that directly contributes to a pathological process (e.g. a very thirsty, salt-deprived animal consumes excess water and develops haemolysis and cerebral oedema: water intoxication).
- A coping response may attenuate or suppress an important component of the animal's normal defence system and leave it vulnerable to a disease unrelated to the original stressor (e.g. attenuation of the immune response by transportation stress renders an animal susceptible to respiratory disease).

In each scenario the transition to pathology is predicated on a changed (or changing) internal milieu that cannot be explained in terms of strict homeostatic dogma. The principle of homeostasis is that the body must hold all its regulated parameters within very narrow operating ranges centred on the relevant 'normal' set points. Students of stress are well aware that that is not how things are in the real world. It is recognized that an animal exposed to intense or persistent stressors may have to vary many parameters of its internal milieu and match them appropriately to environmental demands. Sterling and Eyer (1988) referred to this principle as allostasis, meaning 'stability through change'.

Concepts of allostasis and allostatic load

When an animal perceives a situation as stressful it makes the behavioural and physiological responses that it considers most appropriate. Experience will help the animal assess how much of a threat is posed and what it requires to do to ward off that threat. If a particular stressor has been encountered previously and been found to be easily controlled, the response will be measured accordingly; habituation will ameliorate the physiological perturbation and the biological cost will be reduced. The responses are mediated by the SA and HPA axes and, if the stressor is mild and short-lived, homeostatic regulation will modulate the perturbations within tolerable operating ranges until the regulated

parameter(s) can be returned to the fixed set point(s). A simple example: if, for whatever reason, blood glucose concentration falls, the neuroendocrine axes will set about correcting the deficit by typical homeostatic responses that implement glucose-sparing measures augmented by gluconeogenesis.

It is entirely appropriate that those components of the internal milieu that are absolutely essential for life (for instance, oxygen tension, pH, body temperature) should be governed according to strict homeostatic principles that operate within narrow ranges about fixed set points. However, life expects the body to be capable of adapting to marked variations in its natural environment and that is possible only if the animal can continuously readjust a number of parameters toward new set points and wider operating ranges that are appropriate to the challenging circumstances in which it finds itself. Put very simply, different circumstances demand that the several interacting systems vary their homeostatic set points to ensure that their activities remain in synchromesh. Allostasis enables the SA axis, the HPA axis and the cardiovascular, metabolic and immune systems to effect the changes in the internal milieu that make the most beneficial use of the animal's biological resources; in brief, they induce a new steady state based on a panel of readjusted set points in counter-balancing systems.

Allostasis is a useful concept but, as McEwen and Stellar (1993) pointed out, it does not take into consideration the strain on the body produced by the activities of physiological systems adjusting to repeated challenges, the consequent changes in metabolism or the impact of wear and tear on a number of organs and tissues that can predispose an individual to disease. They introduced the term allostatic load to describe the aggregate biological costs that result from chronic overactivity or underactivity of allostatic systems.

As McEwen (1998) perceived it, there are three phases in the body's response to challenge: it must mount an adequate allostatic response, it must maintain that response until the stress ceases and it must shut off the response when the threat has passed. Thus, allostatic load can accrue when:

- There is an inadequate response that leads to compensatory hyperactivity of other regulatory systems;
- The body is subjected to repeated challenges from multiple stressors;
- There is failure of habituation to repeated challenges of the same type;
- Delayed shut-down prolongs the response after the threat has passed.

When circumstances improve, with environmental stress consistently at a low level, the animal may

discharge much of the allostatic load, to the benefit of its health and production.

On the other hand, if life remains stressful the load will accumulate and the animal will find it progressively more difficult to make effective readjustments in response to further challenges: in a figure of speech, a point may be reached at which all the slack in biological reserves has been taken up and the next coping strategy will propel the animal into overt dysfunction. In many instances, the final challenge that breaches the boundary between the compensated state and 'pathology' may be relatively minor and, if it is identified, it may be assigned an exaggerated degree of causal importance that is an impediment to the exploration of the real sources of allostatic load within the herd, which must be the ultimate target for the dedicated clinician. More immediately, failure to see the 'big picture' may militate against the efficacy of treatment of the diagnosed ailment – it is unlikely that targeting what, in essence, may be just the tip of a dyshomeostatic iceberg will successfully restore the animal to full health and production. Recognition of the bases from which the allostatic load has accrued should enable the clinician to implement a more holistic, more successful, approach to the problem.

In summary, the concept of allostatic load provides a rational hypothesis to account for the contribution of environmental stress to the pathogenesis of dyshomeostasis, a sometimes precarious state of readjusted parameters that, when propelled into decompensation, can be manifest as any of a range of different ailments in individual animals within a herd.

Allostatic load and the veterinary practitioner

How should the concept of allostatic load inform the veterinary practitioner in the field? How does it relate to the major problems encountered in intensive cattle enterprises: lameness, mastitis, infertility, metabolic disorders, welfare, behavioural problems and levels of production?

'Life is stress, stress is life'

Life is a minefield of potential stressors that each creature has to negotiate by recourse to its repertoire of cognitive, behavioural, neural, endocrine and immunological modalities. The ability to adapt successfully to the multifarious challenges of life – or, in the words of Sterling and Eyer (1988), the ability of the 'organism to vary parameters of its internal milieu and match them appropriately to environmental demands' – is called allostasis. When the adaptive responses put those

parameters persistently outside their normal operating ranges – whether because of many significant challenges or because the allostatic responses remain turned on when no longer required – the body incurs a cumulative biological burden that constitutes its allostatic load.

The biological costs of each challenge to homeostasis are influenced by the genetic background of the animal, its previous history, the magnitude of the allostatic load it has accumulated already and the functional priorities of the current phase of its life cycle, as well by the nature of the stressor, its novelty, its intensity, its frequency, its duration and the types of responses it elicits.

Thus, when clinical disease is manifest the cascade of environmental factors that have contributed to the current state of the sick animal will have operated at two levels: the proximate and the ultimate. The proximate factors (infectious, metabolic, toxic or whatever) have made the immediate challenges that caused the presenting signs. The ultimate factors have been responsible for the allostatic load, for the depletion of energy reserves and the cumulative wear and tear of vital organs and their regulatory controls that have predisposed the animal to the ravages of the proximate stressors. In brief, allostatic load is the burden of costs that have been paid at several toll-bridges on the road to clinical disease. Increasingly, trends in intensive systems of animal production will force us to bring that toll into sharper focus in our deliberations on the pathogenesis and treatment of ailments and on the husbandry and welfare of farm animals.

The stress response can be mobilized in response to physical or physiological stimuli, and also in expectation of them. As is evident from the early part of this chapter, the brain is the coordinator of the body's responses to the stimuli: it decides whether or not a potential stressor poses a threat, and how the animal should cope with it. The cognitive appraisal of the environmental stimulus determines the response: if it is not perceived as a threat, it does not elicit a stress response. On the other hand, novel stimuli will be perceived as threats *ipso facto*, even though they may not be particularly aversive in character; the intensity of the responses will decline as the novelty wears off. It is neither possible nor desirable to isolate livestock from the aversive stimuli that are a feature of the complex, dynamic environment of the modern intensive cattle enterprise. Some types of mild stimuli are beneficial; for instance, they induce a state of arousal in which metabolic processes are adjusted for rapid expenditure of energy and they 'tune' the cognitive and motor mechanisms that the animal will call upon whenever it is challenged by a significant stressor. Furthermore, there is convincing experimental evidence that when the stress

system is activated in that manner, productivity is improved and some immune functions are enhanced, at least in the short term.

Practical considerations

The scientific literature, particularly the medical literature, has concentrated unduly on the negative aspects of stress, on its role in the pathogenesis of disease; in reality, the stress system has evolved as an essential defence mechanism that plays a very positive role in the survival of organisms beset by stressors. The task is to manage the sources of environmental stimuli to the mutual benefit of the animal and of the commercial imperative; that requires attention to the structure and hygiene of the physical facilities, and to the social contexts, metabolism, physiology, vulnerabilities and coping strategies of the animals. Several of those topics are dealt with in some detail elsewhere in this book; here, under several subheadings, we cherry pick some clinical conditions that illuminate the central thesis: that allostatic load is a significant factor in the pathogenesis of many ailments, that sick animals should be seen as sentinels of stress within the herd and that the therapeutic, prophylactic and managerial measures are unlikely to be entirely satisfactory unless that fact is taken into consideration. Although the vast literature on the stress response has yet to generate a unitary paradigm that would inform the clinical judgement of a veterinary surgeon in relation to those decisions, there are two less ambitious constructs, mentioned above, that are relevant to the message of this essay: the partitioning of metabolic fuels and the counter-regulatory activity of the corticosteroids.

Partitioning of metabolic fuel

Each organism has a limited energy budget from which it must allocate resources prudently if it is to maintain the body and perpetuate the species. When the supply of energy falls below total requirement, the available metabolic fuels are partitioned according to priorities set to ensure the survival of the organism (Fig. 67.5). The energy equation can go into negative balance either because the intake has been reduced below normal expenditure, or because the expenditure has been increased to meet special needs, as happens in early lactation or when the animal has to cope with major stressors. In the trade-off between competing energetic requirements, environmental stressors can exercise a defining role. Top priority is given to maintenance of basic cellular functions, thermoregulation and locomotion for foraging (not a problem in a modern cattle enterprise). When the short-fall is severe, less and less of the intake goes to growth, fat storage or reproduction; in extreme circumstances these activities will be suspended until they can be resumed when the energy balance has been restored.

Counter-regulation by glucocorticoids

As mentioned, negative feedback by glucocorticoids plays a significant role in protecting the organism against 'overshoot' by either limb of the stress system (Fig. 67.3). In addition, they contribute to the effort to conserve energy whenever stressors threaten homeostasis: they exert inhibitory effects at more than one point in each of the endocrine axes that regulate growth, thyroid function, reproduction and immune function (Fig. 67.6).

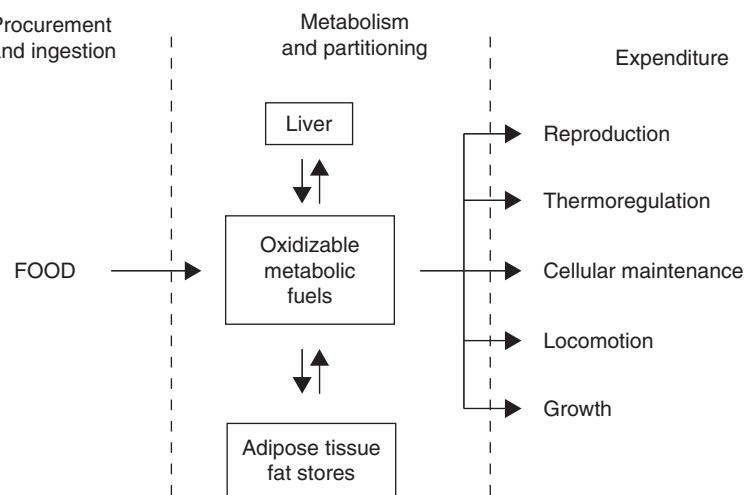

Fig. 67.5 Partitioning of metabolic fuels. When the supply of energy is insufficient to meet demands, non-essential processes such as reproduction and growth are deferred, and fat stores are mobilized to ensure that the essential processes of basic cellular metabolism, thermoregulation and locomotion are maintained. (After G.N. Wade & J.E. Schneider, 1992).

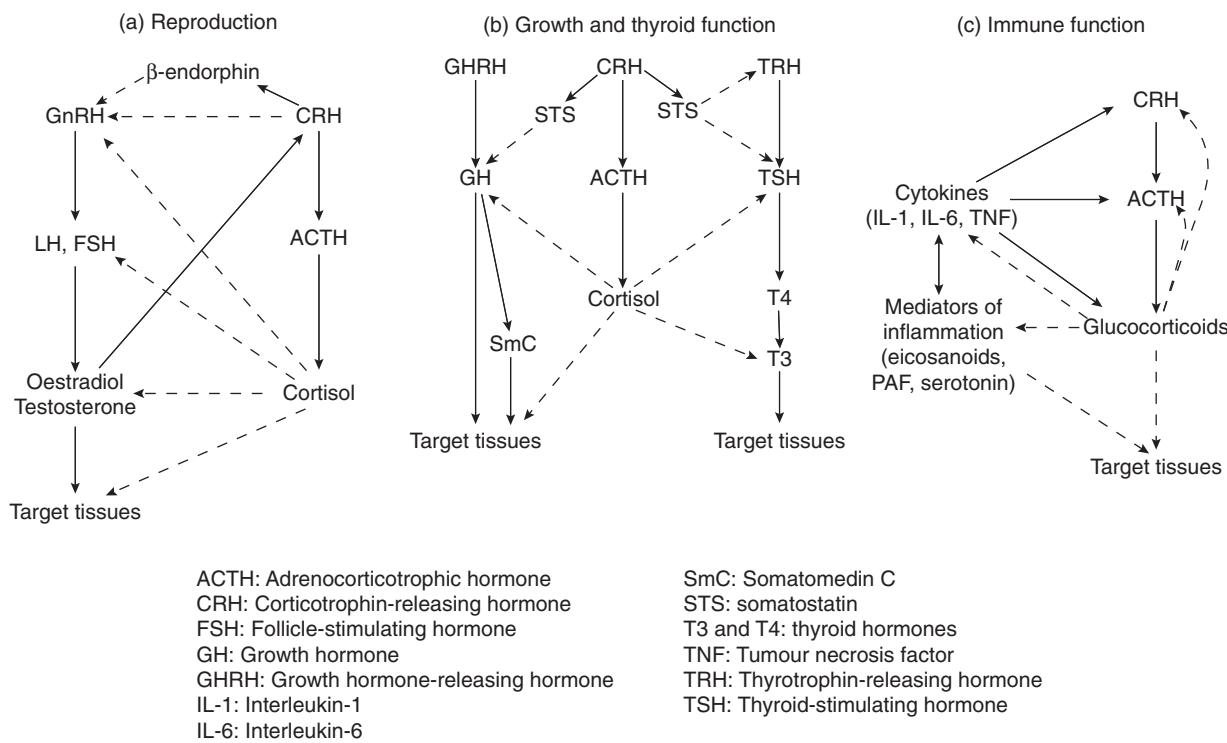

Fig. 67.6 Interactions of the HPA axis with the systems that subserve (a) reproduction, (b) growth and metabolism, and (c) immune function. Solid lines represent direct or indirect activation; dashed lines represent direct or indirect inhibition. (After Stratakis & Chrousos, 1997.)

Clinical implications

Social context (see Chapter 55)

Each herd of cattle develops its own social structure, a hierarchy in which social rank is held at a price. Social interactions within the group can be stressful: determined subdominant animals challenge the dominant animals; in turn, dominant animals bully subordinate animals. Several lines of evidence suggest that the magnitude of the allostatic responses to social stressors is influenced greatly by the social rank of the animal: the biological costs are greatest at the two extremes of the hierarchy. The allostatic load – and the loss in productivity – depends on the animal's perception of the threat to its well-being and on its coping strategy. The active coping strategy of the dominant animal can be as costly as the passive coping style of the subordinate animal. When an animal is exposed repeatedly to the same predictable stressors, the intensity of the stress reaction tends to decline progressively. This process of habituation appears to be stressor-specific; the animal retains the capacity to make an acute response to a novel stressor. Therefore, within a settled herd the toll of social stress can be attenuated by good stockmanship that seeks to shield the animals from all that they will perceive as novel, frightening, painful, unpredictable, frustrating or uncontrollable.

Social stress may be a source of significant allostatic load.

Foot lameness (see Chapter 31)

It is accepted that poor quality horn is a significant factor in the pathogenesis of foot lameness in lactating dairy cows. The defect in the horn is associated with impaired keratinization in the epidermis of the horn, a process that is known to be influenced by the dominant hormones in late pregnancy and early lactation. Particularly relevant to the present discussion is the evidence from hoof explants in organ culture that glucocorticoids inhibit the synthesis of hoof protein. It has been suggested that the elevated systemic concentrations of glucocorticoids during lactation could contribute to the deterioration in horn quality in the lactating cow. It is conceivable that other stressors that induce the release of more glucocorticoids would exacerbate that deterioration. For instance, poor quality horn that predisposes to foot lameness is not uncommon in recently-calved heifers joining the milking herd for the first time; in those circumstances, horn is being produced by an immature animal whose endocrine organs are secreting unprecedented quantities of lactogenic hormones augmented by the hormones released in response to the social stress – and whose metabolic stability is being challenged by the unaccustomed demands of her first

lactation. Thus, the presenting ailment may be a manifestation of a 'big picture' that incorporates a number of elements of systemic dyshomeostasis – abrupt exposure to a novel hormonal milieu, unrelenting demand for an unprecedented quantity of energy, and social stress.

Allostatic load may find expression in a presenting ailment that has no obvious anatomical link to the systemic dyshomeostasis that has made the host animal vulnerable to 'pathologies'.

Infertility (see Chapters 33–37)

Reproductive functions in the female are more susceptible to the effects of stress than are those of the male, for two reasons: firstly, because she has to budget for a vastly greater investment of metabolic resources over a much longer time; secondly, because stressors are prone to disrupt the precision with which a number of hormones must be secreted in appropriate quantities and in a delicately ordered and exquisitely timed sequence in order to establish a pregnancy. It is known that short-term stressors (such as fear engendered during herding, handling or transport, electric prods or stray voltage) can interfere with fertility if they challenge the cow at a critical juncture. To a considerable degree, the response of the female to stressors is predicated by a desire to conserve energy until the threat is past; clearly, that is the case when she falls into a negative energy balance and suspends her reproductive activities *pro tem*. Fortunately, the suspension leaves the regulatory neuroendocrine apparatus intact and normal business should be resumed when the energy balance has been restored. In reality, spontaneous resumption often takes longer than is ideal for the commercial enterprise; this is particularly significant in relation to the low calving rates achieved in the early post partum period – which can be a cause of considerable economic loss, especially in a herd where a seasonal breeding programme is in operation.

Over the past 20 years, the dairy industry in the UK has switched from a predominantly British Friesian cow population to predominantly North American Holstein cows and, further, it has engaged in intense selection for milk yield. The records show that over that period the pregnancy rate to first service has declined at an average rate of approximately 1 per cent per annum, and that atypical ovarian hormone patterns have been contributing factors to that reduction (Royal *et al.*, 2000). The response to hormonal therapy has not been consistently good; it has fallen considerably short of that which current knowledge of reproductive biology would lead us to expect.

A plausible hypothesis advanced to account for the decline in fertility in high-producing cows was that

reproduction is suppressed while the animals are in negative energy balance: that the hypothalamic-pituitary-gonadal (HPG) axis is inhibited while the cow 'milks off her back'. Most high-producing dairy cows enter the breeding season in a negative energy balance; some will not have achieved a positive balance before the end of the third month after calving, at which time they are expected to be in-calf again. From an energetic perspective, this means that the biological costs of reactivating cyclic activity of the HPG axis and its associated organs have to be abstracted from a budget that is in negative balance because it has to support, either in sequence or in parallel, the extensive hormonal changes (qualitative, quantitative and temporal) that accompany the transition from pregnancy to lactation; the biological costs of uterine involution; the extraordinary nutrient demands of lactation and the regulation of the associated metabolic adaptations; the extensive adaptations in cardiovascular and digestive physiology; the biological costs of immune defence of organs newly opened to ascending infection (uterus, mammary gland); the transition from housing to pasture and the associated meteorological and nutritional changes; together with any number of contingency costs. Despite all that massive drain on body reserves, approximately half of the mated cows conceive to first service. It is clear that although the energetic perspective provides a rational account of the drain on body resources, it does not provide a comprehensive explanation for either the infertility of a sizeable number of clinically normal cows or for the relatively poor response to hormone therapy in those animals.

It is likely that much of the infertility reported in clinically normal cows is due to unrecognized allostatic load; in other words, it is not a disease in the traditional sense, rather a suspension of service due to a fault in the signalling system. Therefore, the protocol for clinical assessment of cows being prepared for the breeding season should include a check-list of potential stressors to which the animals due for examination are most likely to have been exposed; the prophylactic management of the breeding herd should take account of the findings.

The effects of stress on reproductive functions are complex; however, it is reasonably close to the truth to say that most of the adverse effects are mediated by interactions between the HPA axis and the HPG axis (Fig. 67.6(a)). Corticotrophin-releasing hormone (CRH) can suppress the secretion of gonadotrophin-releasing hormone (GnRH) via an opioid-mediated mechanism, supranormal levels of androgens from the adrenal glands can distort the negative feedback regulation at the hypothalamus and pituitary gland and glucocorticoids can exercise inhibitory effects at all critical points in the HPG axis (and even as far as the target

tissues for gonadal steroids). It is probable that the most important factor in the suspension of reproductive activity is interference with the pulsatile release of GnRH by the hypothalamus, which alters the pulsatile release of LH by the pituitary gland that, in turn, regulates ovarian activity. However, in practice, inhibition at other points in the HPG axis may be just as significant if it reduces the prospects of success when exogenous hormones are used to 'kick start' the inactive axis. For instance, exogenous GnRH may be an adequate stimulus to provide a functional pulsatile release of LH, but its ability to improve calving rates may be constrained if it does not lead to the removal of inhibition or to the acquisition of essential receptors at other points around the HPG axis or in the peripheral target organs.

A plausible alternative hypothesis is that the counter-regulatory components of stress responses to various challenges experienced during early lactation exert a residual inhibition on the biochemical activities of the HPG axis and that this inhibition can be of varying duration depending on the magnitude of the allostatic load and the ability of individual animals to cope with it.

Allostatic load may find expression as a biochemical lesion.

Metabolic diseases (see Chapters 46, 47)

The peripartum period is a stressful time in the life of a cow. During the 'transition period' (the last four weeks of gestation and the first four weeks of lactation) cows experience enormous changes in the hormonal milieu, a negative energy balance and a plethora of stressors that arise from changes in feeding and management regimes. Not surprisingly, a considerable proportion of the metabolic and infectious diseases to which cows are subject occurs during the transition phase, many of them having metabolic perturbation as the ultimate source of allostatic load. Metabolic perturbations can both induce and be induced by allostatic load.

It is recognized that absorption of glucose by the intestine contributes little to the energy homeostasis of lactating cows. The large and immediate requirement of the lactating mammary gland for glucose is met by a reduction in utilization by several other tissues and by an increase in synthesis from fats and proteins by the liver (gluconeogenesis). The key role is played by lipid metabolism that provides a rich supply of substrate for gluconeogenesis. The amount of energy reserves upon which the postparturient cow can draw is a product of the feeding regime during the recent dry period. At the onset of lactation there is extensive mobilization of body fat and in many cows this gives rise to a state of subclinical ketosis, a condition that impairs immuno-

logical defences. When the stored fat is mobilized, some is deposited in liver, kidneys, adrenal glands and muscle. The fatty infiltration of the liver can be severe in cows that are overfat at calving and in cows that mobilize fat faster than it can be utilized. Subclinical fatty liver has been linked to increased susceptibility to ketosis, milk fever, mastitis, lameness and infertility.

The important features here are that metabolic perturbation can be a significant primary cause of allostatic load borne by a cow as she enters the transition period and that the magnitude of that load can be a significant factor in determining how she copes with the subclinical metabolic problems that invariably arise in the early weeks after calving. Failure to cope renders her vulnerable to a plethora of stressors that are rife at that time and act as proximal factors in the pathogenesis of several clinical diseases, metabolic or infectious.

Inappropriate nutrition can be a significant factor in the pathogenesis of a variety of metabolic and infectious diseases.

Coping with pathogens

By definition, pathogens are stressors. The magnitude of the biological costs they impose on their hosts is determined by the virulence, infective dose and novelty of the pathogen and by the nature, location, intensity and duration of the host response, together with the pre-existing allostatic load of the host. In turn, stress is a risk factor for a variety of infectious diseases, particularly in the periparturient period and especially in individual cows who enter the transition period with appreciable allostatic loads, and in cows that are genetically predisposed to exaggerated responses of the HPA and SA systems to stressors.

Risk of infection can be increased when the stress response leads to behavioural changes that increase exposure to pathogens, when it impairs the immune response (whether to an invading pathogen or to a latent resident), when it contributes to the progression of an existing pathological process or when it is prolonged unnecessarily.

It is accepted that stress has a negative effect on the immune response and it is often said that the effect is largely due to the corticosteroids released during the stress response. The reality is a very much more complex scenario that involves the nervous, the endocrine and the immune systems. The different types of immune cells possess receptors for the signals issued by the HPA and SA axes; in turn, immunocytes release cytokines that modulate the activities of the stress system.

Recent research indicates that stress may boost humoral immunity as it suppresses cellular immunity – a response that is due to the effects of glucocorticoids

and catecholamines on the differentiation of T helper cells. The stress hormones modulate the secretion of different types of cytokines by antigen-presenting cells (macrophages and other phagocytic cells); those cytokines influence the differentiation of antigen-naïve T helper cells (Th0) into two subsets (Th1 and Th2) that, in turn, secrete cytokines that are involved in the acute phase response, in sickness behaviour and in the differential regulation of cellular and humoral immunity. The cytokines secreted by Th1 cells promote cellular immunity, those secreted by Th2 cells promote humoral immunity. The Th1 and Th2 responses are mutually inhibitory; it is thought that the Th2 shift that accompanies a vigorous stress response might have important implications for the course and outcome of infectious, allergic, autoimmune and neoplastic diseases. Some immunocytes secrete hormones: for instance, lymphocytes can synthesize ACTH, growth hormone and prolactin – messengers that probably act locally in a paracrine fashion. In addition, there are functional contacts between nerve fibres and immunocytes: for instance, lymphoid organs are innervated by nerve fibres that release noradrenaline or neuropeptides which interact with the immunocytes to cause changes in cellular trafficking, lymphocyte proliferation, antibody production and cell lysis. The physiological and pathophysiological consequences of all this cross-talk are most evident to the veterinarian in the periparturient cow.

The transition period is recognized as a time of relative immunosuppression and increased susceptibility to infectious diseases – whether viral, bacterial or parasitic. The periparturient cow is at serious risk of infection because, at parturition, the uterus and the udder lose the physical barriers that have protected them from ascending infections; thus, bacterial pathogens may enter while the defences are at their weakest. Leukocytes play key roles in the defence of both organs: prompt migration of neutrophils (PMNL) is essential to overcome the bacteria; however, the activities of the leucocytes are depressed as a consequence of the negative energy balance, the subclinical ketosis, the fatty liver and the raised circulating concentrations of glucocorticoids. Some recently-calved cows develop a severe systemic illness when the influx of PMNL does not materialize in response to invasion of the udder by *Escherichia coli*. However, in most instances the cellular and humoral responses control the proliferation of the invading bacteria without achieving total elimination; for instance, *Staphylococcus aureus* frequently is relegated to subclinical residence in the udder. This is an important adaptive strategy: its immediate effect is to protect the organ from serious tissue damage, while it sets up a mechanism by which the organ can maintain a satisfactory level of local immunity to cope with

future challenges. This strategy is used in dealing with a range of microbes and parasites and, in addition to enhancing the host's immune repertoire, it represents prudent use of energy reserves since the likelihood is that the biological cost of total elimination would be far greater than the net cost of maintaining a resident population to which the host becomes habituated – and which brings such benefits as on-going priming of local immunity to the pathogen and competitive inhibition of other pathogens that might attempt to invade the location.

Given that infectious agents impose an increased metabolic and nutritional load on their hosts, it is astonishing that voluntary reduction in food intake appears to be a beneficial coping strategy in some viral, bacterial and parasitic diseases. For instance, there is experimental evidence that when mice infected with *Listeria monocytogenes* were force fed to the same energy intake as their uninfected controls, they had a higher mortality rate and a shorter survival time than did the infected mice that were anorexic. Clearly, in this instance, force feeding nullified the benefits of a natural coping strategy and became an iatrogenic instrument of death. It is legitimate to question the wisdom of force feeding sick animals.

The two coping strategies just discussed – subclinical infection and anorexia – are somewhat at variance with the thrust of conventional wisdom; nevertheless, their adoption by diverse species indicates that they bring significant benefit to the host. Therapeutic interventions should not run counter to the way of nature.

Therapeutic interventions in infectious diseases should be consonant with coping strategies, including those that appear to be contrary to conventional wisdom and expectation.

Altered behaviour

Changes in behaviour may be evoked as coping strategies (confrontational, submissive or socially neutral) or they may emerge in the course of stress-induced illness – in the form of listlessness, exaggerated sleepiness, weakness, depressed locomotor activity, shivering, diminished social interaction, anorexia, decreased foraging and absence of body-care activities. Current opinion amongst those who study infectious diseases is that those behavioural changes are an integral part of an adaptive response to antigenic challenge and that they are elicited by the pro-inflammatory cytokines that are released from immunocytes to mediate both the local (inflammatory) and the systemic (febrile and behavioural) components of the reaction to foreign antigens. In that interpretation, sickness behaviour and fever share two significant attributes that are of fundamental concern to the therapist: each is an important

component of the natural defence system; in excess, each can be detrimental to the host.

Cytokine-induced anorexia can be interpreted as a way to reduce the availability of some nutrients (e.g. iron, zinc) necessary for multiplication of the pathogens. Sleepiness and reduced activity can be interpreted as ways in which to conserve energy that the sick animal will re-allocate to new priorities geared toward victory over the pathogens (e.g. inflammatory and immunological responses). Therefore, as far as is possible, our treatment modalities should not nullify the natural benefits of sickness behaviour – as force feeding did to the *Listeria*-infected mice.

The behavioural changes evoked by the stressors may be transient (e.g. failure to groom during illness), persistent (e.g. stereotypies) or life-threatening (e.g. learned helplessness). Learned helplessness is an unmotivated state in which an animal gives up trying to cope with the exigencies of life, is indifferent to its own well-being and is unresponsive to therapeutic or punitive interventions. Originally, the term was used by scientists who assessed the coping abilities of dogs exposed to repeated electric shocks. They found that dogs that had been subjected to unavoidable shock treatments in a preliminary experiment just sat and took the shocks when the experiment was repeated in a situation from which there was a fairly obvious means of escape. Subsequently, it has been recognized that chronic stress can lead to learned helplessness in other species (including humans), notably when they have endured repeated failed attempts to achieve an objective.

The author believes that he has encountered this cognitive aberration in cattle originally thought to be suffering from metritis, mastitis, acetonaemia or hypocalcaemia, but most convincingly in a subset of downer cows that did not have the physical or biochemical defects to account for their predicament (pp. 439, 797). From clinical experience, he suspected that some of the underlying allostatic load in the helpless downer cow had been brought forward from the dry period and, perhaps, from previous lactation(s). If the conjecture is correct, it follows that a comprehensive record of health and production parameters should reveal more about the bases from which the load accrued than would the most recent metabolic profile. Learned helplessness may be associated with either infectious or non-infectious conditions; it is regarded as a putative animal model of depression. The pathophysiological mechanisms have not been elucidated but some evidence from animal experiments hints at an imbalance between the activities of the two limbs of the stress system, with the HPA axis in the ascendant. It would not be prudent to treat such animals with corticosteroids, as is often advocated for the downer cow syndrome.

Quite often the downer cow syndrome is seen as an incomplete response to treatment for milk fever: it is said that the longer the interval between the time the cow becomes recumbent and treatment for milk fever, the greater the incidence of the downer cow syndrome. One has to entertain another possibility: that some recently-calved cows, already burdened with substantial allostatic loads and with the added stress of acute hypocalcaemia, may find *rapid* intravenous injection of essential ions to be a stressor too many – sufficiently stressful to necessitate a period of recumbency in which to recover the will and the confidence to resume normal activities. When management fails to recognize the cow's immediate need for a period of relative inactivity she will be subjected to repeated premature attempts to force her to stand; this will increase the risk of physical damage and, by the same token, it is likely to reinforce the state of helplessness that now is at the core of her problem.

It is tempting to speculate that the dispirited state may have a morphological basis somewhat analogous to the neuronal damage seen in the hippocampus of chronically stressed humans, shrews and rodents. If that were the case, the evidence from the other species would be reassuring: the neuronal damage is neither terminal nor irreversible. Most of the affected cattle should respond to standard treatment, always provided the clinical problem is not compounded by musculoskeletal damage incurred during ineffectual attempts to get the cow on her feet before she is ready to do so of her own volition or by complications arising from prolonged recumbency.

These observations on altered behaviour highlight two significant aspects of animal health: firstly, sickness behaviour is an adaptive response to infectious or non-infectious stressors; it provides the allostatic base from which the recuperative process develops and it is instrumental in setting the endogenous rhythm for that process; secondly, any therapeutic intervention that jolts the periodicity of the process becomes an additional stressor that is likely to delay or distort resolution.

Sickness behaviour is a strategy that may be invoked to cope with either infectious and non-infectious stressors; interventions that target the behaviour rather than the stressors are liable to delay, distort or prevent the recuperative process.

Concluding comments

The primary aim of this chapter is to draw attention to the concept of allostatic load and to encourage practitioners to appreciate how important a role it plays in the pathogenesis of most of the ailments they

encounter. More often than not, clinical disease is the product of a cascade of environmental stressors: some can be designated as ultimate factors that have been responsible for the allostatic load that has made the animal vulnerable to the proximate stressors (infectious, metabolic, toxic) that are the immediate causes of the ailment. If we wish to keep pace with current trends in intensive systems of animal production we will have to take greater stock of ultimate stressors than has been our wont. Increasingly, our task will be to devise and monitor herd health programmes that manage the sources of environmental stimuli to the mutual benefit of the livestock and the profit-and-loss account. In that context, it does not require great insight to realize that curtailment of allostatic load is the key to improvement in the overall health and productivity of the herd.

When the accumulated allostatic load attenuates the animal's ability to cope with further challenges, the host becomes vulnerable to all sorts of stressors, even those that are only mildly aversive. In that situation, a relatively minor proximate stressor may propel the host into clinical disease, particularly one that reflects the functional priorities of the current phase of the animal's annual life cycle. For that reason, the differences in presenting signs shown by herd mates should not obscure the fact that each sick animal has had a significant allostatic load and, in that sense, each clinical case should be seen as a sentinel of stress within the herd.

Allostatic load is not something that can be measured by standard biochemical or physiological techniques. Research scientists use hormone assays and heart rates to monitor responses to acute stressors, but those parameters are not indicative of allostatic load. The best sources of the required information are comprehensive life-time records of health and production parameters. The onus is on the herd veterinarian to ensure that the appropriate records are compiled, that they are used to identify both ultimate and proximate stressors and that the information so gained is taken into account whenever therapeutic or prophylactic interventions are contemplated.

Glossary

- AROUSAL:** the state of general alertness. It is reflected in conscious state, in cognitive activity, and in behaviour.
- AUTOCRINE:** hormone (or cytokine) acts on the cells that produce it.
- BRAINSTEM:** the stem-like region that links the cerebrum with the spinal cord; consists of the midbrain, pons and medulla oblongata.
- CYTOKINE:** protein or glycoprotein (produced by one or more cell types) that regulates the activity of other cells.
- ENDOCRINE:** hormone is secreted directly into blood stream and acts on target cells elsewhere in the body.

HABITUATION: extinction of a conditioned response by repetition of the conditioned stimulus; perceived threat diminishes as novelty wears off.

HYPOTHALAMIC–PITUITARY–ADRENAL (HPA) AXIS: the hormonal interplay between those three organs; the principal hormones involved are corticotrophin-releasing hormone (CRH) and arginine vasopressin (AVP; formerly ADH) from the hypothalamus, adrenocorticotrophic hormone (ACTH) from the pituitary gland and cortisol from the adrenal cortex.

HYPOTHALAMIC–PITUITARY–GONADAL (HPG) AXIS: the hormonal linkage between the hypothalamus (releases GnRH), the pituitary gland (releases the gonadotrophins, FSH and LH) and the gonads (secrete testosterone, oestrogens, progesterone).

LOCUS COeruleus: a small pigmented cluster of noradrenergic neurones in the dorsal brain stem on the floor of the fourth ventricle. It contains more than half of the noradrenergic neurones in the brain; they project widely throughout the CNS and they are highly responsive to alerting/stressful stimuli, including those that activate the HPA axis.

PARACRINE: hormone (or cytokine) acts on a different cell type which lies in close proximity to the producer cells.

PROXIMATE CAUSE: an environmental factor that acts as an immediate stimulus for a biological event (e.g. a disease).

SYMPATHOADRENAL (SA) AXIS: consists of two components: the sympathetic nervous system and the adrenal medulla. The major biologically active products, the catecholamines (adrenaline and noradrenaline), serve both as neurotransmitters and as hormones. Within the CNS they act as neurotransmitters; outside the CNS, adrenaline acts principally as a hormone, while noradrenaline acts principally as a neurotransmitter at sympathetic post ganglionic terminals.

ULTIMATE CAUSE: an environmental factor that increases the probability that a particular biological event will be elicited by another factor that is seen as the immediate stimulus.

European dairy farming trends

Europe stretches from the 70th degree of latitude (north of the polar circle) to the 40th degree of latitude into subtropical regions. Many different climatic conditions and huge differences in landscape exist. These differences work out in very variable disease problems and different husbandry systems. In Denmark, northern Germany, The Netherlands, northern Belgium, north west France and in Italy at the borders of the river Po, flat land with fertile pastures is located. These areas are suited for dairy farming. Annual milk production is high and may reach 8000kg with 4 per cent fat corrected milk (The Netherlands). However, in Sweden, southern Germany, southern Belgium, eastern France and Austria a hilly or mountainous landscape exists. These areas are less suited for dairy cows, but more suited for suckler cows and beef production. Traditionally, in these areas dairy herds with limited numbers of cows occur. Italy, Spain, Portugal and Greece have a rather hot climate during summer time; dairy farming is difficult and of reduced extension. The average annual milk production is 3000kg (Greece), although exceptionally dairy farms with a high production level occur (Portugal). In this chapter attention will be focused mainly on dairy cattle management in north west Europe.

In 1998 just over 82 million cattle, including 21 million dairy cows over 2 years old, were present in Europe. In Table 68.1 the number of cows and the agricultural area per country are given. In The Netherlands and northern Belgium the ratio of cattle to agricultural area is more than two animals per hectare, in Ireland 1.5, while the other countries have less than one cow per hectare agricultural surface. This quotient applies to the agricultural area and gives an indication of animal density in a country. In countries with a low quotient cows may be kept on a limited part of the agricultural area and in some areas the actual number of animals

per hectare may be as high as or even higher than in The Netherlands and Belgium.

Total milk production in Europe is fixed by the quota system introduced in 1983. Placing a ceiling on milk production per country puts a limit on the number of dairy cows. As a result of fruitful breeding programmes and efficient feeding regimes the annual milk yield per cow increased during the last decades. The number of dairy farms and dairy cows will be reduced even more during the next decade, with an increase in the number of cows per farm.

The diets of dairy cows in The Netherlands and Belgium contain substantial levels of concentrates. The constituents of these concentrates are partly grown in Europe, but for the larger part, in particular protein, they are imported into Europe. Nitrogen, phosphate and other minerals are actually imported into these countries, but a limited amount of minerals is exported as milk and meat. Therefore, an imbalance exists between the amount of minerals imported into these areas and the amount exported to other areas of Europe or to other parts of the world. The mineral surplus is applied into the ground as manure. This causes an accumulation of elements (nitrogen) and puts a further stress on the reduction of the number of cows on environmental grounds, especially in The Netherlands and Belgium.

During the last decades, the average education level of the farmers increased sharply and as a consequence veterinarians must take another role. The veterinarian will be called in to take their part in prevention of diseases and to sustain the milk production level on dairy farms rather than to cure sick animals. Therefore a shift in the veterinary skills is inevitable: the veterinarian has to support the management system of the client, mainly by doing the thinking for prevention of diseases and to optimize production levels.

In the past, much attention was paid to certain aspects of food quality, e.g. the cell count in milk, but nowadays the consumer's attention is even more focused on food safety. Although the quality of products for human consumption increased during the last decade, the confidence of the consumer in these prod-

ucts continuously declined. The latter aspect is emphasized by BSE. The supposition that BSE prions might have caused the vCJD in man (see p. 909) and the possibility that prions entered the human food chain without appropriate check on the source of the animals for food production caused a shift in public opinion. The threat of disease caused by products of animal origin and the threat of antibiotic resistance in human bacteria due to the application of antibiotics in food animals increase the attention paid by the consumer to the chain in which human food is produced. The chain must be completely transparent and the methods to control the processes must be supervised by independent people.

Furthermore, increasing attention is paid by the public to animal welfare. The consumer demands food from animals that are kept under conditions that allow them to function more or less naturally. Reducing the frequency of microtraumata by comfortable barns beyond doubt increases the durability of dairy cows. In the future veterinarians may participate in the supervision of the production of food from cows by paying attention to their comfort.

Knowledge of diseases, and especially knowledge of their cause and aetiology, the consequent knowledge to prevent problems and the skills to prevent a decline of milk production and disasters on dairy farms must be an essential characteristic of veterinarians in the next decade. Veterinarians may also contribute to the achievements of dairy farmers by increasing the quotient milk production versus manure per surface unit.

Two aspects for veterinary prevention programmes must be considered: prevention of the introduction of

infectious diseases and of diseases that are indigenous in all cattle populations, such as mastitis and lameness.

Infectious diseases

In north west Europe a number of major infectious diseases have been eradicated, e.g. rinderpest, BCPP, tuberculosis, brucellosis and EBL. In 2001, FMD re-emerged in north west Europe and caused severe (UK), moderate (Netherlands) or mild (France) epizootics, focusing attention on this disease again. Until this outbreak attention was mainly focused on the eradication of BSE, IBR, BVD and on a limited scale of paratuberculosis (Johne's disease) (see p. 857).

Veterinarians must be fully aware of the agents and their epizootiology. The Achilles heel in the infection chain must be found for each individual pathogen to develop effective eradication strategies.

FMD (see Chapter 43c)

As long as FMD exists somewhere in the world, the risk of introduction of the virus into Western Europe by food products from infected animals remains real. Intensive traffic movements of people over the world increase the risk of accidental introduction of contaminated food products. When the FMD virus is introduced into a West European country, the risk of an epizootic depends on the time lapse between introduction of the virus and the diagnosis, and of the number of animal movements over the country or to other countries during that period (see p. 705).

IBR (see p. 289)

In the 1980s, voluntary eradication programmes for IBR were started in the Scandinavian countries. However, there was no thorough economic basis for the eradication of IBR. IBR is also not a threat for human health, the economic damage is limited and clinical disease can be prevented by an appropriate vaccination programme. However, as Scandinavian countries became officially free of IBR several other European countries were forced to achieve IBR negativity as well. It was mainly a political decision to eradicate IBR.

Eradication programmes were successful in Switzerland, Denmark, Sweden, Finland and Austria. The basis for the success of these programmes was that all serologically positive cows, which might be latently infected, were eliminated. The percentages of animals found serologically positive for IBR in these countries did not exceed 20 per cent of the dairy cows.

However, percentages of serologically positive animals turned out to be as high as 50–60 per cent in The Netherlands and Belgium, and therefore the above mentioned method was not applicable. Vaccination programmes using gene deleted vaccine virus, but with a serological response distinguishable from field virus infections, are applied to all cattle herds that are not proven negative for BHV1. These programmes started recently (1998), so there is no evidence that these schedules will turn out to be completely successful.

BVD (see p. 853)

Bovine virus diarrhoea virus (BVDV) has a real economic impact on infected farms and the disease deserves full attention for eradication. Although some Scandinavian countries have voluntary eradication programmes, the efforts to eradicate this virus are far less intensive than the efforts to eradicate IBR. In Sweden and in Denmark voluntary programmes for the eradication of BVDV have been in progress since 1993. The backbone for the eradication programme is the detection and destruction of all persistently infected animals. A herd has to start with a virological search for the presence of persistently infected animals. After the elimination of these animals a regular serological survey of the animals between 6 and 12 months is performed, and later on by testing for the absence of antibodies against BVDV in bulk milk samples.

Paratuberculosis (Johne's disease) (see p. 857)

Johne's disease is caused by *Mycobacterium avium paratuberculosis*. After infection by the oral route during the first months of life, clinical disease characterized by diarrhoea and emaciation may develop later

in life. In the last phases of the disease bacteraemia develops and as a consequence milk and meat might be infected with the bacterium.

In man, Crohn's disease has a pathology that is very similar to paratuberculosis in the bovine. *M. avium* ssp. *paratuberculosis* was isolated from the intestines of patients with Crohn's disease, but not from the intestines of humans suffering from other intestinal disorders. The PCR for *M. avium* sp. *paratuberculosis* is significantly more often positive in patients suffering from Crohn's disease than in those suffering from other gastrointestinal disorders. This does not prove, however, that *M. avium* ssp. *paratuberculosis* is the causative organism for Crohn's disease. The agent might take advantage of the pathological changes in the intestines of human patients with Crohn's disease to colonize the bowel. It demonstrates, however, that the agent must be present in the human environment and probably in human food. Actually, about 6 per cent of milk for human consumption in the UK was contaminated with *M. avium* ssp. *paratuberculosis*, although it is unclear whether the bacteria in milk are viable.

It is, however, important to ensure that the human food chain is free from this bacterium and veterinarians are obliged to pay attention to the eradication of the agent from the cattle population. On the other hand, efforts to eradicate paratuberculosis (Johne's disease) in all countries are limited.

BSE (see p. 909)

Bovine spongiform encephalitis prions are suspected to be the cause of the [new] variant Creutzfeldt Jacob Disease ([n]vCJD). These prions are present in tissues from the central nervous system and jejunum of cattle with overt clinical signs of the disease. Cows are believed to contract the disease by consuming ruminant proteins produced from infected ruminants. The major breakthrough was the total elimination of animal proteins (except fish and poultry proteins) from the ruminant food chain. The consumer requires a guarantee that animals for human consumption have never consumed animal protein and puts emphasis on the source of the meat and its control chain.

Metabolic diseases (see Chapter 46)

The increased capacity for milk production necessitated improved feeding regimes. The quality of grass silage and corn silage increased and facilitated higher production levels. Next to roughage a substantial amount of concentrates are fed. Concentrates are added in the milking parlour or in concentrate stations, where each

Table 68.2 Prevalence of disease problems in 8272 cow years in nine dairy farms in The Netherlands during a 10-year period.

| | |
|---------------------|--|
| Fertility problems | 34.9% |
| | including 19.0% irregular heat periods |
| Udder problems | 24.6% |
| | including 22.5% mastitis cases |
| Locomotory problems | 36.7% |
| | including 6.8% laminitis |
| | including 17.7% solar ulcers |
| Metabolic problems | 19.7% |
| | including 5.5% acetonaemia |
| | including 14.4% milk fever |

individual cow can obtain an amount relative to milk production, or a total mixed ration is provided.

Indications for a causal relationship between food, feeding and diseases are increasing and substantiated by experimental work. Metabolic disturbances also significantly influence the health of claws and may exacerbate the consequences of external forces (mini-trauma) on claws, causing lameness (see Table 68.2).

Veterinarians should be fully aware of the relationships between food, metabolism and disease, and must be able to translate food changes into possible deviations of the health of the animals in a herd. Thus the veterinarian involved in cattle herd health management must be familiar with food constituents and components and their digestion and metabolism.

Large quantities of rapidly fermentable starches in the diet may cause disturbances of rumen fermentation, resulting in low milk fat percentages, off feed syndrome, laminitis and ruminal acidosis consecutively, depending on the grade and the period of acidosis. These phenomena are mainly observed in herds with high milk production levels being fed high amounts of concentrates in the diet. Although there are no exact data on the incidence of these diseases in Europe, in The Netherlands and Belgium these disturbances have occurred rather frequently in the past, but are now decreasing due to the lower percentage of easily fermentable starches in the concentrates.

If the energy in food is maintained in accordance with the milk production level, cows lose body weight moderately during the first few weeks of lactation. The negative energy balance during the first weeks after parturition is physiological (energy intake by food and energy from reserve fat equals energy demand). If this equilibrium is disturbed by low energy content of the food acetonaemia some three weeks after parturition develops, characterized by high levels of β -hydroxybutyrate and low glucose levels in the peripheral blood. This problem is still known but occurs less frequently than previously due to increased quality of the diet

(roughage). In experimental farms in The Netherlands with a management above average the incidence of this disease was limited to 1 per cent of the cows.

A disease biochemically very similar to acetonaemia may develop within two weeks after parturition. In the peripheral blood high levels of non-esterified fatty acids (NEFAs), high levels of β -hydroxybutyrate and low levels of glucose are found, indicating severe energy deficit, but with very high levels of triacylglycerol in the liver. This phenomenon is known as fatty liver, a very peculiar phenomenon in that the peripheral body is deficient in energy supply, while in the liver high levels of energy (up to 25 per cent of triacylglycerol of wet liver tissue) are available (see p. 801). The cow is ill and may die from energy depletion while abundant energy is present but is not made available for the metabolism. The origin of the disease is considered to be a sequel of excess of energy supplementation in the last part of the lactation period and during the dry period. About 10 to 12 weeks after parturition, the initial decrease in body weight due to the physiological negative energy balance turns and becomes positive. The body weight increases until drying off.

During the dry period the body weight must be kept constant. However, the increasing energy value of the roughage produces an energy surplus during the dry period and as a result many cows increase their body weight and are fat at calving. Although exact mechanisms are poorly understood, many cows in a fat body condition at calving (BCS 4 or higher on a 5 point scale) suffer from a decreased appetite after calving. This reduced appetite may be related to or caused by leptins, by high levels of NEFAs, by a combination of these factors or by other not yet described causes. In these fat animals with often high milk production the energy intake is short in comparison to the energy demand. Increased lipolysis, in order to compensate for energy demand, results in the accumulation of triacylglycerol in the liver, i.e. fatty liver. In the short term this metabolic disease may result in emaciation and death; in the long term it may cause reduced reactivity of the immune system, making the cow more vulnerable to common bacterial infections. There may be a high prevalence of mastitis in the post partum period in animals suffering from fatty liver. Ova mature during an eight-week period and the first ovulation after parturition in these cows produces an ovum matured during the period with high levels of NEFAs in the blood. These ova are less fertile and may result in lowered conception rates. This metabolic disturbance causes decreased ovarian activity with prolonged intervals from calving to heat, resulting in prolonged intervals from calving to conception. The incidence of fatty liver is not known, but it is suspected to occur more frequently than anticipated.

Dietary deficiencies are rarely diagnosed in dairy herds in areas with a high milk production. The diet receives adequate levels of minerals and vitamins from the addition of concentrates, the composition of which is monitored by the manufacturer. However, as many farms start to feed home-produced diets composed from basic substances there is a risk of miscalculation and thus excesses or deficiencies may occur. The veterinarian will be asked to support management decisions taken by the owner and to diagnose failures

in management which result in reduced fertility, reduced immunoreactivity or in lameness.

Introduction

The purpose of this chapter is to indicate some of the differences between cattle problems in Africa and the rest of the world and to highlight some of the conditions that are of major importance to livestock production. North Africa is part of the Mediterranean area and it is separated from the rest of Africa by the Sahara Desert, where there are few cattle. SubSaharan Africa has a variety of climatic conditions, from almost no rainfall to heavy, regular and seasonal rainfall areas, and in consequence there is a variety of environmental types and eco-systems. This in turn has led to many different lifestyles from the sedentary agriculturist to the nomadic pastoralist who moves his herds as conditions dictate, e.g. the Fulani in west Africa would prefer to graze their animals in the south where there is more rain and the grass is better for the cattle. However, during the rainy season the tsetse flies are active, so the cattle are moved north to escape their bites. When the dry weather returns and the pastures in the north become depleted of grass they return their animals south. In large measure the distribution of the human population has been governed by this fly (*Glossinia* spp.). To many African people, the well-being of their animals governs their lifestyle. The differences in the ecology of the continent govern the behaviour of disease agents, parasites and vectors: therefore, cattle diseases to be considered here fall into three main categories:

- *Epizootic diseases* that have mostly been introduced into the continent from Europe – rinderpest (p. 707), contagious bovine pleuropneumonia (p.

868), foot-and-mouth disease (p. 700), rabies (pp. 908, 1164), tuberculosis (p. 862) and brucellosis (p. 280).

- *Parasitic diseases* caused by either by helminths, e.g. *Haemonchus contortus* (p. 275), or *Fasciola gigantica* (p. 276), or by tick-borne protozoa, e.g. *Theileria parva* (p. 750) or *Anaplasma marginale* (p. 761), or by the biting flies (p. 747) (*Glossinia* spp.), or the various species of *Trypanosoma* (p. 756).
- *Plant poisonings* caused by the varied and extensive flora of Africa. Among such a profusion only a few examples can be given.

Epizootic diseases

Rinderpest (see p. 707)

First among cattle diseases is rinderpest, the greatest scourge of cattle, and indeed their owners, that the world has ever seen. When rinderpest was imported into Britain in the mid nineteenth century it ruined farmers, bankrupted insurance companies and was directly responsible for the foundation of what is today the State Veterinary Service. The Royal Agricultural Society considered that rinderpest was responsible for the death of more than 400 000 head of cattle in Britain in six months of 1866 at a cost in 1866 figures of £8 million. It was introduced into Egypt in 1890 and in five years it had travelled to South Africa, killing not just cattle but also huge numbers of game animals as it passed.

Following Macmillan's famous 'winds of change' speech to the South African parliament in 1960, African countries raced towards independence. The cold war was beginning to push America and Russia: both wished to develop spheres of influence in Africa and so they poured money into the continent. Joint Project 15 was set up, with almost limitless funding, to eradicate rinderpest from Africa. A vaccination campaign, using the Muguga tissue culture vaccine, almost succeeded in eradicating the infection. Unfortunately pockets of virus persisted in Chad and Ethiopia and from these the disease 'recolonized' Africa. The Pan African Rinderpest Campaign (PARC) was set up with the aim of erad-

icating rinderpest within a period of 10 years. PARC has the advantage of superior immunological tests and it would seem that the goal may be achieved. Similar projects in the Middle East and southern Asia also seem to be achieving success: it is possible that early in the new millennium global eradication of rinderpest may become a reality.

Foot-and-mouth disease (see p. 700)

In Africa, foot-and-mouth disease (FMD) is more important for its political impact than for the disease that it actually causes. It is endemic throughout much of the continent and the African buffalo (*Syncerus caffer*) has been shown to be a carrier of the SAT strains. This makes the eradication of the virus from the continent problematical. Control measures follow the normal international pattern, with the exception of Botswana, which has developed its own technique of control. The country is divided by cordon fences (some hundreds of kilometres in length) into different areas of 'infected', 'clean but vaccinated' (buffer) and 'unvaccinated' areas. Movement of cattle from one area to another is strictly controlled, including physical examination of every animal by the Veterinary Department. At each biannual vaccination the animal is branded and only branded animals are allowed into the abattoirs. As a result of this control, Botswana is permitted to export meat into the European Union from the 'unvaccinated' areas.

For many years Kenya was allowed to export meat into the European Economic Community. Movement controls broke down, the disease spread and Kenya is no longer able to export its meat to Europe. Other countries with no export trade outside the continent make little or no official attempts to control the infection.

Tuberculosis and brucellosis (see pp. 280, 862)

Bovine tuberculosis in Africa is complicated by the presence of a large number of 'cold blooded' or atypical strains of *Mycobacterium*. These make the interpretation of the tuberculin test more difficult and today outside South Africa there is little done to control the disease at the official level. In most countries with a commercial dairying industry (e.g. Kenya, Ivory Coast) the industry itself tries to ensure freedom from both tuberculosis and brucellosis, thus enabling producers to market 'attested' milk.

Parasitic diseases

The African continent has the climate, soils and hence ecology to support a great diversity of animals and their

parasites. Unlike the Amazon Jungle the tropical forests of Africa are not so large as to make huge tracts of land uninhabitable. Africa has probably more species of tick than any other continent and because of the extensive savannah areas these creatures have had plenty of hosts and time, so that a reasonable equilibrium has built up between animals (including indigenous domestic cattle), ticks and the parasites that they carry. This equilibrium was destroyed when the Europeans imported exotic cattle in an attempt to increase productivity of the native cattle. For some unknown reason cattle, and indeed humans, have failed to build up resistance to the parasites carried by the tsetse flies (*Glossinia* species) (see p. 747) – the trypanosome (*Trypanosoma* species) (see p. 756). In large measure it has been the trypanosome that has determined the distribution of cattle in Africa and consequently it has played a part in the distribution of the human population. Tsetse fly are recorded in 37 African countries and more than 10 million square kilometres of land are infested. There are few breeds of cattle that have developed a trypanotolerance and these are mostly confined to west Africa.

The reason for the difference in resistance may well be associated with the feeding habits of the parasites. Hard ticks (and these are the only ones of importance to cattle) are sedentary and remain on the host, or at least each stage of the parasite remains on the hosts and feeds by sucking blood. There are three types of hard tick: one-, two- and three-host ticks, depending upon whether or not at the completion of each stage of life the tick remains on the host to moult or whether it drops off. A one-host tick spends its life on one animal: the larvae moult to nymphs, the nymphs to adults on the same animal. The gravid female drops off to lay her eggs on the ground. The two-host tick usually moults from larva to nymph on one animal but the nymph drops and moults to an adult on the pasture. The three-host tick drops off at each moult. It is obvious that three-host ticks are more efficient at spreading infections than the one-host variety. By contrast, the tsetse fly takes each meal where it finds it and moves from animal to animal: there is no time for a host-parasite interaction and the parasite moving from host to host has accustomed itself to varying host immune mechanisms.

Each species and genus of tick has a different distribution, a different life cycle and differing host preferences and site predilections. Specific ticks transmit specific infections: e.g. *Rhipicephalus appendiculatus* (the brown ear tick) transmits East Coast fever (ECF) (theileriosis) (p. 750) and other theilerial parasites, whereas *Boophilus decoloratus* (the African blue tick) transmits *Babesia bigemina* (the cause of bovine babesiosis) (p. 748) and *Anaplasma marginale* (the

cause of anaplasmosis) (p. 761). By the same token, there are different species of *Glossinia* that inhabit different ecological niches and that transmit different species of *Trypanosoma*. The demonstration by Bruce, at the end of the 19th century, that it was the tsetse fly that transmitted pathogenic trypanosomes to livestock led the way to understanding the role of arthropod vectors in animal disease. The tsetse fly has been a major impediment to the development of a large part of the continent and environmentalists would say that this has been a good thing! With the rapidly increasing population in Africa and the need for more food it is essential that tsetse flies and ticks be controlled.

It has been known for many years that some animals in a herd are more resistant to a specific disease than others, and some more susceptible. Breeders have used these characteristics and, as mentioned above, trypanotolerant breeds of cattle are found in west Africa. It has been demonstrated recently that some cattle have an increased resistance to tick infestation. This increased resistance is associated with immune mechanisms. It has been said that the trypanotolerant Ndama breed is more resistant because the animals are better able to control the parasitaemia, although the mechanism by which this occurs has not yet been demonstrated. Resistance to *Babesia bigemina* (p. 748) has been shown to have more to do with resistance to the tick, than to the parasite itself. Resistance to tick infestation was first demonstrated in Australia. It was also noted in Africa that indigenous breeds kept with exotic animals often showed much lower (down to 1/6) tick burdens. It has been possible to breed cattle with increased resistance to the one-host tick, but so far not to the multi-host ticks.

It is unlikely that tick resistance can be developed to the point where there is no transmission of the protozoal diseases. Consequently a combination of resistance with acaricide treatment will probably always be required. Before deciding upon a programme of tick control by acaricides it is essential to know which ticks are to be controlled, and when. For many years Malawi had a policy of strategic dipping of cattle: in the north of the country it was confined to the wet season when the number of ticks increased dramatically. In the dry winter the tick burden was at a minimum and so the gain was less than the cost. In areas of Africa where ECF is not a problem it is often not necessary to attempt acaricide dipping or spraying of cattle. In areas of Africa where ECF has been introduced, there may be a mortality rate approaching 100 per cent, and then it may be necessary to use chemicals to keep the tick burden to a minimum. In the absence of ECF, there are two options: the first is to control the remaining tick-borne diseases by chemotherapy and vaccination and to ensure that the young animals are exposed to the infec-

tions in order to reduce the dipping and work towards endemic stability; the second is to try and control the ticks by intensive dipping.

Over the years there has been a different approach to the control of tsetse flies. Perhaps the greatest natural control of the fly was the epidemic of rinderpest that started in Egypt and moved south at the end of the nineteenth century. Not only were cattle killed, but there was a massive destruction of game animals and hence a lack of food for the tsetse flies: e.g. rinderpest eliminated the tsetse fly from the Limpopo valley between Botswana and South Africa and in almost 100 years the valley has not been recolonized. Human activity has an effect:

- Clearing forests for timber or settlement destroys the habitat of the *fusca* group of flies (*G. brevipalpis* in particular).
- Clearing the savanna has made the greatest impact on the *morsitans* group (*G. morsitans* and *G. pallidipes*). These primarily feed on game animals and clearing the bush results in destruction of the wildlife. At levels of human habitation in excess of 40 per square kilometre, the *morsitans* group dies out completely.
- The *palpalis* group may be beneficially affected by human activity, as these are the flies of the riverbank, and it is rare for human activity to clear the bush by the side of rivers. Cattle graze on the cleared land but pass through the riverine bush to get to the river. The establishment of game parks has provided breeding grounds for tsetse flies and food for them to eat!

Pesticides have been used to control the flies, by knapsack spraying the area of the flies' resting sites. Organochlorine compounds such as DDT and dieldrin were widely used and effective, with synthetic pyrethroids taking over when the organochlorines were banned. A more efficient form of spraying was from the air. Today with the rotary atomizers and night flying equipment, the spraying is much more efficient and in the Okavango Swamp in Botswana, the use of endosulphan has reduced the environmental contamination – only 8g per square kilometre are used and the drug targets the tsetse fly rather than other insects; so far as is known, the only detrimental environmental effect that it has is to inhibit fish reproduction for a season.

Tsetse flies can be caught in traps and although this was not successful at eliminating flies from an area, work with traps led to the discovery that the flies are attracted by the colour blue. The use of odour to attract the flies only had limited success, but the development of targets impregnated with insecticides has had a striking success. As the fly lands on the blue cloth it receives a dose of insecticide.

Trypanosomosis

This disease occurs in humans, cattle (where it is known as nagana), camels, horses and pigs, but the infection occurs in most wild mammals. Trypanosomes are protozoa that possess a kinetoplast and a flagellum and require two hosts to complete their life cycle: a mammal and an insect (in South America, chagas the human disease is transmitted by blood sucking bugs). The trypanosomes multiply in the mammalian host and, with the exception of *T. equiperdum* which is venereally transmitted, they are ingested by blood sucking insects: in Africa normally by tsetse flies. Multiplication within the fly varies with the *Trypanosoma* species, but the infective stage ends up either in the salivary gland or in the faeces. Other biting flies are able mechanically to transmit the parasite to a new host.

There are three major species that infect cattle: *T. brucei* (p. 759), *T. congolense* (p. 758) and *T. vivax* (p. 758). The last has become established in South America where there are no tsetse flies and so transmission is by means of other haematogenous flies, and it is assumed that no development of the parasite occurs in these flies. Trypanosomes multiply by longitudinal binary fission in the fly and the mammalian host, although sexual processes occur only in the fly. Mature trypanosomes are ingested by feeding flies and they undergo development in the salivary gland or gut. Development and maturation occur in the vector, after which the parasite is transferred to another mammalian host. Transmission is either by the presence of the trypanosome in the saliva or by contamination of the host's skin by trypanosomes in the faeces of the fly.

A critical factor in the epidemiology of trypanosomosis is that, once infected, a tsetse fly remains infected for life. The development of the parasite in the fly varies from a few days in the case of *T. vivax* up to 45 days in the case of *T. brucei*. The role of game animals cannot be overemphasized; the present policy of game ranching in conjunction with rearing cattle and the increasing numbers of game parks has increased the risk of disease in cattle. Another significant factor in the epidemiology of the disease is the use of trypanocidal drugs, which may in turn lead to the development of resistant trypanosomes.

The pathogenesis is not completely understood: the trypanosome multiplies at the site of infection and local lymph nodes become enlarged, before the parasite is found in the blood. Then the classic intermittent parasitaemia ensues. As the parasites increase in number, so does the febrile response: as they decrease, so does the fever. The body mounts an immunological defence against the parasite and the trypanosome changes its external antigens to defeat the host. The outcome of this battle often depends upon extraneous factors such

as the nutritional state of the host. Tissue lesions vary with the species: *T. vivax* and *T. congolense* are mainly intravascular parasites inducing changes in the endothelium of the capillaries, whereas *T. brucei* has an affinity for tissues. The anaemia seen in trypanosomosis is caused by a multiplicity of factors including haemolysins and enzymes such as proteinases or phospholipases. The trypanosome attaching to the erythrocyte makes it a target for the body defence mechanisms. If the animal does not die in the acute stages it becomes progressively emaciated. Mixed infections tend to cause more severe disease.

In endemic areas the disease causes huge economic losses. Clinical disease is more commonly caused by *T. vivax* and *T. congolense*; *T. brucei* causes much less serious disease. However, there are no specific signs for trypanosomosis and they are dependent upon the degree of damage to specific organs and the severity of the anaemia. Acute disease with death within two to six weeks is seen in animals introduced into an endemic area, but chronic disease with the animal surviving months or even years is more common. Acutely affected animals rapidly lose weight and all the classic signs of fever may be seen. In the chronic form the animals show periods of weakness and lethargy followed by a recovery; the animal becomes pale with raised pulse and respiratory rates. Good nutrition may help an animal to throw off this chronic infection, but the more normal outcome is for the animal to become thinner and thinner. The infection induces immunosuppression, which can allow other infections such as anaplasmosis to take over.

It can be very difficult to diagnose this disease because the parasites are not always present in the blood and there are no specific clinical signs. Moreover there is no relationship between the number of parasites and the severity of the disease. Trypanosomosis must be considered to be a herd problem and so the presence of parasites in the blood of a 'normal' animal should be taken as significant. In many endemic areas there are inadequate laboratory services to assist in making the diagnosis and so many veterinarians consider that response to treatment is a good way to confirm the diagnosis. Serological tests have until recently suffered from an inability to produce specific antigens. However, the indirect fluorescent antibody test and the enzyme-linked immunosorbent assay have recently been introduced into the arsenal of tests used for making a herd diagnosis, and monoclonal antibodies have been produced to identify the three bovine species of trypanosome. The main problems in the differential diagnosis are with the other protozoan infections, i.e. anaplasmosis (p. 761), babesiosis (p. 748) and East Coast fever (p. 750), however, in these diseases it is usually a simple procedure to demonstrate the parasite.

The control of the infection by the use of drugs presents a continuing problem and the Veterinary Departments in many African countries control the use of them to prevent the development of resistant strains of trypanosomes. There is more to treatment than drugs and a good plan of nutrition is essential; all animals, and particularly work oxen, must be rested during convalescence. One of the major problems facing trypanosomiasis control is that today there are only four drugs effective in treating the condition, the most recent of which (isometamidium) was introduced in 1961; moreover, no pharmaceutical company is working on this problem. Care must be exercised in using a combination of drugs because some of the drugs have a combined toxicity greater than that of the individual drugs.

Because of the problems of drug resistance it is essential that optimum use must be made of them, that is to say they should be used in a strategic way whenever possible to coincide with the local rainfall and hence fly patterns. However, the most important factor is to reduce the fly population and hence the parasite challenge. The Zimbabwe Veterinary Department has made great strides in vector control going back over a period of more than 50 years. This is well described by Connor (1994). Many countries in Africa have units within their Veterinary Departments (e.g. Botswana, Kenya, Ghana and Zimbabwe) devoted to tsetse fly control. However, Basil Parsons, the Kenyan parasitologist, was of the opinion that 'when the last man leaves the African continent, he will be bitten on the backside by a tsetse fly'.

East Coast fever (see p. 750)

In 1965, the owner of a 'high grade' (mostly Jersey cross indigenous Kenyan cattle) herd of cattle went on holiday leaving his manager in charge. Because they were 'high grade' they had to be dipped in acaricide every five days to prevent ticks introducing *Theileria parva parva* (*T. parva*). Unfortunately the manager allowed the fences to be cut and the neighbour's indigenous cattle were able to mix. The farmer returned to find 75 of his best heifers dead from East Coast fever (ECF). The infection is transmitted by the three-host tick *Rhipicephalus appendiculatus* and the disease is characterized by the multiplication of the lymphoblasts infected with theilerial schizonts throughout the body.

The disease was first recognized in 1897 by Robert Koch, who called it African Coast fever. Following the ravages of rinderpest and the introduction of European stock in an effort to replace the dead animals, ECF spread south from East Africa down to Cape Province in South Africa, killing more than one and a quarter million cattle. The disease was eradicated by a process of dipping in acaricide, movement controls and destocking of infected pastures.

As with trypanosomes, so *T. parva* alternates between its mammalian and invertebrate hosts. The piroplasms in the erythrocytes of an infected bovine are ingested by the tick in its blood meal and these develop via a sexual stage to a stage that invades the gut cells of the tick. Further development results in a motile stage that invades the body cavity and migrates from there to the salivary gland, where large numbers of sporozoites are produced; these are the infective stage for the bovine, being injected when the tick feeds. Because the vector is a three-host tick and because there is no transovarial transmission the infection is transmitted by nymphs infected as larvae, or adults infected as nymphs. Should an infected larva feed on a non-susceptible host there will be no transmission from the larva to the adult.

The disease affects only cattle, the African buffalo (*Syncerus caffer*) and the Asian water buffalo (*Bubalis bubalis*). No other ungulates are infected and the parasite depends upon *Rhipicephalus appendiculatus* for transmission. This tick is widespread in the warm humid areas of Africa, and were the parasite to be introduced to these areas the infection would be rapidly disseminated. The peak incidence of the disease is just after the rainy season. Zebu cattle which carry low burdens of ticks rarely show clinical disease: they are infected as calves and may show a febrile reaction with complete recovery; mortality is low. However, if susceptible animals are introduced into this endemic area and become infested with ticks, acute disease will follow. The disease can be introduced into a clean area if an infected animal is brought in or if conditions are such that an area can be colonized by the tick. In the absence of control measures, the mortality can reach 90 per cent.

The disease is primarily one of the lymphatic tissue. The sporozoite enters lymph cells at the place of entry and within a few days schizonts can be seen in the cytoplasm of the cells. Lymphocyte proliferation occurs at the site and within five days infected cells can be found in the drainage lymph node. Massive proliferation of lymphoblasts ensues and more distant lymph nodes, spleen and thymus become affected. Finally all the parenchymatous organs become involved. Within a few days lymphocyte proliferation is replaced by lymphocyte destruction, resulting in immunosuppression. The outcome of the disease depends upon the survival of sufficient lymphocytes to effect an adequate immune response. Release of piroplasms which then invade the erythrocytes appears to have no specific pathogenic effects.

East Coast fever is characterized by fever with all its complications – lethargy, constipation or diarrhoea, respiratory signs and abortion, together with enlargement of the superficial lymph nodes. Auscultation of the lungs indicates severe pulmonary oedema. Because the ticks

live in the ears it is often the parotid lymph nodes that first show enlargement. Death occurs from five days to three weeks after the onset. Exotic animals that recover often become emaciated and can remain unproductive for months.

On post-mortem examination the three classic findings are severe lymph node enlargement, a massive pulmonary oedema and splenomegaly. Congestion and oedema can be found in any of the internal organs. Numerous small white foci may be present in the kidneys, indicating lymphoid hyperplasia in the cortex. There may be emaciation and subcutaneous oedema. Diagnosis is confirmed by the examination of smears stained with Giemsa stain, of lymph node, spleen, blood or almost any organ. The presence of large lymphoblasts is strongly suspicious: the presence of schizonts is conclusive.

In some cases it is possible to observe lymphocytes containing schizonts in blood smears. It may not be possible to demonstrate schizonts in zebu cattle and so demonstration of rising titres of antibodies should be made, using the immunofluorescence techniques. Among the conditions to be considered in the differential diagnosis are rinderpest (p. 707), bovine virus diarrhoea (p. 853), contagious bovine pleuropneumonia (Chapter 49(b)) and trypanosomosis (p. 750); the presence of the schizonts is conclusive. At the Veterinary Research Laboratory, Kabete, Kenya, in the mid 1960s, each morning the staff were confronted by a line of men with bicycles, in the baskets of which were a selection of viscera from a dead animal. The farmers were only interested to know whether or not the animal had died from anthrax (if not, then they could eat the meat!); most animals had died from ECF.

Although tetracyclines have some effect against *T. parva* they are only consistently effective during the incubation period. The development of parvaquone, napthoquinone and febrifugene has resulted in success rates for treatment of over 90 per cent. However, some animals may remain carriers following treatment. Because immunity to the natural disease persists for more than five years, there has been a massive search for a vaccine and millions of pounds have been invested in this work at the Veterinary Research Laboratory, Kabete, the Kenya Agricultural Research Institute (formerly East African Veterinary Research Organisation), Muguga, and latterly at the International Laboratory for Research on Animal Diseases (now ILRE), all in Kenya. The vaccine consists of injecting a controlled number of sporozoites obtained from schizonts, originally from infected ticks but now from tissue culture, and then following this with treatment; initially a tetracycline was used but today the newer drugs have taken its place. Because the vaccine is only effective against homologous strains different preparations must be used

in different places and so the famous 'Muguga cocktail' was developed. This in turn has its problems, in that Directors of Veterinary Services are not happy to use live, virulent strains of *Theileria parva* from foreign countries and this means that it is not possible to produce the vaccine on a large, regional scale. The vaccine is expensive and not without its problems and so it is only used by commercial farmers. Work to improve the vaccine using molecular techniques is in progress.

Because of the behaviour of the tick and the parasite it is possible to control the infection by isolation of susceptible cattle, but they must not be fed purchased hay which might contain ticks. Tick control can keep ECF at bay providing that mistakes are not made in dip strength or dipping interval. Leaving the pasture free from cattle for 18 months or more will 'sterilize' the pasture because the parasite cannot survive that long: the ticks will feed on other animals, but there will be no transmission of the parasite and so it will die out. The control of cattle movement is also a good way to halt the spread of the parasite. Because ECF control requires a comprehensive infrastructure many countries have employed communal dipping as a means of bringing the cost within the grasp of the smallholder. To be effective, control measures for ECF need to be long term, take into account the whole management of the herd and the farmer must be eternally vigilant.

This account has concentrated on the disease caused by *Theileria parva parva*; however, this is not the only theilerial disease. Corridor disease caused by *Theileria parva lawrencei* was first seen in Zimbabwe and is an infection transmitted by ticks from the African buffalo. It is indistinguishable from ECF. Zimbabwe theileriosis, caused by *Theileria parva bovis*, is also clinically indistinguishable from ECF, but is treatable with tetracyclines and shows differences in its epidemiology. The cause of 'turning sickness' (p. 752) is a theilerial parasite but its identity is in doubt. The disease is manifested by nervous signs and infected lymphocytes can be found in the brain. None of these conditions has the economic importance of ECF.

Plant poisonings

The foreword to *Plant Poisonings and Mycotoxicoses of Livestock of Southern Africa* (Kellerman *et al.*, 1990) says it all!

'Southern Africa is well known for the diversity and beauty of its flora. It is perhaps ironical, but not entirely unexpected that the sub-continent should be "blessed" with a possibly unequalled variety of poisonous plants and toxic fungi.'

'About 600 indigenous poisonous plants are known to occur.'

'In this part of the world, where livestock are traditionally kept under extensive conditions on veld that is frequently denuded by droughts, overstocking and uncontrolled fires, the animals are often forced to eat poisonous plants which they would normally avoid. Devastating outbreaks have been reported under such conditions, for instance, during 1926–27 about 600,000 sheep died of plant-induced photo-sensitization in the north western Cape Province and during 1929–30 over one million were killed by *Geigeria* spp., in Griqualand West.'

It is only possible to give a few examples with a view to stimulating the reader to carry out his own researches. Among many strange poisonings, perhaps the most odd is that caused by *Pavetta harborei* (Rubiaceae) (gousiekte). The original report concerned a mob of fat cattle waiting in the holding pens at the railside of Mahalapye Station, Botswana. The train came into the station, sounded its horn and 18 beasts dropped dead. The author found it hard to believe until he had a similar experience (on a much smaller scale): when he was investigating an outbreak of this disease, he drove into a kraal, shut the door of his truck and a fat bullock in excellent condition dropped dead. A post-mortem examination revealed no gross abnormalities. There had been a severe drought and the only green plant on the range was *Pavetta harborei* and the animals had been eating it for several months. The lesions produced by this plant are caused by one or more cardiac glycosides and produce a diffuse hyaline degeneration and necrosis of heart muscle, with the muscles being replaced by fibrotic tissue. There is no treatment for this condition and the only control is by preventing access to the plant. Since there are few farm fences in Botswana the only remedy is to dig up the plants – a forlorn hope.

A second plant which kills by means of a cardiac poison is *Dichapetalum cymosum* (Dichapetalaceae) (Mogau [Tswana] or gibflaar [Afrikaans]), the toxic principle of which is monofluoroacetate. In the rumen this is converted into fluorocitrate which interferes with the Krebs cycle. The plant has been likened to an underground tree: the tips of the branches protrude above the soil while the vast majority of the plant is underground, making it very difficult to eliminate. Unlike *Pavetta*, mogau is an acute poison which acts within four to 24 hours of ingestion, but as with *Pavetta* the animal drops dead without any premonitory signs. There are no post-mortem lesions and there are often no histological lesions. The only way to confirm the diagnosis is to demonstrate the leaves in the rumen.

Massive losses occur from this plant; in the Maun District of Botswana in 1984 one farmer lost 34 animals (10 per cent of his herd) and more than 700 cattle deaths were reported in the District. At the same time in the Chobe Game Park more than 70 buffalo were found dead by the side of the Chobe River. If the farmer sees his animals eating mogau he can save them by restricting their access to water for 24 hours. Because of its nature *Dichapetalum cymosum* is even more difficult to eliminate from the pasture than *Pavetta*.

A plant that is found throughout Africa and beyond is the castor oil shrub *Ricinus communis* (Euphorbiaceae). It has been grown as both a crop plant and as an ornamental plant in gardens because of the striking leaves and its red stems. The toxic principle is ricin, a toxalbumen, that is immunogenic and so repeated ingestion of small doses produces immunity. Ricin is found in all parts of the plant, but particularly in the seeds. Pure ricin is one of the deadliest substances known to man (Georgi Markov, the Bulgarian refugee, was murdered by this poison being injected from an umbrella on London Bridge!). The toxin is not so potent when ingested and the author remembers seeing an outbreak in Kenya in which 25 yearling dairy heifers were involved. All recovered, but the moment they were turned back into the field they went straight back to the plant and started eating it: they were removed from the field. The classic signs of the disease are a profuse watery, haemorrhagic diarrhoea, accompanied by inappetence, pain and bellowing. The normal post-mortem picture is of a severe haemorrhagic gastroenteritis. Since there is no way to demonstrate ricin, it is essential that a careful examination of the rumen contents be made for the seed or leaves. The best means of control is to keep the animal away from the plant.

This is just a small sample of the 'unequalled variety of poisonous plants' that are found in Africa. For those whose interest has been stimulated, the books by Kellermann *et al.* (1990) and Watt and Breyer-Brandwijk (1968) make excellent and entertaining reading.

Conclusion

In conclusion it must be said that only a small number of diseases have been discussed from a continent of infinite varieties. There are virus diseases such as lumpy skin disease (p. 887) or bovine malignant catarrh (p. 935); there are protozoal diseases such as elephant skin disease or Ondiri disease (p. 763), rickettsial diseases such as heartwater (p. 765). There are many, many problems and the governments have no money to control the major diseases, how much less these minor infections. Africa is in need of our help.

Introduction

Rabies is the most feared of all diseases. Once humans show signs of disease, they die. This virus disease affects all warm-blooded vertebrates and is usually transmitted by the bite of a carnivore. The virus enters the peripheral nerves and spreads to the spinal cord and brain, a process that might take several months. The nervous disease that ensues may last from a few days to several weeks before the animal dies. In humans one of the characteristic signs is a fear of water – hence its alternative name of hydrophobia.

The disease appears to have had a wide distribution since time immemorial, but it was Louis Pasteur who demonstrated the association between the causal agent and nervous tissue. By serial passage in laboratory animals he transformed the field ('street') agent into a 'fixed' agent with a shortened reproducible incubation period. Not until the twentieth century was it shown that the agent of rabies was a virus which could pass filters that retained bacteria. And in the same year, 1903, Negri demonstrated the intracytoplasmic inclusions in the nerve cells of infected animals. These Negri bodies form the basis of diagnosis even today.

Aetiology (see p. 908)

Rabies virus belongs to the family Rhabdoviridae and is classified as a lyssavirus, from the Greek word for rage. In recent years the rabies-related viruses have been added to this genus. Today the rabies virus is referred to as lyssavirus serogroup 1: the Lagos bat, Mokola and Duvenhage viruses are serogroups 2, 3 and 4, respectively. What previously was thought to be a single, simple agent has been shown to belong to a complex grouping. Studies using monoclonal antibodies have shown that within a given geographical area the virus adapts to its environment, resulting in distinct biotypes. Despite this, the antigenic structure of rabies virus has remained stable, which is a boon for diagnostic workers.

This is not the place to discuss the structure of the virus: suffice it to say that it is bullet shaped, and contains a single-stranded genome of RNA and five structural proteins. Following attachment to a cell the ribonucleoproteins are released and act as a template for replication in the cytoplasm. These accumulations of viral proteins in the cytoplasm give rise to the bodies described by Negri.

The rabies virus is delicate and is destroyed by sun and ultraviolet light, heat and many of the common disinfectants, e.g. 0.2 per cent quaternary ammonium compounds. However, it remains viable in nerve tissue, the length of viability depending upon temperature and storage conditions.

Because of the work of Pasteur, rabbits were used as laboratory hosts for experimental work up to the Second World War, since which time the mouse has been the principal experimental animal. At the same time the virus was adapted to grow in embryonated eggs; these were later used to produce very successful vaccines for use in animals. In 1958 the virus was first grown in tissue culture and there is a multiplicity of cells in which the virus will grow. The rabies-related viruses will also grow in tissue culture. Recently the human diploid cell line has been used for the production of a very successful human and animal vaccine.

Epidemiology

It is mostly island countries that are reported to be free from rabies infection – Great Britain, Ireland, Malta, Cyprus, New Zealand, Australia, Japan, Fiji and certain Caribbean islands. Some mainland countries are also free from the infection – Denmark, Portugal, Spain, Sweden, United Arab Emirates and South Korea. These are not exhaustive lists but the majority of the countries in the world have endemic rabies.

Europe

Rabies has been known and feared here since time immemorial. Dogs, foxes and wolves have all played their part in the spread of the disease. From the end of the second world war rabies in foxes has become a serious problem with the disease moving westwards and eastwards from Poland, reaching France in 1968. Vaccination and rigorous control of urban dogs has reduced the disease dramatically in the past 30 years. The upsurge of rabies in foxes has resulted in an increase in the disease in cattle; until today cattle rabies is more common than dog rabies. However, human rabies has been on the decline for many years and today it is a rarity in Western Europe. The move to reintroduce the wolf into Scotland has been halted for the time being by the fear of rabies.

Africa

It is likely that far more rabies occurs in Africa than is reported. In the 1960s rabies was mostly controlled throughout the continent. War, strife and the breakdown of veterinary services have resulted in an upsurge of the disease, but less disease is being reported from many countries. There is some debate about whether rabies existed in sub-Saharan Africa or whether it was introduced by the European colonists. The answer is probably both: as will be seen below there is some evidence of virus modification in west Africa.

The first outbreak of rabies confirmed on the African continent was in the Cape Province of South Africa in 1892 in a dog imported from England that spread the infection to dogs, cats and cattle. The outbreak was controlled and the disease was not confirmed again for more than 30 years. A rabies-like disease affecting mongooses and humans on the western side of the country was known and, in 1928, rabies was confirmed in two children bitten by a yellow mongoose (*Cynictis penicillata*). Since then rabies has been regularly diagnosed throughout South Africa.

Although suspected for many years, rabies was not confirmed in Botswana until 1938. Workers in Botswana believe that there are four manifestations of rabies:

- (1) *The urban dog cycle*: in the towns dogs spread the disease which can spill over into other species, most commonly man. Cattle are not involved in this cycle.
- (2) *The jackal cycle*: this is the rural cycle with the disease spreading between the black backed jackal (*Canis mesomelas*) and being transmitted to cattle, small ruminants, wild ungulates and man. It is jackals that infect most cattle.
- (3) *The mongoose cycle*: this is seen in the yellow mongoose in south eastern Botswana. The disease mostly cycles within the burrows of these animals but can affect wild and domestic cat populations. The domestic cat is responsible for most human infections in this part of Botswana. Cattle are not involved in this cycle.
- (4) *The kudu cycle*: this is really a Namibian problem but may involve Botswana. The kudu (*Tragelaphus strepsiceros*) outbreak was responsible for the death of more than 30 000 kudu between 1975 and 1985, but still continues. The disease spreads from kudu to kudu: herbivores are normally thought to be 'dead end' hosts because they do not spread the disease. Kudu groom each other, which may account for this atypical spread.

In East Africa the disease was first confirmed in 1912, with intermittent outbreaks until the 1960s. The war with Somali insurgents after Kenya's independence resulted in wholesale destruction of the herbivores in the northern districts of Kenya. The jackals and hyenas, being deprived of their prey, moved into the villages and there was an upsurge in human and dog cases. Jackal and urban dog cycles remain a problem to this day throughout east Africa. However, disease in cattle is not a major problem. In central southern Africa, rabies is a problem in cattle when the jackal population is allowed to increase.

Non-fatal rabies-like disease is seen in west Africa and classical rabies does occur. The author will never forget walking into a house in northern Nigeria to find a mother protecting her children from a rabid dog that had entered the house. After dogs, cattle are the animals most commonly seen with rabies in West Africa.

In the countries bordering the Mediterranean, rabies has been known since time immemorial: it is primarily a disease of urban dogs, but it spills over into herbivores, including cattle, and humans. The Saharan countries are sparsely populated by animals and man and in consequence rabies is not a major problem in countries such as Mali, Niger or Somalia.

North America

Was rabies endemic in America or was it brought by the Europeans? The latter may hold good because the

disease was not seen until the middle of the eighteenth century. It is also possible that the disease came across the Arctic at the time of the human and animal migration when the Bering land bridge existed. The disease is well reported in Eskimo folklore. It was not common in the USA until the civil war, after which it increased in dogs on a regular basis until the end of the second world war. With increasing vaccination of dogs and consequent decrease in the number of cases there has been a concomitant increase in the amount of sylvatic rabies. Today there are approximately 4000 cases of rabies a year in the USA, of which almost 90 per cent is in wild animals (bats, foxes, raccoons and skunks being the animals principally affected); domestic cats and herbivores (including cattle) make up the remaining 10 per cent of cases. The number of cases of rabies in cattle has remained static over the past 30 years, during which time the disease in dogs and cats has been decreasing, thus demonstrating that it is not the urban dog cycle that involves cattle. Cattle rabies occurs most frequently in those states that have the highest levels of skunk rabies (Iowa, Texas and Minnesota), indicating that it is this sylvatic cycle that involves cattle. The decrease in urban dog rabies with an increase in the sylvatic cycle has also been seen in Canada.

It has been said that some wild species of mammal are natural or 'reservoir' hosts for the virus and that the rabies virus persists in these animals without inflicting harm until the virus is transferred to a different mammalian host. The extension of this theory is that the infection will not be controlled in domestic animals until it is controlled or eliminated from these hosts.

Bats present another problem. In addition to the role of vampire bats in the spread of rabies (an important cause of the disease in cattle), 30 of the insectivorous species of bats have been shown in the Americas to be infected with the true rabies virus (*Lyssavirus 1*). It was originally thought that all true rabies viruses belonged to a single strain. However, recent work has suggested that there are species-specific biotypes of the virus.

The Caribbean, Central and South America

The introduction, from India, of the grey mongoose (*Herpestes auropunctatus*) in an attempt to control rats and snakes in the sugar plantations has not been an unequivocal blessing. It soon became the principal carnivore on the islands. Today almost 50 per cent of the mongoose population has antibody to rabies virus in its blood. Rabies has been eradicated from many of the islands but the mongoose population presents a serious threat should the virus be reintroduced. In Mexico the major problems are urban dog rabies and vampire bat rabies. The vampire bats are of several different genera but the most important is *Desmodus rotundus*. These

animals occur from Mexico to Perú and are responsible for huge losses in the cattle population: some authorities quote annual losses of half a million for South America alone. It has been thought for many years that vampire bats are 'true carriers' of the disease, in that they can be infected without being affected and yet still be capable of transmitting the infection. Recent work suggests that this is not so and that the bats have a variable length of incubation period before they succumb. The urban dog cycle is seen in the large South American cities, but it is not important to cattle rabies.

Asia

There are many Asian countries with huge cities as in South America, and again urban dog rabies is a serious problem. As a result, India has an enormous human death toll: some authorities put it as high as 25 000 a year, although this figure is disputed. There is little hard evidence of the level of infection in the dog population in any of these poor Asian countries; there is even less information on the incidence of the disease in the cattle populations. More is known about the disease in India than in other Asian countries and jackal and mongoose cycles are known to occur.

Transmission

Rabies is normally transmitted by a bite, but not all animals bitten contract the infection. Although the virus is present in the salivary glands of infected carnivores for several days before the animal shows signs of disease, it is not normally secreted in the saliva until clinical signs are apparent. There is no convincing evidence of a species' susceptibility to rabies other than epidemiological data. Despite this animals have had their susceptibilities rated, as in Table 70.1.

The site and severity of the bite is also important: the nearer the brain, the more rapid the onset. Non-bite transmission is not common. Transplacental transmission has been demonstrated in cattle, dogs and humans. There are reports of oral transmission from dam to offspring in humans and sheep via the milk. The only

Table 70.1 Susceptibility to rabies.

| Very high | High | Moderate | Poor |
|-----------|----------|-------------|---------|
| Foxes | Cattle | Humans | Opossum |
| Jackal | Cats | Primates | |
| Coyotes | Skunks | Dogs | |
| | Rodents | Sheep/goats | |
| | Mongoose | Horses | |

species in which this is a significant route of transmission is the kudu, which transmits the infection by licking. There has been a report of aerosol transmission of rabies virus to two humans in a bat-infested cave in Texas, which was confirmed by placing animals in insect-proof cages in the cave. Transplantation of corneas from cadavers to patients has resulted in the transmission of the disease.

The study of the outbreak in foxes in Western Europe over the past 30 years has shown that normally the infection spreads from one family group to its neighbour, with the occasional jumping of a group. Because fox ranges are much larger in Canada than in Europe, the disease spreads more rapidly there – up to 100 km a year compared with 20–60 km here. Within a wild animal species it is thought that the disease spreads at a rate related to the number of animals available. As the disease kills them so there is less opportunity for spread and the disease becomes quiescent. The number of cases in cattle can indicate the weight of infection in the predator.

The level of urban rabies in a population is controlled by the size of the city and the numbers of dog, the socio-economic status of the people and the efforts of government to control the disease. Rabies was a serious problem in Lima until the Veterinary Department supported by the World Health Organization instituted effective vaccination campaigns.

The understanding of the pathogenicity and spread of rabies-related viruses is as yet incomplete and anything that muddies the waters of rabies control needs investigation. One of the problems is that rabies-related viruses have been isolated from domestic animals vaccinated against rabies. There have also been cases of rabies-related viruses in humans that have no history of a bite by a wild animal. Rabies-related viruses have been demonstrated in bats in Australia, where rabies has never occurred. Recently, bats infected with these viruses have been found in Britain; they are thought to have come from Europe.

Pathogenesis

A skin wound following a bite from an infected animal is the common route of entry of the infection, hence the common route of entry of the virus is the sensory nerve endings in the affected area. With deep bites the virus enters the stretch proprioceptors of the muscle or the motor nerve endings in the muscle. The virus is thought not to enter through the cut surface of damaged nerves. Both sensory and motor nerves may be infected. Experimental work has shown that the virus multiplies at the site of infection and that it remains there for some time (more than two weeks in some cases). Once viral repli-

cation has commenced there is transport of particles of the genome along the axon to the central nervous system. Viraemia can occur but it is thought to be of importance only in animals with damaged immune systems or pregnant animals. The mechanism of spread from neuron to neuron is not properly understood, but the genomic material may complete its maturation or there could be direct transmission of the genomic material at the synaptic junctions. Once it reaches the brain the spread there is rapid, although adjacent structures are thought to be the first affected. The accumulation of virus in particular parts of the brain is thought to be responsible for the clinical signs. Once the virus reaches a particular site in the cord the virus can travel in a centrifugal direction out to the tissues. Thus the virus can be found in a range of tissues and organs. However, it is thought that the spread to the salivary glands occurs once the virus spreads within the brain.

Emaciation or failure to thrive is often seen and this is caused by damage to the hypothalamus and interference with the production of growth hormone. Cell mediated immunity is suppressed. Post exposure vaccination is known to be effective, but the mechanism is still not definitely understood. However, the production of virus neutralizing antibody correlates with resistance. Passive antibody has been shown to be effective in animals that have been infected, if given in large enough doses. While it is in the nervous system it seems that the virus does not stimulate the immune mechanisms but once it has passed into the non-nervous tissues, antibody production is stimulated. It is then too late to help the animal.

Recent workers have suggested that the pathogenicity of rabies is eminently suitable for the persistence of the virus and the spread of the disease. The virus is hidden from the immune system until it is too late. The distribution in the brain spares the neocortex and results in behavioural changes that promote confrontation between rabid and healthy animals and these changes coincide with the arrival of the virus in the salivary glands. The high mortality ensures that there is a minimal accumulation of immune individuals in the population and the occasional long incubation period ensures that the virus survives until there are sufficient susceptible individuals present in the population!

Clinical signs

Man

The incubation period in humans varies from a week to a reported 19 years. However, only 15 per cent of cases have incubation periods in excess of 90 days. Non-specific signs are the first to develop: malaise, headache,

anorexia, nausea or diarrhoea. Some patients experience pain or itching at the site of the wound. This is followed after a few days by the acute, agitated form of the disease: the patients are excitable, rush about and undergo convulsive seizures which occur at random or following stimulation. They become unable to swallow and this is followed by hydrophobia. Death may supervene in about 10 days or the patient may slowly develop paralysis and pass into a coma before death. A small percentage of patients develop signs similar to the dumb form of dog rabies. There is a gradual onset of paralysis; once the respiratory muscles are affected the patient dies. There are only three recorded cases of humans recovering from clinical rabies, all from the New World.

Dog

In the dog the incubation period is commonly two to eight weeks, although there is a record of a dog imported into Britain that developed rabies eight months after it arrived. It is likely that the prodromal period seen in humans occurs in dogs but is recognized by few owners, after which the dog passes into the classic 'furious' phase, showing nervousness, restlessness and exaggerated response to stimuli. Self-infliction of injury at the site of bite is not uncommon. They may attack anything – human, animal or inanimate objects – and some will eat anything, including stones and lumps of wood. There is no forgetting the look in the dog's eyes: a fixed stare or a far-away look which is difficult to describe. They may howl between the convulsive seizures and they often die during a seizure, or paralysis ensues, the animal passes into a coma and dies.

Dogs that develop the dumb form of the disease may show periods of furious activity. The muscles of the jaw are often the first to be affected and so the dog lies with its mouth open. The dog is unable to eat and many owners suspect that the dog has a bone in its throat. Argentine veterinarians believe that the disease is caused by two different strains of the virus: the furious form by the strain involved in the urban dog cycle and the dumb form by animals involved in the fox cycle.

Cattle

Much less is known about rabies in cattle than in either humans or dogs. The incubation period is said to be between two and 12 weeks (three to 21 weeks in the USA). Where the disease is transmitted by jackals it is not uncommon to find several animals affected at one time (although this was not the experience when the infection was introduced into Ghanzi District in Botswana, where the single animal was the norm). The affected animal separates itself from the herd, shows

anorexia and docility. Usually there is a drop in milk production and bulls become more sexually active. After a few days the aggressive phase may begin with the animal attacking anything. A fixed stare may be seen and the animal grinds its teeth. Inability to swallow in many African animals results in saliva running from the mouth and you put your arm down the throat to relieve the choke at your own risk! Salivation occurs in less than half the bovine cases in the USA. As the disease continues, paralysis of the tail is seen, posterior paresis and a swaying gait are noted and the animal bellows. Loss of condition ensues and the animals go off their legs, develop paralysis and between bouts of convulsions go into a coma and die. In north west Argentina a completely dumb form of the disease is seen in cattle, with the animal showing progressive paralysis. Other domestic animals show variations on the pictures described above.

The classic sign of rabies in wild animals is the loss of fear of humans. This was very dramatically seen in the kudu outbreak in Namibia in which the animals would walk into houses. Jackals become very friendly but have sudden mood swings. Wild cats become more aggressive with rabies, although even some of these animals become docile. Most humans bitten by rabid mongooses are bitten while handling these animals, thinking that they are tame.

Necropsy and pathological findings

No consistent macroscopic lesions are seen. There may be emaciation and self-mutilation. The histological findings are, however, consistent in the central nervous system. There is perivascular cuffing, focal and diffuse gliosis, neuronal degeneration and intracytoplasmic inclusion bodies from 2 to 8 µm in diameter: these are the acidophilic Negri bodies. There is a marked species difference in the presence and distribution of these bodies. In the Ammon's horn (the usual place to look for such bodies) the number of bodies in humans and dogs is variable. In herbivores, particularly goats and donkeys and to a lesser extent cattle, large numbers of Negri bodies of variable size are found. In cats, Ammon's horn is a poor source of Negri bodies and so it is more common to make the smears from the cerebellum.

Diagnosis

The history and origin of the animal will suggest the possibility of rabies and abnormal behaviour of any sort should lead the clinician to suspect rabies. In most

countries rabies has to be reported to the state or national veterinary authorities. If they suspect rabies as the cause of the problem the normal action is to keep the animal under observation for up to 10 days and to kill it for laboratory diagnosis if the disease is suspected. With the advent of the fluorescent antibody test it is no longer necessary to wait for clinical disease to progress before the animal is killed for examination. This is particularly so with wild animals or animals of unknown ownership.

The animal should be killed in such a manner that the brain is not damaged; it should be divided sagittally into two halves, one half should be immersed in a large quantity of 10 per cent formal saline (histological examination) and the other half should be put into a large jar of glycerol-saline (viral examination). Both jars are placed in a special container with sufficient absorbent material to soak up the liquids should the bottle break; the parcel should be sealed and all should be sent to the laboratory. In Botswana, where there were daily temperatures of up to 40°C, samples that were delayed for a week *en route* could still be examined with a good chance of success.

The tissue in formalin is used for making histological sections and, in negative cases, may often help to confirm a differential diagnosis, e.g. babesiosis in cattle and distemper in dogs. Smears are made from the Ammon's horn and can be stained by Seller's stain (a Romanovsky stain) in which the eosinophilic bodies stain pink. This technique is rarely used today because it has been replaced by the use of the fluorescent stained antibody test in which the smears along with control positive and negative smears are stained and examined under the ultraviolet light microscope. A definitive test is to make a suspension of the brain and inject this into the cranium of sucking mice. If rabies virus is present, the mice will die within 30 days and Negri bodies can be demonstrated in their brains. Unpublished results from Botswana show the relative value of these tests (Table 70.2).

Complete comparability between the fluorescent antibody test (FAT) and the biological tests was demonstrated. Following this work, biological tests were only

carried out on samples that were negative to the FAT. Histological examination was abandoned. Recently an ELISA test has been developed which apparently gives similar results to the FAT. The results can be read with the naked eye and thus an accurate diagnosis can be achieved without the need for expensive equipment. Viral tissue culture, the detection of viral nucleic acid and serological tests are not used in diagnostic laboratories but are restricted to research and investigation laboratories. Monoclonal antibodies have been used in the identification of the rabies-related viruses.

Differential diagnosis

There are many diseases that can be confused with rabies in different animals. Distemper and canine hepatitis are the most common infections in dogs, heartwater (p. 765), cerebral babesiosis (p. 748), cerebral theileriosis (p. 750), meningoencephalitis caused by *Haemophilus somnus* (p. 907) and BSE in cattle and parasites and toxic plants and chemicals in all species. One should first eliminate rabies and BSE and then proceed to the differential diagnosis.

Vaccination (see p. 1018)

Pasteur produced the first vaccine by suspending spinal cords from infected rabbits in an atmosphere of sodium hydroxide for various periods of time. The drawback to this vaccine (used for many years) was that the patient had to receive 14 injections on a daily basis. There was also the possibility of the patient developing a neuropathy (paralytic neuritis) following vaccination. The next vaccine was produced in sucking mice because these immature creatures have less myelin, so reducing the risks of auto-antigenicity. Hen (for animals) and duck (for human) eggs were the next vaccines produced and both were used extensively for upwards of 20 years. In some African countries the Flury strains are used to this day and they work well – high passage for cats and cattle and low passage for dogs. Today the vaccine most

FAT, fluorescent antibody test.

commonly used in man and animals is the human diploid vaccine. Post exposure treatment of humans in Botswana is given on days 0, 4, 7, 11, 17 and 84.

Oral vaccines have been developed for use in the control of the disease in wildlife, particularly for foxes in western Europe. It has been shown that foxes will take chicken head bait laced with the vaccine in a capsule. This has proved very successful in controlling the disease in foxes. So far it has not been extended to other species of wild animal. Future research will undoubtedly be into the production of recombinant vaccines using harmless viruses: in this way it might be possible to vaccinate all species of wild animals that carry the rabies virus.

Control

In Britain, as in many other islands free from infection, the perfect control measure was in place, namely the prohibition of importation of carnivorous animals unless they underwent six months' quarantine. This was changed in 2000 to a system of movement controls and vaccination. It is interesting to speculate when the first case of rabies will be diagnosed in Britain. Most countries in the world have laws in place to control this disease. These vary from the strictest in Australia, where carnivores may only be imported from countries free from infection and they are still required to be kept in quarantine for six months, to poor countries such as Tanzania where almost nothing is done (there were 400 human deaths in the Mwanza region a few years ago because there was no money to buy vaccine!).

What is needed to control the disease is an efficient laboratory to diagnose the infection and an efficient veterinary service to undertake field studies to determine the areas of the country in which the infection is most prevalent, the various species of animal that are involved and the populations of these animals. It is necessary to determine whether there are wild-life reservoirs of infection or whether it is purely a problem of urban dogs.

With this information it is possible to plan the campaign of control and budget for its costs. In most Third World countries rabies vaccination is supplied free to dog owners during the campaign, either at predetermined vaccination sites or on house to house visits. Owners who require their animal to be vaccinated outside this time usually have to go to a private veterinary surgeon. In Botswana, at the time of vaccination, the dog is painted on the head. Once the vaccinations are completed then control teams go into the area and capture or shoot all dogs without the paintmark. Other countries do not have such draconian measures. In countries where there is little control of the dog popu-

lation such slaughter may be counterproductive: rapid reproduction will soon increase the numbers and all the increase will be susceptible. Cats are not usually vaccinated because they play less part in the disease cycle. In countries where there is movement of animals then some form of permanent marking or certification is required. Although the modern vaccines produce immunity that lasts for three years it is normal practice to mount a vaccine campaign on a yearly basis. Movement control from the affected areas is practised and only vaccinated dogs are permitted to leave the area. It is considered that an area can be considered rabies-free if there has been no case of the disease in the last two years.

In Botswana, cattle owners are not permitted to vaccinate their cattle against rabies. A susceptible cattle population acted as a marker for the infection of jackals. The economics of vaccinating cattle in Africa are such that the farmer would not recoup the cost of the vaccine as it is cheaper to let the odd bovine die. This is not the case in South America where the vampire bat can wreak havoc in a herd. The author knows of no country in South America that has a policy of cattle vaccination: it is left to the individual owner.

The presence of rabies-related viruses in a country complicates the control of rabies. It is known that with some viruses the rabies vaccine provides some protection and so this has been used in human patients bitten by bats. In the National Veterinary Laboratory, Botswana, it was the policy that staff were not routinely vaccinated against rabies. It was thought that confidence would breed carelessness. It was known that pre-exposure vaccination even with the tissue culture vaccine would not give adequate protection, if it were not followed up with post exposure vaccination. Over the years several staff members received the treatment course of rabies vaccination.

With rabies eternal vigilance is required.

Introduction

With an area of approximately 2.1 million square kilometres and an estimated population of over 19 million people, the Kingdom of Saudi Arabia dominates the Arabian Peninsula. Within its boundaries, the country holds the two most sacred sites of the Islamic faith, the Holy Mosques of Mecca and Madinah, and Islam is the all-embracing force which is seen in every aspect of Saudi society. The nation was united into its present form by King Abdul Aziz in 1932 and is still ruled as an absolute monarchy by his descendants.

Saudi Arabia consists almost entirely of desert or semi-desert areas and is one of the driest countries on earth, with an annual rainfall in most areas of around 100 mm. The rainfall that is seen is irregular and unreliable. There are two distinct seasons with summer lasting from March to early October, when daytime temperatures are consistently above 40°C and commonly reach as high as 50°C, while at night the temperature will remain above 30°C. The daytime temperatures during the winter months are usually in the range 20–30°C. Coastal regions suffer with extremely high humidity, especially in the summer, whilst the central regions are characterized by a very dry atmosphere.

Saudi Arabia has the largest known oil reserves in the world, together with vast amounts of natural gas and mineral wealth. The discovery of these natural resources had a dramatic effect on the nation during the latter half of the twentieth century and the health of the economy is now closely linked to the price of oil on the world market.

Cattle industry

The dairy industry is sophisticated and is concentrated in the hands of relatively few large, integrated compa-

nies, both privately and state owned. In addition to farming activities most dairy companies have their own processing plants and distribution systems.

The full range of pasteurized fresh dairy products that would be found in any Western country is readily available. The largest selling product is a traditional Middle Eastern fresh natural drinking yoghurt called *laban*. About 60 per cent of fresh milk production is fermented into *laban* while approximately 25 per cent is processed as fresh milk. The retail price of a litre of milk has fallen rapidly due to competition pressures from the equivalent of 75 pence (US\$1.05) in 2000 to about 53 pence (US\$0.80) in 2002.

In contrast to Europe, a higher value is placed on fat than protein in milk and this is reflected in the nutrition of dairy cows and in sire selection. This is primarily because of the demand for traditional breakfast cream called *ghiste*. However the demand for skimmed and semi-skimmed milk is increasing and both products are readily available. Milk quality is generally excellent and most companies produce milk with a bacterial count and somatic cell count that would qualify for the highest payment bands offered by UK milk purchasers.

The beef industry is quite small. The majority of locally produced red meat consumed is sheep, goat and camel and the best quality beef is imported. Most local beef is slaughtered at up to 18 months of age and is referred to as veal. Veal cattle are usually castrated Holstein bulls sourced from the dairy sector. There is also a small amount of beef produced by nomadic farmers who keep suckler cows.

There are effectively no private veterinary surgeons working in the cattle industry; veterinary surgeons are exclusively employed directly by individual farming companies.

Dairy farming

Milking cattle are Holsteins which are zero grazed with a diet based on home-grown alfalfa hay and maize silage. Saudi Arabia is fortunate in having enormous underground reservoirs of water and it is this water which is used for both dairy farming and arable pro-

duction. Certain areas of the desert are extremely fertile if water is provided and the basis of crop and forage production is an irrigation system known as the *centre pivot* (Fig. 71.1). A pivot consists of a bore hole producing water which then passes into a horizontal overhead pipe mounted on wheels which makes a slow circuit and irrigates a circular area of land around the bore hole. Nutrients may be added to the water as required and pivots may have a diameter of up to 800 m. From the air pivots may be seen as 'green circles in the desert'.

Forage is supplemented with imported products such as soya, flaked maize, cottonseed, cottonseed hulls, sugar beet pulp and fishmeal. Feed is usually fed as a total mixed ration off the floor with the cattle in lockable head stanchions. Feeding time provides an opportunity for breeding and other management procedures.

The best dairy units have around 4500 to 5000 dairy cows together with a large youngstock rearing operation. Cows are milked four times a day in a two hundred stall parallel parlour which operates 24 hours a day, with breaks between shifts for cleaning and routine maintenance. A farm of this size has a total staff of about 145 men, including everyone from the farm manager to cooks and administration staff. Rolling herd average milk yield in the best units is over 12 000 litres per head. Lactating cows are housed in groups of 300 and considerable effort is spent to ensure that this number of animals calves in as short a period as possible to fill the house quickly. The spread of calving dates in the house must be minimal so that they can be managed and fed as a single group. First lactation cows are housed separately from older cows.

The extremely high temperatures experienced both day and night throughout the summer months make careful control of the cows' environment essential. Efficient milk production is difficult without effective

Fig. 71.1 A centre pivot irrigation system.

cooling during the summer months and even during the winter cooling still plays an important role. A good illustration of the high temperatures experienced is the fact that mercury clinical thermometers are of little use in the summer. The air temperature is considerably higher than the normal body temperature of a cow and so it is almost impossible to make an accurate measurement of a cow's rectal temperature.

The technology for cow cooling was originally developed in the arid regions of Arizona, USA. One commonly used cooling system involves a large electrical fan mounted in the roof which blasts air downwards onto cattle. The air may be cooled by evaporating controlled amounts of atomized water into it. A cow house will need a whole series of fans to provide effective cooling and for much of the year these will be operating 24 hours a day (see Chapter 8). Cooling is also essential in parlour collecting yards (Fig. 71.2).

Cows are housed on sand and, over time, the original sand bedding accumulates increasing amounts of dung. This provides a peaty type of bedding which is com-

Fig. 71.2 Coolers over a collecting yard. Note the udder washers on the floor.

fortable and works extremely well, provided it remains dry. To maintain the beds in good condition houses are groomed four times a day by scraping the top layer of bedding outside and leaving it in the sun to dry, whilst previously dried material is scraped back inside. It is possible to maintain a house for several years before completely cleaning out and starting with fresh sand. Rain is uncommon, but when it does fall it can cause serious problems with the bedding which is associated with an increased incidence of mastitis and lameness.

Mastitis is maintained on well-run units at a level of less than 20 cases per 100 cows per year, and levels would be considerably lower in some cases. Meticulous attention to the Five Point Plan for many years has been very successful in reducing contagious mastitis to very low levels and most of the cases are environmental mastitis. There is still a lot to be learned in the management of cows and housing in this type of system to reduce environmental mastitis further.

Staff are divided into several teams with responsibility for areas such as milking, feeding, health, breeding, calving and youngstock rearing. Because of the large number of cows being dealt with, members of these teams gain a great deal of experience.

Role of the veterinary surgeon

The veterinary surgeon has an essential, proactive role to play in the productivity and health of the herd.

First and foremost he must establish performance targets, monitor them continuously and intervene immediately when performance starts to deviate from that target. As well as collecting, handling and interpreting data this involves working closely with farm staff at all levels to investigate problems as they arise. Examples include the calving live birth rate, incidence of mastitis, conception rates, incidence of ketosis and cow and calf mortality. If any of these parameters fall below the set target investigations must start immediately.

Secondly, he must establish the optimal working practices for each team and produce written manuals to set these out in a clear and methodical manner. It is important to utilize the very best current knowledge available in an area and produce firm guidelines that can be applied simply on a very large scale.

Thirdly, he has the responsibility for the maintenance of herd disease security. There is probably no other situation in the world where herd disease security takes on such an important role. Foot-and-mouth disease (FMD) and rinderpest are a real risk and if either of these were to enter a large unit the results could be catastrophic.

FMD is endemic in the region and attempts to control it on a national scale are thwarted by the move-

ment of livestock into the region from the Horn of Africa and from more northerly states such as Turkey, Iraq and Iran. The greatest threat to dairy units comes from the large, mobile population of sheep and goats in the region and these may commonly be infected whilst showing only minor clinical signs.

Prevention of FMD is maintained in two ways: physical security of the unit and a stringent vaccination policy. The principle of physical security is that livestock, people and vehicles do not enter the unit unless absolutely necessary. When they do, sensible precautions are taken in terms of disinfection of vehicles and provision of farm overalls and footwear. However, these precautions are no substitute for preventing entry to the unit and this must always be the main thrust of physical security.

Farms are fenced with a single point of entry (Fig. 71.3) which is manned 24 hours a day. Cattle sales and disposals are done through a separate gate at the perimeter so that cattle trucks do not enter the farm (Fig. 71.4). There is a large separation between the perimeter fence (Fig. 71.5) and the cow houses, typically 200 m or more. Essential deliveries are kept to a minimum and lorries are disinfected before entry. Visitors are not allowed and all company staff entering the site must leave their vehicles outside the perimeter fence.

There are special risks when companies with multiple sites have to move livestock between their own farms. The risk is reduced by using lorries exclusively for their own animals, efficient disinfection and ensuring a member of farm staff always accompanies the driver to ensure that cattle are not exposed to any unnecessary risk during transit. Forage is only sourced from suppliers known to have effective fencing to keep their pivots free from livestock.

Fig. 71.3 A farm gatehouse, which is controlled to reduce the risk of foot-and-mouth entering the farm.

Fig. 71.4 Loading ramp at the perimeter fence for livestock movement. Cattle are moved through a separate gate from the main entrance to ensure that cattle trucks do not enter the farm.

Fig. 71.5 Farm perimeter fence. Security is important in a region where foot-and-mouth is endemic. The perimeter fence is separated from the cattle housing by several hundred metres.

One feature of farming in this region is that a large proportion of farm staff are expatriates from countries such as the Philippines, Kenya, Sri Lanka, Nepal, Pakistan, India, UK and Ireland. Most staff are resident on site and this reduces the chance of staff coming into contact with other local livestock.

Preventing the movement of cattle and personnel does nothing to prevent the chance of airborne spread between units. This is a particular risk if another dairy unit in the region is suffering a clinical FMD outbreak. The chance of infection by airborne spread appears to be greatest when humidity is above 60 per cent.

The second component of FMD prevention is vaccination. The antigenic components included in the vaccine available in Saudi Arabia are authorized by the Saudi Ministry of Agriculture and Water, based on the best scientific advice available from authorities such as the Institute of Animal Health at Pirbright, UK. FMD vaccination is carried out every 75 days in all stock over 6 months old. This routine is carried on a predetermined day and all cattle are included regardless of any other considerations. Calves less than 6 months old are given a course of three vaccinations at 4, 5 and 6 months old before joining the whole herd schedule.

Vaccination against FMD is a tremendous cost to any dairy organization. Apart from the direct costs of vaccination and time involved, milking cows often suffer a significant but short lived reduction in milk yield. Typically total daily milk production may fall by an amount equivalent to between 0.5kg and 2.0kg per cow for a 24- or 48-hour period immediately following whole herd vaccination. This cost is, at present, an unavoidable loss associated with the keeping of dairy cattle in the region. Dairy companies do vary in the vaccination schedule employed depending on their own circum-

Fig. 71.6 A 100-stall parallel milking parlour.

stances and the schedule described above would be amongst the most vigorous seen in the region.

Despite the great attention given to FMD prevention, outbreaks of the disease do occur sporadically and they will probably remain a feature of dairy farming while the disease remains endemic in the region.

A fourth role is the development of effective control and contingency programmes for a number of diseases which may occur. FMD provides the most obvious example but other diseases such as mycoplasmal mastitis, brucellosis and tuberculosis, all of which may occur, need definite policies in place to deal with them. In the case of mycoplasmal mastitis a control programme must ensure that sensible precautions are in place to prevent it, that sampling and laboratory procedures are effective in continuously monitoring for the disease and that should an outbreak occur a well-organized response can be implemented immediately.

Other roles include the coordination of parlour testing and maintenance, which assumes great importance when cows are being milked around the clock in one or two hundred stall parlours (Fig. 71.6); maintenance and monitoring of raw milk quality, co-ordination with consultant nutritionists and selection of bulls.

Function of the health team

Staff on a large dairy unit are commonly divided into a number of specialist teams, one of which is the health team. The principle of a health team's activity is that problems must be detected early and rapid intervention must ensure that affected cows are returned to full productivity as soon as possible. Any cows that do require treatment are moved to a separate hospital area which has its own dedicated milking parlour. All the milk produced in this parlour is disposed of as waste to prevent any mastitic or drug-contaminated milk from entering the main milk output of the farm.

Health teams concentrate most of their efforts on the observation of cattle in their houses. All cows are locked in their stanchions for feeding four times each day and it is during this 'lock up' period that health teams walk the cows and observe carefully for any signs of abnormality. Particular attention is given to cows within the first three weeks after calving. These fresh cows are checked four times a day whilst others are checked twice a day. Although this type of dairy farming is carried out on a large scale, great attention is paid to the health of individual cows as judged by careful observation and basic clinical skills. Health men have to be satisfied that each and every cow is eating properly and looks healthy at the time of each lock up.

Any cows that show problems are removed and given a full clinical examination in a crush. Cows are then returned to their houses or retained in the hospital for treatment as necessary.

The most common disease identified in fresh cows is ketosis and the diagnosis of this condition is assisted with the use of a urine dipstick. Any fresh cow that is submitted for clinical examination will have a urine test done as a routine. The incidence of diseases such as ketosis and left displaced abomasum is recorded daily and this information is used by nutritionists, the farm manager and the feeding team to assess the effectiveness of their feeding management.

Careful observation of cattle at frequent intervals during the day is a very time consuming activity, but it is considered essential to the effective management of a dairy unit. A successful health team is judged by an empty hospital area and not by the amount of sophisticated treatments being given to cows in it.

Summary

The dairy industry in Saudi Arabia has developed rapidly over a period of about 25 years and has been greatly influenced by the experience gained from dairy farming in arid regions of the USA. It is now probably as efficient and advanced as anywhere in the world. Prevention and control of foot-and-mouth disease is a major challenge and is very expensive.

Regardless of the size and scale of any operation, a herd is comprised of individual cows. A herd can only operate efficiently if full attention is given to the individual members of that herd. This applies as much in a unit of five thousand cows as it does in one of fifty.

New Zealand

Dairy farming

New Zealand's dairy herd of slightly over 3.3 million cows is small by comparison with Europe and America. However, about 90 per cent of the milk production is processed for export as butter, cheese and milk powders, making New Zealand a major contributor to the world dairy trade. New Zealand's unique climate favours extremely efficient livestock production from clover and perennial ryegrass pastures, top dressed with phosphatic fertilizers, which enables the unsubsidized dairy industry to compete on the world market.

Dairy farming is concentrated in areas of reliable high rainfall (Northland, Waikato, Taranaki and Southland) and where irrigation is possible and cost-effective (Canterbury). Most production is from New Zealand-Friesian and Holstein-Friesian cows (57 per cent), although there are still a significant number of Jersey (16 per cent) and crossbred herds (19 per cent). The average herd size is about 230 cows and managed by one person, but herds of 800 cows or more are not uncommon. About 30 per cent of the dairy farms are operated on a share milking basis where, for example, the owner is responsible for the farm maintenance and the fertilizer costs, whilst the share milker owns and milks the cows. This system traditionally provided a route of entry to the industry for young farmers, who could eventually accumulate enough capital to buy their own property.

The majority of dairy farms are seasonal producers, traditionally spring calving over a two month period timed with the lush spring growth, and supplying milk processing factories for nine to ten months of the year.

Recently, there has been an increased interest in autumn calving, thereby spreading the workload for both the farmer and the dairy factory. Inputs to factory supply herds are low, with little supplementary feeding, no winter housing, efficient milking plant and a low labour requirement. Farms are subdivided into small paddocks and most lactating cows are mob stocked and shifted daily. The annual production of 3000–3500l/cow is low by comparison with grain-based systems. Cows are stocked at an average of 2.7/ha and produce 600–1200kg milk solids (fat and protein)/ha. Only small amounts of hay or silage are conserved for winter feeding and the use of temporary electric fencing enables a variety of winter grazing systems to ration winter pasture and ensure adequate spring growth. A small number of town supply herds have a greater reliance on winter feed and produce milk to quota all year round.

Beef production

The majority of the beef produced in New Zealand is exported to the USA as processing beef, some is exported to North and South East Asia and about a fifth is consumed locally. About 50 per cent of the total beef production is from suckler cows and 50 per cent is derived from the dairy industry, comprising cull cows and Friesian bulls which are reared to between one and two years-old on lowland pasture. The original role of suckler cattle in New Zealand was to improve pasture quality for more profitable sheep grazing and to prevent reversion to bush. Whilst recently the price of beef has improved relative to wool and lamb, most of the country's 1.4 million suckler cows are still kept on steep and rolling hill country farms in a complementary role to sheep. Angus cattle with mature weights of about 475kg are the predominant breed, although there are many herds of Hereford and crossbred cows. The numbers of Charolais, Simmental and Limousin cattle are low by comparison with Europe, partly because of their high grazing requirements for maintenance relative to production.

Typical herds of 150–200 suckler cows achieve calving percentages of 80–85 per cent depending on the topog-

raphy of the country. Beef production is wholly dependent on pasture nutrition so virtually all suckler cows are spring calving. The various classes of cattle are kept separate and regularly moved around the farm along with the sheep. Pasture is prioritized depending on the nutritional requirements of the different classes of livestock at different times of year and care is taken to avoid competition with sheep, especially during the late winter–early spring period. Winter grazing is managed by the rotation of mobs around paddocks. Store cattle are mostly finished on intensive lowland farms, where weight gains from about 1 kg/day in spring to 0.5 kg/day in autumn are achieved on a pasture-only diet.

Animal health

The unsubsidized New Zealand beef and dairy industries are very sensitive to world production and market trends. The important economic constraints on production and requirements for veterinary input are, therefore, different when compared to the current situation in Europe. Reproductive performance is the most important determinant of herd profitability and forms the basis of veterinary input to most herds. The treatment of individual sick animals is often uneconomic, especially in extensively grazed beef cattle where early signs of disease may not be seen. However, there is an important role for veterinary advice on the control and prevention of production limiting diseases. Whilst respiratory disease and calf scour are relatively unimportant diseases in animals which are not housed, dependence on a solely pasture diet can predispose to specific animal health problems. New Zealand's volcanic soils are generally deficient in trace minerals and in the absence of supplementary feeding, trace element deficiencies (copper and selenium) are commonplace. Mycotoxicoses such as facial eczema and ryegrass staggers, which are seldom seen in Europe, can also be important production limiting diseases. Most lameness in dairy cattle is associated with the unavoidable need to walk long distances from pasture to the milking shed, and consequently the lameness-causing lesions differ from those seen in winter-housed animals. Problems of winter pasture feeding and management, the metabolic demands of late pregnancy and early lactation and stress associated with prolonged wet spring weather often result in a high incidence of metabolic diseases in dairy cows.

Reproductive management

The pattern of pasture growth in New Zealand means that suckler cows must be spring calving and a mean calving interval of 12 months is therefore essential. Most suckler cows are mated in large groups with two

to three bulls per 100 cows, depending on the topography of the farm. Most reproductive problems are associated with an extended calving period and veterinary input is, therefore, based on the achievement and maintenance of a compact calving period.

- Heifers or cows which calve late during one season inevitably calve late during the following season or do not become pregnant before the end of a compact mating period.
- Calves which are born late in the calving period are younger and lighter at weaning than those born earlier and, therefore, of lower sale value.
- The labour requirement for supervision is lower when the calving period is compact.
- Feed budgeting is more accurate for heifers and cows calving over a known short period.

The annual performance of most of the country's beef cows and the published results of field studies of more than 150 000 suckler cows (Hanly & Mossman, 1977) indicate that the average pregnancy rate is 60 per cent for each oestrous cycle, provided that heifers or cows are cycling and the bulls are sound. After calving, there is a post-partum anoestrus period of at least 40 days, which is related to body condition at calving and to the plane of nutrition and is about 20 days longer in calved heifers than in mature cows with the same body condition. Thus, provided that all heifers or cows are cycling at the beginning of the mating period, a 5-oestrus-cycle (105-day) mating period is required for 99 per cent of cows to be pregnant. However, in subsequent years if the bulls are introduced on the same date, not all cows will be cycling at the time of bull introduction and a 99 per cent pregnancy rate will not be achieved by 105 days. Therefore, a mean calving interval significantly greater than 365 days is required to sustain a 99 per cent pregnancy rate. Alternatively, a sustainable 365-day calving interval can be achieved when bulls are removed after three oestrus cycles, although annually about 6 per cent of the cows will not be in calf (Mossman & Hanly, 1977). In the absence of annual cow subsidy support and provided that the difference between cull and replacement cows is low, this not-in-calf rate is more than compensated for by increased weaning weights due to the greater mean age of calves at weaning.

Good heifer management is the key to achieving satisfactory reproductive performance in the whole herd. Provided that heifer management is correct, nutrition is adequate and sound bulls, matched for size, with high libido and low estimated breeding values for calf birth-weight are used, the achievement of good reproductive performance in subsequent years is relatively straightforward. Traditional heifer calving at three years of age presents few problems. However, about 30 per cent of

New Zealand beef heifers are first calved as two-year-olds, which necessitates careful management to avoid dystokia and subsequent reproductive problems. Heifers weighing 65 per cent of their mature weight at 14–15 months of age should be cycling and achieve target pregnancy rates when mated. For 15-month-old Angus, Hereford and Simmental heifers, this critical minimum weight is in the order of 270kg, 290kg and 310kg, respectively. Heifers intended for calving as two-year-olds are preferentially managed and regularly monitored to ensure that target weights are achieved through good nutrition and control of growth-limiting diseases, such as parasitism and trace element deficiencies. Heifers which do not reach the critical minimum weight at 15 months of age are usually culled from the breeding herd or mated the following year to avoid the problems of poor pregnancy rates and failure to rebreed as second calvers. On many hill farms, or on lowland farms with heavy breeds of cattle, the achievement of critical minimum weights by the age of 15 months is not possible and calving as two-year-olds is uneconomic.

Bulls are removed from the herd of replacement heifers one cycle ahead of the cow herd to overcome the problem of a longer post-partum anoestrous period in calved heifers. When cows are mated over a period of 63 days, this is achieved by mating replacement heifers for only 42 days or by mating heifers for 63 days, but introducing the bulls 21 days before the start of mating in the cow herd. Forty-two-day heifer mating is suited to calving at two years of age, because animals are three weeks older at the time of bull introduction, which can make a significant difference to achieving critical minimum weights and subsequent herd reproductive performance, while 63-day heifer mating is best suited to traditional three-year-old heifer calving.

Poor body condition at calving results in long calving to conception intervals and a high not-in-calf rate when a short mating period is employed. Furthermore, thin calved heifers that do become pregnant usually conceive late in the breeding season, calve later, wean lighter calves and fail to become pregnant as second calvers. Under intensive grazing conditions, replacement heifers cannot compete with adult cows for nutrients unless managed as a separate group through to their second calving. Having achieved good heifer management, day-to-day management is based on assessing the body condition of cows in accordance with their reproductive status. If feed inputs are below requirements, cows will lose weight and fail to reach target condition score for mating and eventually fail to rebreed.

The same requirement for a compact spring calving period applies to the dairy herd, where 60 to 70 per cent of the cows conceive to proven sires by artificial insemination. About 30 per cent of inseminations are per-

formed by the farmer and 70 per cent by trained technicians. Heat detection is assisted by the use of tail paint. Poor reproductive performance in dairy cows is often associated with extended post-partum anoestrous periods due to failure of winter/spring pasture to meet the nutritional requirements of advanced pregnancy and early lactation. Intravaginal progesterone releasing devices (e.g. CIDR, InterAg, NZ; Cue-Mate, Duirs, NZ; PRID, Stockguard, NZ) are routinely used in an attempt to overcome this problem and to induce oestrus in later calving animals.

Major problems

Copper deficiency (see p. 298)

Copper deficiency is an important cause of ill-thrift in cattle over the age of six months. Severe scours and copper-responsive post-parturient haemoglobinuria in dairy cows used to be common in some areas, associated with high spring levels of molybdenum in peat soils or the application of molybdenum to pasture as a fertilizer. There are also reports of poor reproductive performance associated with copper deficiency, although it is unclear whether this is due to copper deficiency, the toxic effects of molybdenum or just secondary to ill-thrift.

Whilst the copper levels of New Zealand pastures vary little throughout the year, the levels of interfering factors, molybdenum and iron, increase significantly throughout the winter and spring. Copper availability is therefore lowest in spring, at the time of year when animal requirements for late pregnancy, lactation and early growth are highest.

Both serum and liver copper concentrations are used in the diagnosis of poor animal performance, but liver is the only useful sample when the reasons for sampling are to determine whether reserves are adequate to last throughout the winter or to monitor a supplementation programme (Ellison, 1992). The correct number of samples is essential (minimum of eight sera or four liver samples), because the laboratory reference values are based on mean values from these numbers. Liver samples are obtained by biopsy or from slaughterhouse or necropsy material.

There are no recipes for trace element supplementation, which depends on many factors including the severity of the deficiency, production system, stocking density and availability of labour (Wakelin, 1992). Short-term supplementation of dairy cattle can be provided by daily drenching with copper sulphate in the milking shed or administration of copper salts through the drinking water, but requires careful monitoring. Intermediate-term supplementation is achieved in both dairy and beef cows by the parenteral injection of

copper glycinate or copper edetate, whilst long-term supplementation can be provided by the oral administration of copper oxide particles (capsules or bullets) or pasture top dressing with copper sulphate.

Selenium deficiency (see p. 302)

About 30 per cent of farmed land in New Zealand is considered to be selenium deficient. The most important selenium responsive condition in New Zealand cattle is ill-thrift in growing calves and growth responses of 5–10 per cent can be achieved by supplementation on most deficient pastures. Selenium responsive infertility and poor milk production have been reported on severely deficient pastures (Grace, 1994). The selenium responsive condition of nutritional muscular dystrophy is now quite rare due to the awareness of selenium deficiency and widespread supplementation.

The selenium status of cattle is usually confirmed by the laboratory analysis of blood glutathione peroxidase (GSH-Px) or selenium concentrations in serum, whole blood or liver, all of which provide useful diagnostic information (Wichtel, 1998). Liver samples collected from finished calves at slaughter are commonly used to determine the need to supplement. Within any herd, there is little between-animal variation in the concentrations of selenium in blood, serum or liver, or blood GSHPx concentrations, therefore samples from three or four animals usually provide adequate information. The New Zealand reference ranges for selenium are based on numerous calf growth response trials (Ellison, 1992). Overseas reference ranges are of no value to New Zealand conditions and vice versa, because the vitamin E status of New Zealand cattle is generally more than adequate due to their year-round pasture nutrition. Economically significant growth rate responses to supplementary selenium are unlikely at liver selenium concentrations above 600 nmol/kg (wet weight).

Sodium selenate or selenite administered orally, as a pour-on or by subcutaneous injection can provide a useful method of short-term supplementation. Long-term supplementation is achieved by controlled release subcutaneous injections of barium selenate paste, intraruminal selenium pellets or pasture top dressing with sodium selenate or sodium-barium selenate prills. Pasture top dressing is an efficient supplementation method where stocking rates are high and is the preferred supplementation method on about 30 per cent of selenium deficient properties.

Facial eczema

Facial eczema is an important cause of ill-thrift and hepatogenous photosensitization during late summer

and autumn, in many areas of the North Island of New Zealand. Facial eczema is caused by ingestion of the mycotoxin sporidesmin, which is present in the spores of the saprophytic fungus *Pithomyces chartarum*. Under the ideal conditions of high humidity (close to 100 per cent) following a prolonged warm period (>20°C with a minimum night temperature of 12°C), spore numbers can increase rapidly in the mat of leaf litter beneath shaded pasture. Sporidesmin is rapidly absorbed and becomes concentrated in the liver where it causes epithelial necrosis of the bile ducts with periductal oedema and inflammation, leading to cirrhosis. Most affected animals show no outward clinical signs. However, the resulting liver damage causes ill-thrift and a significant reduction in milk production. Photosensitization occurs in about 10 per cent of affected animals and is due to derangement of the biliary excretion of phylloerythrin (Bruère *et al.*, 1990).

Outbreaks of facial eczema are both distressing and expensive, therefore intensive monitoring is performed to assess the risk of disease and expedite preventive measures. Monitoring consists of recording weather conditions and carrying out pasture spore counts using spore trapping or pasture washing methods. When counts rise rapidly, or reach threshold value, the options are to move stock to safer pasture, to instigate protective treatment with zinc salts, to apply fungicides to the pasture or a combination of these practices. Fungicide spraying can provide safe pasture for six weeks, but can be expensive, especially when it has to be repeated due to heavy rainfall or a prolonged risk period. Oral administration of large doses of zinc oxide, before exposure to toxic levels of sporidesmin, effectively reduces the severity of liver damage, although the mechanism is unclear. Milking cows can be dosed daily in the milking shed, but other classes of cattle are usually drenched weekly at a higher dose rate to overcome the impracticalities of yarding and handling. Alternatively, zinc sulphate can be administered to dairy herds through the water supply. Wax-coated, slow-release zinc oxide intraruminal boluses (Time Capsule, AgResearch, NZ) are available for use in calves. The boluses slowly dissolve in the rumen to provide four weeks' protection and are useful when animal handling is difficult. Zinc salts have no therapeutic value when administered after exposure to sporidesmin.

Outbreaks of facial eczema can be avoided by judicious farm management practices such as feeding of hay or other supplements during high risk periods, avoidance of close grazing and removal of stock from high risk areas. Affected animals should be provided with shade or if possible housed in darkness during day light hours. Milking cows should be dried off and skin lesions treated topically.

Ryegrass staggers

Ryegrass staggers occurs under close grazing conditions during summer and autumn in perennial ryegrass (*Lolium perenne*) dominant pasture-fed livestock throughout most areas of New Zealand. The disease is caused by tremorgenic mycotoxins (lolitrem A and B) which are produced by the perennial ryegrass endophytic fungus *Acremonium loliae* and is characterized by tremors, incoordination and depressed growth rates. The prevalence of the endophyte in perennial ryegrass is greatest during summer and autumn, in particular in the plants' lower sheaths, old leaves and seedheads. Many modern ryegrass cultivars have been selected for high levels of the *A. Loliae* endophyte, because it is associated with resistance to attack by the Argentine stem weevil (*Listronotus bonariensis*), an important agronomic pest. Such selection has inadvertently resulted in an increased incidence of ryegrass staggers (Bruère *et al.*, 1990).

Clinical signs develop within one to two weeks after introduction to toxic pasture. At rest, the only visible signs may be fine tremors of the head and neck, but when animals are disturbed, clinical signs immediately become apparent with development of head nodding and jerky movements of the neck and limbs. Moderately affected animals have a wide-based, swaying stance and a high-stepping gait. Severely affected animals show a stiff-legged gait and usually collapse when moved. Whilst the disease is distressing to observe, most losses are associated with misadventure. However, affected animals are difficult to handle, interfering with normal management practices. There is no specific treatment for the disease, but animals recover within days of removal from the toxic pasture. However, the avoidance of close grazing of high endophyte ryegrass dominant pastures can be problematic, especially during dry summer conditions.

Lameness (see Chapter 31)

Lameness is a significant problem in New Zealand dairy herds. Unlike the situation in winter housed cattle, the main problems are excessive wear and bruising of the sole, perforation of the sole (septic pododermatitis) and white line disease. Most herd problems are associated with poor design, construction or maintenance of farm tracks and impatient animal handling.

Observational case-control studies of New Zealand dairy herds have shown that when cows walk at their own pace, each limb is accurately placed to avoid injury. The incidence of claw injury is low in herds which are allowed to drift to and from the milking shed, even on rough or poorly maintained tracks. Significant problems occur when cows are hurried by pushing the animals at

the back of the group. The problem is compounded by poorly maintained tracks which cause direct trauma to the sole and slow the herd down, causing further impatient handling. Impatient forcing of cows results in cows skidding as animals from the back of the group are forced against those in the middle; tussling to avoid body contact, resulting in unplanned placement of limbs; abnormal forces being taken on the abaxial wall of the lateral claw as cows attempt to resist being forced off the track; shortening of the stride so that the hind limbs are no longer placed in the same safe spot as the fore limbs and cows being unable to see their lower limbs as their heads are forced up and above the animals in front (Chesterton, 1989).

Most lameness problems can be managed by patient movement of cows along the farm track to the milking shed, proper maintenance of tracks and careful handling in the shed. Congestion points and distractions should be removed and the track surface should be non-abrasive, correctly crowned and well drained, especially the parts closest to the milking shed (Vermunt & Greenough, 1997).

Bloat (see p. 832)

Pasture bloat is a common cause of sudden death in cattle in New Zealand. It is caused by the production of a stable foam which traps the normal gases of fermentation in the rumen (frothy bloat) and inhibits eructation. Pasture bloat occurs most commonly when cattle graze pastures dominated by lush, immature, rapidly growing legumes (clovers, lucerne), but there are also reports of the disease when cattle are grazed on other materials such as turnips, brassica and cereal crops, and young grass with a high soluble protein content. While death is the most obvious loss associated with bloat, subclinical and mild bloat are associated with considerable production losses.

Although bloat susceptibility is heritable, progress in the genetic selection for low bloat susceptibility has been slow (Morris *et al.*, 1991). Outbreaks of bloat with several cows dead and/or stabbed are devastating, and nowadays most farmers take precautions by using antifoaming agents, which are still the only reliable way of controlling or preventing bloat. Historically, farmers have used detergent based products for controlling bloat. These have included oils, marlophens, pluronics or turps, and currently the most favoured are the alcohol ethoxylate derivatives due to their extended persistency of action. Most commercially available products are suitable for daily drenching, trough treatment or pasture spraying. The rumen modifier monensin (Rumensin Liquid and Rumensin Anti-Bloat capsule, Elanco, NZ), is marketed as an effective product in the prevention of milk bloat. Monensin is

not a detergent, but acts to reduce the bacterial/protozoal activity that releases foam producing compounds in the normal rumen.

The Australian scene

Dairy farming in Australia is largely confined to those climatic regions which are favoured by higher rainfall and better quality soils, especially in the eastern seaboard states and Tasmania. Flood irrigation is used extensively in areas where rainfall is very seasonal. Although each of the states in Australia maintains its own highly regulated dairy industry, the entire industry is influenced by the dominance of the southern dairy industry, particularly that of Victoria, which produces well over half of the total Australian production. Like New Zealand, the Victorian and Tasmanian dairy industries depend heavily on world markets for their manufactured and export products. The ability of farmers freely to sell market milk contracts (quota) is limited in most states, as is the ability to establish new dairy enterprises. This is in contrast to New Zealand, where dairy conversions are occurring on a large scale. The average milk price to the farmer is slightly higher than in New Zealand, but is still low when compared to Europe or the USA.

Similar to New Zealand, dairy farming in Australia is highly efficient in labour and land usage and is predominantly seasonal with the majority of the herds being spring calving. The average Australian dairy herd is smaller than in New Zealand, but the degree of 'Holsteinization' of the national dairy herd is further advanced. Dairy cows graze pasture all year round and this forms the major portion of the diet. In addition to this, supplementary feed sources such as grain are widely used. Consequently, the average milk production is higher and the average days in milk longer. Grain is fed at a much lower cost, because of the proximity to the main grain producing areas. Certain animal health

problems associated with this grain feeding (e.g. abomasal displacement, ruminal acidosis, salmonellosis and laminitis/lameness) are therefore relatively common.

Specific diseases common to Australia but exotic to New Zealand are the insect-borne diseases such as anaplasmosis, babesiosis (ticks), ephemeral fever or 'three-day-sickness' and Akabane disease (midges).

animal health, give expert advice in milk production, reproduction and growth, help design and modify facilities, design and monitor food safety protocols (pathogen- and chemical-free meat and milk) and provide information to producers on-cost-effective production of meat and milk products sold.

Veterinary involvement

Milk production trends

Production of high quality nutrient-dense milk and meat is a primary goal of dairy operators throughout North America. As our populations become more aware of human health concerns regarding food safety, they have required that we provide them with products without pathogens or chemical contaminants. As they should, consumers expect their food to be safe, wholesome and highly nutritious. With urbanization, consumers have become less aware of how their food is produced, both as a raw and manufactured product. Animal welfare issues have increasingly become a concern for consumers. Now, more than ever, veterinarians are expected to provide leadership in animal husbandry and care, ensuring that all animals are treated humanely throughout their lives. Veterinarians are in a key position to provide leadership in animal welfare, health and food safety.

As an industry North American dairies are increasing in cow numbers, but the number of facilities continues to decline. Because of increasing animal density it is likely that future dairy owners will face more environmental constraints. Environmental constraints are increasing the operating costs for existing and newly built dairies. Environmental laws are likely to restrict building and expansion of existing and new dairy facilities. Cost of production for meat and milk continues to rise, while the value of raw products sold has increased at a slower pace. The narrowing margin of profit per unit of product sold requires that animals produce meat and milk with high efficiency and that animals remain healthy. Veterinarians are now expected to maintain

The focus of this discussion is to outline those aspects of dairy production (meat and milk) about which veterinarians can provide information to dairy owners to enhance performance of their enterprise. Clearly our training as veterinarians is focused on animal health aspects of dairy cattle production. Ironically, it is often poorly planned and maintained housing, milking parlour/equipment design and inadequate or unbalanced rations that will curtail production and lead to disease. Understanding the requirements for clean comfortable housing and bedding and then helping producers implement those changes greatly increases animal welfare and performance. The use of inorganic bedding (i.e. sand) in properly designed freestall barns has a positive effect on feet and legs, mastitis and milk production. Reducing the time that cows spend standing on concrete reduces the incidence of laminitis and sole abscess formation. Increasing the time cows spend laying down chewing their cud increases mammary blood flow, with the subsequent effect of increasing milk production. Laying down a manure-free environment greatly reduces exposure to environmental streptococci, staphylococci and coliform bacteria, which helps reduce the incidence of environmental mastitis.

Knowledge of nutrient needs from birth to slaughter greatly increases our ability to reduce health problems and manipulate growth, reproduction and milk production. From our classical veterinary training, knowledge of the pathophysiology of disease allows the attending veterinarian to recognize the conditions being diagnosed and guide therapeutic intervention. Taking diagnostic methods to the population level requires an understanding of the epidemiology and dynamics of

diseases in groups of animals. Understanding the aetiopathogenesis of disease allows for intervention on a herd basis after identifying the affected groups and underlying causes of diseases within a herd. Knowing what factors predispose cows to disease and what control methods can be used to remove or attenuate risk for disease in exposed cattle will greatly help dairy owners to produce milk and meat profitably, often with less labour.

Approaching a herd problem – an example

As a case example, an 1100 cow herd had several hundred cows with diarrhoea throughout the lactating herd (900 lactating cows). The incidence of mastitis varied from zero to ten new cases per day. The expected incidence was 0–1/day. In the first 10 days after calving, 30–40 percent of newly calved cows had retained placenta and/or metritis. The expected incidence of retained placenta was 5–8% and was principally associated with dystokia and twin birth. The expected incidence of metritis in newly calved cows was 3–5 per cent and mostly associated with retained placenta. The number of cows with displaced abomasum varied from three to ten per week across all lactating strings, but mostly in the first month post partum. The expected incidence of displaced abomasum was 1–3 per cent of cows calving, with none of the cases coming from cows later than 30 days post calving. Cows dying or being sold as unproductive approached 50 per cent of the milking herd over a 5-month period and the expected rate was 30–35 per cent. The milk production was 30 litres (68lb) per cow per day and the expected production was 35–36 litres (78–80lb).

As an approach to the herd problem, cows identified by the herd manager as poorly producing or sick were held for diagnosis of underlying disease. Visual examination of all cows in the herd was done during biweekly fertility examinations. All calving and mastitic cows had composite milk samples collected aseptically for identification of *Mycoplasma* and aerobic bacteria. Approximately 10 per cent of cows in three groups had blood samples collected: cows before calving, in the first 10 days after calving and approximately 100 days after calving. Metabolic profiles (haemograms and serum chemistries) were run to help determine the underlying causes of disease. Faecal cultures for *Salmonella* sp. were collected, as well as blood for determining exposure to or active infection with bovine virus diarrhoea (BVD). Antepartum blood samples were collected to determine serum non-esterified fatty acid (NEFA) levels. Urine pH was determined to evaluate the effectiveness of the anionic dry cow diet. Diets by produc-

tion string were collected directly from the feed wagon as it delivered feed to cows. Rations, as formulated, were evaluated to determine any deviations from governmental recommendations (Subcommittee on Dairy Cattle Nutrition, National Research Council, 2001).

Antepartum cows had elevated NEFA levels, indicating weight loss in the last weeks before calving. Cows had low calcium levels before and after calving with only rare milk fever, suggesting that the antepartum diet was not well balanced for prevention of hypocalcemia. Urine pH was 8.0 in antepartum cows, indicating that the anionic diet was not effective. Non-lactating and lactating cows had high serum magnesium levels, suggesting higher than normal intake of magnesium (Mg). Diet analysis suggested that antepartum cows did not have adequate protein intake and their daily diet intake was low. This suggested that cows should be losing weight before calving, predisposing them to periparturient immunosuppression, retained placenta, mastitis, metritis and displaced abomasum. The lactating cows also had high Mg levels and diet analysis indicated that they were fed a ration containing 0.6% Mg on a dry matter (DM) basis (upper levels recommend 0.4% DM). Lactating cow diets also contained 22 per cent protein in the DM. *Mycoplasma bovis* was discovered in a few cows with mastitis in the early lactating period and several cows were culture positive for environmental streptococci, staphylococci and coliform bacteria.

Ration and feed analysis suggested the milk cows were oversupplemented with Mg and protein, and effective fibre may have been limiting. *Salmonella* cultures were negative and results of BVD serology and PCR probes for BVD suggested that neither *Salmonella* nor BVD were the cause of diarrhea. As formulated, dry cows should have been fed a ration adequate in energy and protein, but intake was low, probably causing weight loss and contributing to periparturient metabolic disease (retained placenta, mastitis, milk fever, displaced abomasum, ketosis, low milk production). The prevalence of diarrhoea was 80–90 per cent of lactating cows. There was no apparent diarrhoea in non-lactating cows.

New rations were formulated to reduce Mg throughout the herd, reduce protein in the lactating cow rations and to increase the effective fibre in the lactating herd. Close-up and far-off dry cow rations were reformulated to reduce feed sorting and to increase intake for all cows. String cultures (emphasizing newly calved and hospital cows) and retrospective reculture of all cows having had mastitis within the past two months were initiated to identify mycoplasma-positive cows. From interviews with the dairy manager it was noted that most cows were administered 40–120mg of dexamethasone for udder oedema in the first one to four

days after calving. Routine use of dexamethasone was greatly curtailed to alleviate the immunosuppression associated with its use.

After reducing the protein and Mg levels to governmental recommendations for level of milk production, diarrhoea in the milking cow herd was reduced to one to two cases/900 cows per week. These were mostly attributed to indigestion. Replacement of long-stem oat hay with corn silage from the dry cow diets and reformulation of the close-up mineral package reduced the urine pH to 6–6.5 and increased diet intake and uniformity of consumption of these two rations. Of cows calving, retained placenta and metritis incidence was reduced to 6–8 per cent and 3–5 per cent, respectively. The incidence of displaced abomasum declined to 0–3 cases/month. Cows at three to five days post calving or identified with mastitis had milk aseptically collected from all four quarters and all cows positive for mycoplasma were removed from the herd. All purchased cows were routinely monitored for contagious mastitis and treated, segregated, culled or returned to the supplier as needed. It was thought that periparturient immunosuppression, both from poor feed intake and from use of dexamethasone, facilitated the mycoplasma outbreak. After initial identification of the index mycoplasma-positive cows it took approximately one month to bring the incidence down to zero. Evaluation of the freestall environment and cows in the milking parlour indicated that the freestalls were not well maintained (wet and manure/urine contaminated), but the cows were clean and dry when milked. It was recommended that the freestalls be dug out and refilled with sand to encourage stall acceptance and reduce exposure to organic bedding.

Veterinary monitoring on the dairy farm

In addition to traditional veterinary tasks of routine health care (including biosecurity protocols), surgical and reproductive intervention, and disease monitoring, veterinarians should be involved in facility design, selecting equipment and monitoring its performance (feed trucks, milking equipment), personnel training and management, ration formulation, monitoring milk production and heifer growth, forage production and monitoring of stored feed quality.

Disease monitors

Routine monitoring of disease prevalence and incidence allows the veterinarian to interpret changes in expected levels of disease and whether intervention

may be needed to reduce disease to expected levels. Identifying factors that may contribute to lower than expected levels of disease can advance the science of veterinary medicine. Communicating new ways to reduce disease incidence can allow those of us in practice to contribute to our personal growth, advance our clients' needs and advance the way veterinary practice is carried out.

A traditional and still important area for veterinary intervention is development of cost-effective vaccination protocols and evaluation of their success. This should be done for all stages of life and production. Evaluating calving and calf facilities and performance is a way to begin routine herd health monitoring and intervention. Evaluation of the calving facility cleanliness, calving protocols for ensuring healthy cows and calves after calving (e.g. hygiene in assisting with dystokia or the force applied when pulling calves), colostrum monitoring (bacteria counts, amount, density) and calfhood disease control (cleanliness of the calving and newborn facilities, cleanliness of the feeding utensils, milk and feed and protocols for routine disease treatment) are good starting points. Focusing veterinary care in these areas has a high return on investment for producers as they are areas that are often neglected, yet have a great effect on profitability when well maintained.

Mastitis monitoring (see Chapters 23, 25)

Mastitis control and evaluation of pathogens in milk is still a very important service provided by veterinarians. Evaluation of types of bacteria in individual and bulk tank samples, individual and herd somatic cell counts and total bulk tank bacteria counts can direct where and when intervention is needed to correct a herd/equipment problem. Routine milking equipment evaluation, quality control for teat dips and milker training schools are valuable services to producers to help ensure the sale of quality milk.

Fertility monitoring (see Chapter 41b)

With several strategies of intervention for improving pregnancy rates within a herd (e.g. timed insemination and prostaglandin synchronization programmes), assessing the success and cost-effectiveness of these programs is important. Evaluation of personnel skills on a facility will help determine the likelihood of success and whether these types of programmes should be used in an enterprise. Use of bull breeding may be most appropriate for some herds, while in others highly successful artificial breeding programmes can greatly aid in creating a high quality and uniform genetic base for a herd. Goals for reproductive performance have been well described

over the past 40 years, but with the advent of products such as recombinant bovine somatotropin (rBST) some of these goals have changed. Some have suggested that increasing the calving interval in these rBST herds can be economically advantageous. However, maintaining a high proportion of the herd pregnant (50 per cent or more) with good conception rates (2.0–3.0 services/conception) still remains a primary goal to ensure profitability of a dairy enterprise.

Evaluation of body condition at calving, one to two months after calving, at conception and at cessation of lactation can help maintain reproductive performance. Increasing rates of anoestrous cows in early lactation (60–120 days in milk) suggest weight loss in the dry period or early post-parturient period (0–90 days), heat stress or inadequate nutrition in the current ration. High levels of endometritis at 30–45 days' lactation suggest problems in the periparturient period and require that all factors contributing to the endometritis be identified (e.g. nutrition, hygiene practices, dystokia, twinning). Correcting these deficits will help keep the herd reproductively sound, reduce treatment costs, lower culling rates and help maintain profitability.

The use of progesterone assays to verify heat detection accuracy (at the time of insemination) is another tool the veterinarian can use to help monitor herd health, although anoestrous cows can also lack detectable levels of progesterone. Holding breeder training schools to teach or review heat detection techniques, semen handing and proper insemination techniques can maintain high fertility in a herd.

As part of any herd monitoring programme, evaluation of the incidence of periparturient disease allows for a retrospective evaluation of the health of non-lactating cows and cows in the first month of lactation. Recording and evaluating the incidence of ketosis, displaced abomasum, milk fever, diarrhoea, pneumonia, mastitis, etc., are critical so that action or target levels for intervention may be set. Certainly diseases should be monitored at all stages of life (birth to sale) and goals of performance evaluated for each stage of production. Routine monitoring of urine pH and fresh cow metabolic profiling (Ca, Mg, P, K, Na, Cl, liver function, serum protein) will help evaluate the success of non-lactating and early lactating feeding and housing programmes. This will help ensure that cows perform well throughout lactation. Monthly or bimonthly evaluation is appropriate and can be more or less inclusive depending on the frequency of farm visits.

Production monitoring

Routine evaluation of production parameters, such as feed intake, calf growth and milk production (milk flow, butter fat, solids not fat, protein, lactose, somatic cell

count) will help guide decision-making for feeding changes, forage selection, production, harvest, storage and removal for feeding. Examination of foodstuffs can help identify those practices that alter cow health and milk production. Poor quality forage production, harvest, storage and removal for feeding can directly affect both feed intake and cow health. Overly mature feed that is too dry when ensiled can become mouldy or compost, leading to both an unhealthy feed and one that is unpalatable and poorly available. Too wet a forage or contamination of feed with animal carcasses can lead to high levels of clostridial growth, predisposing animals to diseases such as botulism. Improperly stored corn, barley, canola, cottonseed, soybeans and other protein meals can lead to mould production and subsequent mycotoxicosis. Contamination of feed from bird droppings and wild and domestic animal faeces allows for spread of *Salmonella*, *Leptospira* and other shared pathogens. Cross-contamination of feeds with cattle manure increases the spread of Johne's disease, BVD, *Salmonella* spp., etc. Recommendations for facility design to limit feed transmission of infectious diseases facilitate disease control at the population level. This type of activity is analogous to the design of vaccine and treatment protocols that veterinarians have engaged in for years. Taking steps to reduce exposure of the animals on farms to these agents is also becoming a goal for limiting contamination of food at the consumer level.

Feed sorting, or the selection of high concentrate feedstuffs over forages by cattle, increases the likelihood of lameness, subacute ruminal acidosis, reduction in the production of fat in milk and ultimately lower milk yield. Directing forage production (selecting seed, fertilization, planting density), timing (immature or mature) and method of harvest (e.g. kernel processing or rolling of corn silage as it is harvested, chop length), size and dimensions of storage facilities for forages, management of forage removal (face management of silage) will help producers keep cattle healthier and more productive. Veterinarians, by the very nature of our relationship with producers, often are in the best position to evaluate feeding practices. If we are evaluating those practices it makes sense that we are the ones directing how to feed the cows for health and production. An evolving role of veterinarians is routine ration evaluation and formulation. Because cow health is directly affected by improper nutrition, it is increasingly important that veterinarians become directly involved in ration formulation.

As part of the routine evaluation of cattle health, veterinarians should monitor why cattle are sold from the herd and the number sold in a given time. Culling rates directly affect profitability. While production may appear very good for cows in a herd, this can be deceiv-

ing if the number of cows entering and leaving the herd is high. If replacement costs are low and the value of milk high that strategy could be very profitable. Today in North America, cattle prices are high and the average price for milk sold has remained relatively steady. If a producer has a high cull rate (45–55 per cent of the herd/year), milk production per cow can be quite high (13000 litres (£3000) per 305-day lactation). However, because of the high removal rate and high cost of replacements, this strategy can reduce net profitability or prevent a dairy from growing if cows are removed for disease. If the high cull rate is because cows are being sold for dairy production (highly valued cattle) to other herds and the producer has an excellent calf raising programme, this strategy could prove to be very profitable. Helping producers evaluate their return on investment of a given strategy is an appropriate task for veterinarians to engage in.

In summary, the role of veterinarians is rapidly changing in North America. Today more of the focus of veterinarians will be in operations management, including herd health, personnel training, udder health and milking equipment evaluation, facility design, nutri-

tional and financial advice including commodity contracts, crop selection and forage production. The opportunities for veterinarians are ever expanding, allowing several avenues of input into animal agricultural production.

| The practice of beef cattle veterinary medicine in North America | 1190 |

Introduction

The North American beef industry is very diverse and complex. It is distinctly separate from the dairy industry, with the exception of cull dairy cows and castrated male dairy stock (steers), which are eventually added to the beef supply. 'Dual purpose' breeds are very seldom used for true dual purposes. There are three sectors to the North American beef industry: the cow-calf, cattle feeding and meat packing sectors. A very short synopsis would say that the cow-calf sector provides cattle for the cattle-feeding sector, which provides cattle for the meat packing industry. One may wonder why the meat-packing sector would be included in this discussion. It has become evident in recent years that all three sectors must work together and share information in order to deliver a beef product that provides a good eating experience for the end consumer. So, in this light, each of these sectors will be discussed.

Cow-calf sector

Cattle distribution

This sector is undoubtedly the most diverse. This is due to the fact that it uses grazed forage (primarily grass) as its primary raw material. Grazable forage is available in every geographic region. The landscape and climate throughout North America differ greatly between geographic regions. As the landscape and climate changes, so do the types of forages available in that region as well as the type of herd management. Cattle herds are developed in such a way to best deal with the environment in which they live. For example, in the southern United States, *Bos indicus* breeds are very popular

because of their ability to deal with the extreme heat. In the northern United States *Bos taurus* breeds are used because of their ability to withstand the cold temperatures.

Sixty per cent of the United States' cattle herd is located in the south east. Amongst others, states in this area would include Florida, Georgia, Alabama, Mississippi, Louisiana, Tennessee, Kentucky, North Carolina and South Carolina. In this area, only 1 to 5 acres (0.4–2 ha) are required to sustain a cow and her calf for one year. There are a few very large herds in this region, the vast majority are very small herds. Many of these small herds are either a hobby or a secondary source of income for the producer. Often, these producers simply have a small parcel of grass that would not be utilized at all unless the producer owned a few cows to graze it. These producers are not necessarily in the cattle business to produce beef, but rather use cattle to harvest a forage that would otherwise go to waste. Because of this, genetic control of production is not taken very seriously in many cases. In recent years, producers and veterinarians in this area have taken steps to improve genetic selection and to market cattle in uniform groups.

The remaining 40 per cent of the nation's cattle herd is spread throughout the rest of the United States' grazable landmass. In some regions of this land mass, only one acre (0.4 ha) is required to support a cow and her calf, while in other areas, as much as 100 acres (25 ha) is required to support a cow and her calf. Generally, as the carrying capacity of the land decreases, the size of the herd increases. The regions that have a high carrying capacity are also regions that produce a great deal of cereal grains. Cow-calf producers in these areas take advantage of the crop residues by allowing their cattle herds to graze the fields after they have been harvested, glean the grains that were missed by the harvesting machines (combines). In regions where there is very little cereal grain production, there is more reliance on harvested forage (grass hay, alfalfa hay, etc.) for winter feed. Herds in these regions can be as small as one up to as many as 15 000 head or more.

It is generally considered to be good management for cow-calf producers to adhere to a fairly rigid 'calving

season'. Producers will turn bulls out with the cattle for 45 to 90 days for breeding. At the end of this time period, the bulls are removed from the herd. This allows for better use of the producer's time and a more uniformly sized calf crop. Some producers do not adhere to this type of calving season, some of whom allow their cows to have calves all through the year. The majority of calves are born in the late winter or spring and are weaned in late summer or in the fall.

Weaning of calves is yet another area of great diversity within the cow-calf sector. Some producers will go through a strict 'preconditioning' programme, in which the calves are vaccinated once while still on the cow (typically against IBR, BVD, PI3, BRSV and clostridial disease). Then, approximately three weeks later, they are revaccinated against the viruses, implanted with a growth-promoting hormone and weaned. The calves are then fed a grain and roughage ration for anywhere from a couple of weeks to several months, depending on the marketing plans of the producer. Other producers will vaccinate their calves once, pull them off the cow and sell them. Still others will simply pull their calves off the cow without vaccinating them and sell the calves. Most bull calves are castrated at some point prior to marketing, becoming known as 'steers'.

Some cow-calf producers will retain ownership of their calves through the feeding period up to harvest. These producers most commonly send their calves to a 'custom' or 'commercial' feedyard and pay the feedyard to feed the calves for them. This will be discussed in more depth in the cattle feeding section. Most cow-calf producers sell their calves at some point prior to the feeding period. The most common form of marketing calves is done through a livestock auction (also commonly known as a 'sale barn'). Calves are taken to the livestock auction, sorted for size or other common characteristic and sold to the highest bidder. Disadvantages of this type of marketing are that cattle are commingled, thus allowing disease transfer. Cattle can also be sold via 'satellite auctions' in which video images of calves are transmitted by satellite all over the country for bidders to view and bid on. Still more cattle are now being sold over the internet/world wide web. These latter two marketing options offer the advantage of not commingling different groups of cattle, as the cattle are marketed directly from the ranch of origin.

Within the cow-calf sector is a group of producers collectively known as 'seedstock producers'. These are producers who specialize in producing breeding stock to be used by the commercial cow-calf producer. Careful attention is paid to fertility, carcass traits, muscling and performance characteristics (average daily gain, weaning weight, yearling weight, feed conversion, etc.). There is a wide range of criteria that cow-calf producers use to select breeding stock and many of these are

predicted by the use of expected progeny differences (EPDs). EPDs give the bull buyer an idea of how a particular bull's calves may perform in various traits.

Cattle feeding sector

The cattle feeding sector has become very specialized. In the 1960s, many cow-calf producers fed their own cattle to harvest weight. As more science and technology have been put to use, it has become more efficient and cost-effective for cattle feeding operations to get increasingly larger, and less efficient and cost-effective for the cow-calf producer to feed his own cattle. Many of the modern cattle feeding operations (known as 'feedlots' or 'feedyards') can hold 100 000 head of cattle or more at one time.

A feedyard is a collection of pens that are used to confine cattle while they are being fed a high-energy ration. One side of the pen is lined with a concrete feed trough (feed bunks). Trucks, fitted with a special box that is capable of mixing feed, auger feed into the feed bunks as they drive alongside them. Feed management is considered to be one of the most important and detailed jobs around the feedyard. Calling for the wrong amount of feed can hurt the performance of the cattle in that pen for the rest of the feeding period. Feedyard cowboys ride through each pen of cattle every day looking for sick cattle. Sick cattle are removed from the pen and placed in a hospital pen, where treatment is administered and the animal is given time to recover before being returned to the original pen.

Cattle are usually hauled into feedyards by semi tractor-trailers. These large trucks can carry 50 000 to 56 000 lb (22.5–25.4 tonnes). It is not uncommon for cattle to be hauled for 8 to 24 hours before arriving at the feedyard. This puts the cattle under a great deal of stress and increases the chances that they will become sick. Over the years, feedyards have become very adept at dealing with this stress. Many feedyards have pens that are used especially for receiving cattle. These pens are usually smaller than other pens on the feedyard and have excellent drainage so the newly arrived cattle have a dry place to rest. Fresh feed and clean water are provided at all times. After the cattle have eaten, drunk and rested, they are put through a series of procedures known collectively as 'processing'. Processing may include any or all of the following: vaccination (against pathogens such as IBR, BVD, PI3, BRSV, *Pasteurella/Mannheimia*, spp. clostridial pathogens, *Haemophilus somnus*, etc.), implantation with a growth hormone, eartagging, administration of a parasiticide, administration of a vitamin/mineral supplement, castration of bulls or pregnancy examination of heifers. If a heifer is found to be pregnant, the pregnancy may be aborted.

Upon completion of processing, the cattle are moved to a regular pen on the feedyard. Over the next two to three weeks, the cattle are fed a series of rations designed to acclimate the rumen to starch digestion. The 'finishing' ration will contain approximately 90 per cent concentrate. Feeding concentrates at this level may result in lactic acidosis, thus proper feed management is of the utmost importance.

Historically, finished cattle were sold to meat packing companies simply as a commodity. There were no premiums paid for exceptional quality, so there was no reason for feedyards to feed for quality – just performance. Beginning in the 1970s, consumption of beef declined steadily, year after year. It became apparent that more attention needed to be paid to the quality of the beef produced. Meat packing companies and feedyards started to enter into arrangements that would pay premiums for superior beef quality and yield and would penalize for inferior beef quality and yield. These pricing arrangements are commonly known as 'grids' or 'formula pricing'. Most grids are developed to reward for both beef quality and yield, but there are some that primarily reward for yield or primarily reward for quality. Feedyards enter into grid agreements that best fit their feeding abilities. Even with grid agreements, there are still a large number of cattle sold on a cash basis as a commodity.

This discussion would be incomplete if 'stockers' and 'backgrounders' were not included. Stockers are cattlemen who purchase calves at approximately weaning age and turn these calves out to pasture. These calves gain anywhere from 200 to 400lb (90–180kg) while on pasture. The calves are then sold to a cattle feeder or the stocker retains ownership of the cattle through the feeding period. Backgrounders (or preconditioners), on the other hand, are cattlemen who specialize in feeding and taking care of high risk calves (calves that have a high risk of sickness). Many feedyards will send their high risk calves to backgrounders or growyards because the feedyard does not have enough employees to give these calves the level of attention they need. Often, calves in a backgrounding operation are checked two or more times per day for sickness. After a few weeks, the health problems subside. The calves will adjust to a concentrate-based ration and learn to eat out of a feed-bunk. After several more weeks, the calves are removed from the backgrounding operation and sent to their respective feedyard, where they are fed out to harvest.

Meat packing sector

Once the cattle have reached the appropriate harvest weight and condition, they are sent to the meat packing plant. While there are several meat-packing companies

in the United States, there are three very large ones that control the bulk of the industry. As many as 5000 head per day can be harvested through these meat packing plants. Cattle are humanely harvested and the carcasses are hung on an overhead rail to cool. The United States Department of Agriculture provides quality inspectors and veterinary inspectors to ensure a safe, wholesome food supply.

Possibly one of the most positive changes that the meat packing industry has made in recent years is the implementation of information sharing. It is currently possible for a cow-calf producer to receive information about how well his cattle performed, in terms of quality grade and yield grade. This type of feedback is very important for genetic advancement in the cattle herd.

The practice of beef cattle veterinary medicine in North America

Beef cattle veterinary practice has evolved a great deal in the last 20 years. This evolution has developed from a primarily ambulatory practice in which individual animals were treated to a much more production-oriented approach of veterinary medicine. As American food production has become more and more efficient, American society has become less and less aware of how their food is produced. This has led to many misconceptions among the American people about how food animals are handled and treated for disease. Society is very concerned about animal welfare, antibiotic resistance and food safety. Beef producers are very concerned about these things as well, but are also concerned about production performance, cost-effectiveness and the ever-tightening profit margin.

Individual treatment of animals is still a substantial part of beef cattle practice. Veterinarians are still called upon to treat respiratory disease, lameness, reproductive disorders, digestive and nutritional problems, among other things. However, veterinarians are also taking a more active role in preventing these situations. Beef cattle producers are being economically forced to provide cattle with added value. This means that the cattle must have the genetics and the immune integrity to perform well and stay healthy through each stage of production.

Many new opportunities in veterinary medicine have arisen because of this change from individual treatment to preventive medicine. In the cow-calf sector, many new computer software programs have been developed that can help with production parameters, record keeping and genetic selection. Because of the labour intensity involved in beef production, many producers simply do not have the time to get comfortable with the software and its capabilities, although they still want the

information that the software provides. Many veterinarians have taken this opportunity to help their clients by serving as a data analyst. Veterinarians gather the information needed and record the information in the software program. Because the veterinarian has the opportunity to work with several herds, he/she also has the opportunity to understand the software and its capabilities at a deeper level. The veterinarian can then analyse a client's data, work up reports in various areas of production and consult with the client on topics that may include replacement heifer selection, herd sire selection, culling, preventive health programmes, nutrition, effective treatment schedules and the cost-effectiveness of various production practices. There is still plenty of opportunity for some of the traditional services of veterinary practice, such as pregnancy examination, vaccination of calves and cows and treatment of diseased stock, but veterinary consultation has the potential of a wide scope of development in the cow-calf sector.

In the cattle-feeding sector, veterinary consultation already has a tremendous foothold. With the very large numbers of cattle in these feedyards, it is very cost-effective for the feedyard to hire a consulting veterinarian to design health programmes, evaluate treatment protocols, help in the training of new employees and advise on the construction of new facilities and the repair of current facilities. This type of practice can be very satisfying professionally, but there is a great deal of travel involved.

Whether a veterinarian specializes in the cow-calf sector, the cattle feeding sector or both, the issues that the beef industry faces will affect his/her practice. One of those issues is food safety. Food safety has captured the attention of the consumer, the producer and the

veterinarian. Veterinarians play a key role in control and/or elimination of pathogens in the food chain. Educating the beef producer and the consumer in areas such as how these pathogens develop and how they can be controlled is important for human health and for the survivability of the industry. Another food safety concern is the use of growth-promoting implants. The European Union has stopped the importation of beef from the United States that has been exposed to growth promoting hormones. The use of growth promoting hormones has been proven to be a safe practice. However, the EU's ban has caused some Americans to question its safety (see Chapter 63). Veterinarians are playing a key role in quelling rumours and misinformation about the safety of American beef and the use of growth-promoting hormones by applying good, sound science.

Beef cattle veterinary practice will continue to move away from individual animal medicine and move toward population medicine. Veterinarians must be cost-effective and must be able to demonstrate their cost-effectiveness. Applying good science to decision-making is a major key to being cost-effective. Skills in critical evaluation of the scientific literature need to be honed to a high level of precision so science-based decisions can be made. This is very important in an increasingly litigious society, as good science is much easier to defend in court than anecdotal decisions.

There are and will be many, many opportunities available in beef cattle veterinary practice in the future. The beef industry is changing at a rapid pace and the same is true of beef cattle practice. Veterinarians must be willing and able to adapt to a changing industry and be able to recognize an opportunity when it arises.
