Sertoli cells respond to FSH by secreting fluids and proteins that sustain the differentiating germ cells. Follicle stimulating hormone is absolutely essential for the initiation of spermatogenesis in immature animals but once the normal germinal epithelium has been established FSH does not appear to be essential for the start of each successive spermatogenic cycle. Another action of FSH is to stimulate the conversion of testosterone to oestradiol by the Sertoli cells. The Sertoli cells also secrete inhibin, a polypeptide that inhibits the release of FSH by the pituitary gland (Fig. 33.18).

There is no doubt that an intact hypothalamic–pituitary–testicular axis is essential for normal testicular function; however, apart from the fact that FSH is essential for the initiation of the process in immature animals, it is unclear what specific roles in the process of spermatogenesis are played by the individual hormones that constitute the axis. On the basis of information available in the literature, the following deductions have gained wide acceptance:

- Differentiating germ cells lack hormone receptors and, therefore, they are not affected directly by the hormones.
- Sertoli cells have specific receptors for FSH and for androgens but not for LH.
- Testosterone is required for the first mitotic division of the stem cell in the basal compartment.
- Testosterone is necessary for the reduction division of the primary spermatocyte.
- FSH is essential for the final steps in the maturation of the spermatids.
- There is controversy as to whether or not testosterone is required for the earlier steps in the maturation of the spermatids.
- It is likely that all the other steps in spermatogenesis can proceed without the specific intervention of a particular hormone.

Thus, FSH and testosterone exercise direct actions on the seminiferous tubules, while LH does so indirectly via the production of testosterone.

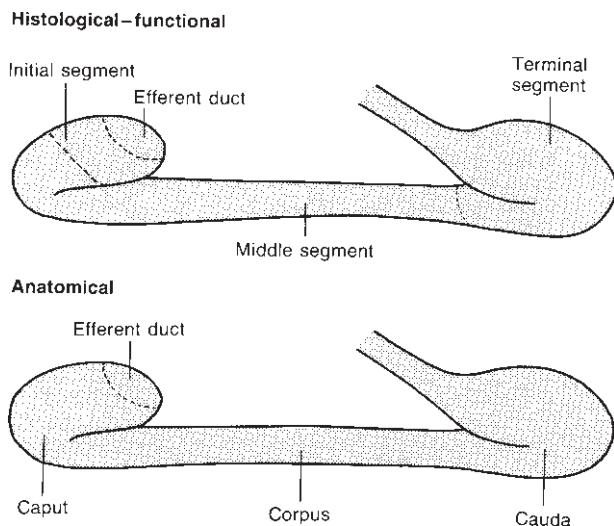

Fig. 33.22 The regions of the bovine epididymis.

It should be noted that even where specific hormonal stimulation is essential, the hormone serves to ensure that the event occurs but it does not alter the rate of progress of spermatogenesis, which is a feature that is determined by genes rather than by hormones.

The epididymis

When spermatozoa are transported from the rete testes through the efferent ducts to the initial segment of the epididymis they are neither motile nor capable of fertilization. They acquire these attributes during passage through the epididymis.

The epididymis is a highly convoluted tubule lined by specialized epithelium and surrounded by connective tissue, which incorporates concentric layers of smooth muscles that increase in thickness from the initial segment to the terminal segment. Anatomists describe the epididymis as consisting of three parts (Figs. 33.15, 33.22): the caput (head), the corpus (body) and the cauda (tail). A more recent histological-functional classification has designated at least eight regions in the epididymis of the bull, but for the purposes of this text it is sufficient to refer to the three principal segments used in that scheme: the initial segment, the middle segment and the terminal segment (Fig. 33.22). The efferent ducts empty into the initial segment, which is specialized for the bulk reabsorption of water and electrolytes. The middle segment, which includes most of the caput and corpus, is responsible for the sperm maturation. The terminal segment, largely the cauda, stores the mature spermatozoa pending ejaculation.

In many species the initial segment is the principal site for absorption of water from the luminal fluids. The

bull is an exception in that the bulk of the water has been absorbed by the efferent ducts before the contents reach the epididymis. The secretions from the epithelial cells of the initial and middle segments induce significant alterations in the functions and composition of most of the component parts of the spermatozoon. The principal functional changes are the acquisition of progressive motility and the ability to fertilize an egg. Fine structural changes have been observed in the plasma membrane, the acrosomal membranes, the nucleus and the tail. Changes in the composition of the plasma membrane appear to be central to the process of maturation of the spermatozoon as it passes through the epididymis; in particular, its protein composition is altered either by adsorption of components from the epididymal fluid or by modification or loss of existing components in response to enzymatic activity of the epididymal fluid. It is important to note that these biochemical changes are associated with the acquisition of the ability to fertilize but they do not complete the process of maturation – this will occur only after the ejaculated spermatozoa have been capacitated within the female genital tract (see p. 499).

Ejaculated spermatozoa have species-specific receptors that bind to the zona pellucida of the egg. The spermatozoa acquire these receptors in the epididymis, under the influence of testicular androgens.

The ability of the epididymis to facilitate maturation of the spermatozoa and to maintain the viability of the mature spermatozoa in the cauda is critically dependent on testicular androgens. Obviously, some of the testosterone reaches the epididymis in the arterial blood but it is probable that most of it comes via the efferent duct system bound to androgen-binding protein. The epithelial cells of the epididymis have androgen receptors and they rapidly convert the testosterone to dihydrotestosterone, which then regulates epididymal functions. It has been clearly established that the maturation of spermatozoa is regulated by dihydrotestosterone rather than by testosterone.

Movement of spermatozoa through the middle segment is by continuous peristaltic contractions of the smooth muscles that surround the epididymal tubule. The rate of transport in this segment is not influenced by ejaculation and in the bull it is estimated to take two to three days. It follows that the fertility of sperm should not be depressed even when the bull is ejaculating frequently. By contrast, the muscles surrounding the terminal segment are relatively inactive except when they are stimulated to contract during ejaculation; it follows that frequency of ejaculation can have a significant effect on the duration of storage of potentially fertile spermatozoa and on the numbers of fertile sperm available for ejaculation at a particular time.

Seminal plasma

The fluid portion of the ejaculate is called the seminal plasma. It consists of the testicular and epididymal secretions in which the spermatozoa are suspended when they pass from the cauda epididymis into the vas deferens plus the secretions from the various accessory glands, which are added as the spermatozoa are propelled along the vas deferens and the urethra during ejaculation. The seminal vesicles contribute fructose, the primary source of energy for the spermatozoa. Prostaglandins in the seminal fluid may assist transport of spermatozoa within the female tract by stimulating contraction of smooth muscle. The bull ejaculates 1–15 ml of semen containing $0.8\text{--}2.0 \times 10^9$ spermatozoa/ml. (Infertility in bulls is dealt with in Chapter 38 and some aspects of artificial insemination in Chapter 39.)

Female physiology

Oestrous cycle

By definition, the oestrous cycle is the interval between the onset of two successive periods of sexual receptivity (oestrus). Both the expression of oestrus and the duration of the cycle are the result of cyclic changes in the ovaries that involve two temporary endocrine structures (the ovarian follicles and corpora lutea) and their

principal secretions (oestrogens and progesterone). For problems associated with the oestrous cycle see Chapter 35.

Oestrus

It has been shown that behavioural oestrus results from exposure of the anterior hypothalamus to both progesterone and oestrogen in physiological concentrations and in the proper temporal sequence. Progesterone on its own inhibits oestrus. Furthermore, in the absence of priming by progesterone, physiological concentrations of oestrogen fail to elicit the signs of oestrus; thus, in the pubertal heifer the first preovulatory follicle produces a surge of oestrogen that feeds back positively on the pulse generator and induces an effective ovulatory surge of LH, but it does not induce behavioural oestrus. In the adult cow the normal sequence is a high concentration of progesterone (P_4) for 10–14 days followed by a rapid decline in P_4 and an immediate increase in oestrogen from the growing preovulatory follicle (Fig. 33.23). This sequence results in behavioural oestrus that appears to be coupled with the preovulatory surge of LH so that ovulation occurs approximately 24 hours after the onset of oestrus.

The duration of oestrus may vary from 8 to 30 hours and the behavioural signs may recur frequently throughout the period or they may be evident during two shorter periods at the beginning and end with a quiescent period between them ('split oestrus').

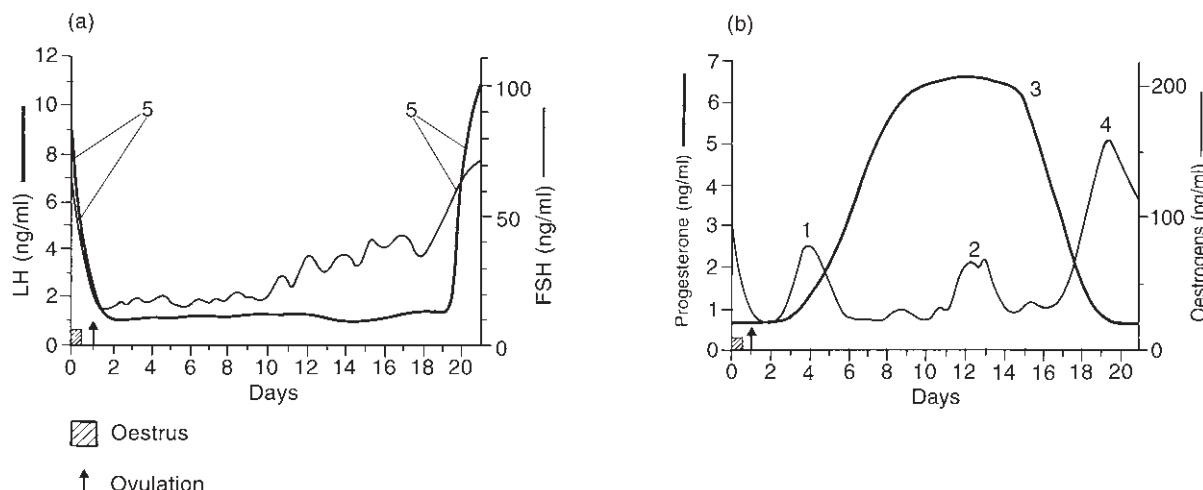

Fig. 33.23 Changes in concentrations of gonadotrophins (a) and ovarian steroids (b) in peripheral plasma during a 21-day oestrous cycle in the cow. During most of the cycle progesterone (P_4) secreted by the corpus luteum (CL) is the dominant hormone, exercising strong negative feedback on the hypothalamic–pituitary axis. However, the tonic concentrations of gonadotrophins released during the luteal phase induce two waves of follicles that are associated with small peaks of oestrogen (1, 2). When the CL regresses, the concentration of P_4 declines (3) and oestrogen concentration climbs to a peak, the oestrogen surge (4), which triggers a surge of gonadotrophins (5) that induces ovulation.

Length of the cycle

The cow is a polyoestrous animal and, if she is not pregnant, she will tend to return to oestrus repeatedly throughout the year at intervals of 18–24 days (mean = 21 days). By convention, the day of oestrus is designated day 0 and the length of the cycle is calculated from that baseline.

There can be considerable variation (within the normal range) in the length of the oestrous cycle: even successive cycles in the same cow may vary by several days. Most of this variation is due to differences in the duration of the luteal phase of the ovarian cycle, i.e. in the functional lifespan of the individual corpus luteum. Luteal regression may begin as early as day 15 or as late as day 19 of normal (20–24-day) cycles.

Regulation of the cycle

From a neuroendocrine perspective, the oestrous cycle is controlled by the secretory activities of three principal components: peptidergic neurones in the hypothalamus, gonadotropes in the adenohypophysis and steroid-secreting cells in the ovaries. It is clear that ultimate control is exercised by the hypothalamus through characteristic cyclic changes in the pattern of GnRH release, which are reflected in the circulating levels of FSH, LH, oestrogens and progesterone. Nevertheless, from the perspective of the practising veterinarian it would appear as if it is the ovary that times the events of the oestrous cycle. That perception will have been reinforced as a result of recent developments in ultrasound technology that have given the clinician visual access to the morphological changes in the female genital tract throughout the reproductive life of the cow; it is likely that it will be strengthened by this presentation, which emphasizes the central importance of the inherent rhythmicity with which cohorts of follicles emerge from the pool of resting follicles. In essence, the following text describes how the responses of the HPG axis determine the fate of the oocytes that are brought forward every seven to ten days in anticipation of being chosen to perpetuate the species.

Follicular development and its control during the oestrous cycle

Basic pattern: Each ovary has a large pool of oocytes, each contained within a follicle. The follicle is the basic functional unit of the female gonad; although it spends much of its lifespan in a dormant state, it does have a brief period of progressive growth and development that ends in either ovulation or degeneration (atresia). During this active phase it is an essential component of the hypothalamic–pituitary–gonadal (HPG) axis. It

responds to the gonadotrophins and it secretes a range of regulatory factors (Box 33.2), including steroid hormones (principally, oestradiol and progesterone) and the polypeptide inhibin; it also facilitates the maturation of the oocyte – but that is not a topic within the remit of this essay.

In its simplest form, the primordial stage, the follicle consists of an oocyte surrounded by squamous pre-granulosa cells. The resting primordial follicles are thought to be under constant inhibitory influences to remain dormant. In due course, either due to a decrease in inhibitory influences or to positive stimuli by some paracrine or endocrine factors, growth is initiated in a cohort of primordial follicles. This process of *recruitment* begins long before puberty and is recurrent throughout reproductive life. The fate of a recruited follicle depends on whether or not the mutual interactions between the component parts of the HPG axis can shepherd it to ovulation. Those follicles that fall by the wayside on the long path to ovulation undergo atresia; obviously, that is the fate of all follicles recruited before puberty; it is also the fate of most of the follicles recruited after puberty.

In the adult ovary, most of the follicles progress slowly through several developmental stages to reach the antral stage after four months or so, at which point the follicle has acquired the histological features depicted in Figure 33.24. There is evidence that follicles can develop to the preantral stage in the complete absence of gonadotrophins; thereafter, they are

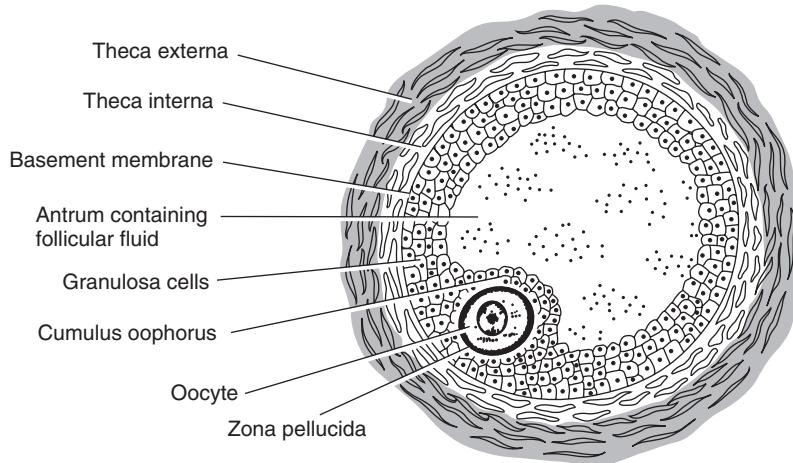

Fig. 33.24 The ovarian follicle has four distinct layers: the theca externa, the highly vascular theca interna, the basement membrane and the avascular granulosa cell layer. The basement membrane prevents direct access of capillaries to the granulosa cell layer.

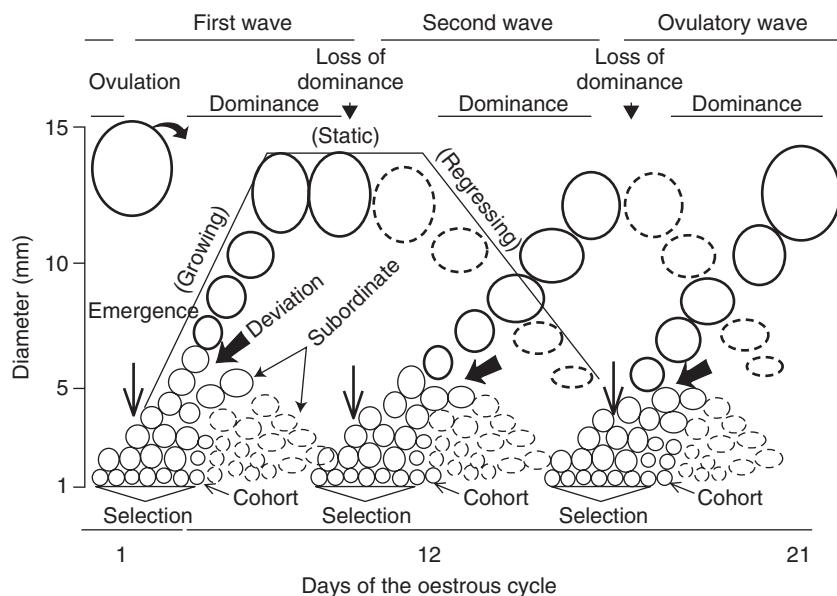

Fig. 33.25 A model explaining the terms associated with each wave of follicular development during the oestrous cycle of heifers. Based on ultrasound analysis, most heifers have one (first wave) or two waves (first wave, second wave) of follicular development during the luteal phase and a single wave of development (ovulatory wave) during the follicular phase. (From Ireland *et al.*, 2000, reproduced with permission of the American Dairy Science Association.)

gonadotrophin-dependent. FSH can stimulate growth of the follicle up to about 9 mm in diameter, while LH is required for further growth and for ovulation. In fact, the HPG axis provides the hormonal milieu that regulates the passage of the antral follicle through a complex sequence of processes known ('in the trade') as emergence, deviation, selection and dominance, and ovulation or atresia (Webb *et al.*, 1999; Ireland *et al.*, 2000).

The inherent pattern of follicular growth in cattle is wave-like (Fig. 33.25); it is set long before puberty and it persists during oestrous cycles, throughout most of pregnancy and during the early anoestrus of the post-partum period. In practice, the *emergence* of a wave is

recorded as the first day on which a 4 mm or 5 mm follicle is detected by ultrasonography as the largest in a new cohort of growing follicles. Over the next two or three days all of the emergent follicles grow at a similar rate but then there is an abrupt divergence of individual growth rates (*deviation*; Fig. 33.26): growth continues unabated in one follicle, now grown to approximately 8 mm in diameter and destined to become dominant; in the subordinate follicles it comes to a halt and, soon, is followed by regression (Ginther *et al.*, 2001). About 8 hours before the beginning of deviation, the granulosa cells in the future dominant follicle acquire LH receptors. LH stimulates increased production of oestradiol and of insulin-like growth

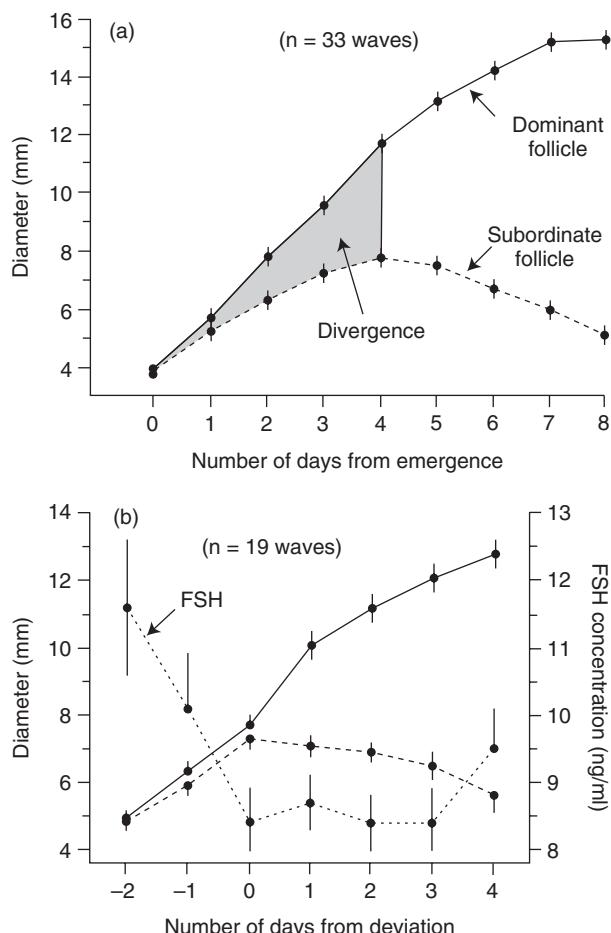

Fig. 33.26 Deviation. The patterns of growth in the dominant follicle and the largest subordinate follicle from the day of emergence. (a) The growth rates gradually diverge. (b) Before deviation, the growth rates did not differ significantly. The concentration of FSH reached a nadir on the day of deviation. factor 1 (IGF-1). Systemically, the high levels of oestradiol and inhibin released by the dominant follicle suppress release of FSH from the pituitary gland; there is inadequate concentration of FSH to sustain the smaller follicles and they become atretic (Figs 33.26 and 33.27). Within the dominant follicle, oestradiol and IGF-1 increase the sensitivity of the granulosa cells to FSH, thus enabling that follicle to respond to (and thrive on) the low concentration that contributed to the onset of atresia in the subordinate follicles. If the largest follicle is ablated *before* deviation, the next largest follicle will proceed to dominance. Thus, the follicular wave has two phases (Fig. 33.28): the growth phase (initiated by FSH) and the dominance phase (initiated when FSH is close to its nadir; LH dependent).

Dominance is a consequence of *selection*, the process that results in the number of growing follicles being

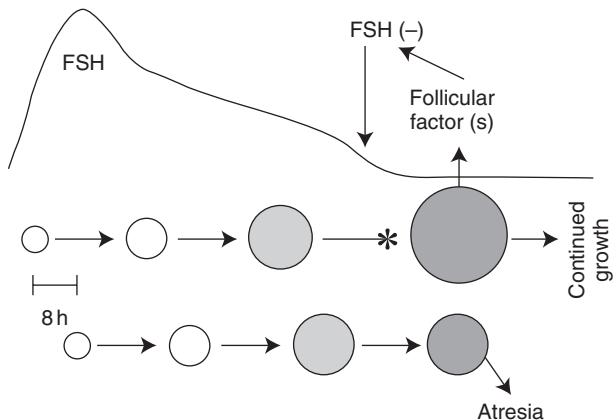

Fig. 33.27 Simplified model of deviation. The future dominant follicle emerges approximately 8 hours before the future largest subordinate follicle. Under the influence of FSH the two follicles grow at the same rate so that the larger follicle retains its initial advantage up to the point of deviation (marked by asterisk). As the follicles grow they secrete increasing quantities of oestradiol and inhibin, both of which diminish the secretion of FSH until there is insufficient to sustain the growth of subordinate follicles; they regress. However, changes in the dominant follicle, such as increased responsiveness to LH and the stimulatory activity of IGF-1, enable it to survive and enlarge in the presence of low concentrations of FSH. (After Wiltbank *et al.*, 2000.)

reduced to what is the ‘species-specific ovulatory quota’: in cattle, usually one follicle, occasionally two. The beginning of the selection phase cannot be identified by ultrasonography but the end of the phase is coincident with the onset of dominance, which can be identified.

Normally, each wave has a span of seven to ten days from emergence to ovulation or to the onset of atresia in the dominant follicle. The dominant follicle has the functional capacity to trigger the neuroendocrine cascade that culminates in ovulation but its fate is determined by the frequency of pulsatile LH secretion at the point of decision, essentially according to the phase of the cycle: the high frequency during the follicular phase enables it to ovulate; the low frequency during the luteal phase or during postpartum anoestrus results in atresia; an intermediate frequency (e.g. when there is suboptimal concentration of progesterone) is associated with extended dominance, which may have a deleterious effect on the competence of the oocyte. The next wave cannot emerge until after the dominant follicle has begun to regress.

Cyclic pattern: Usually, the bovine oestrous cycle has either two waves (modal days of emergence: days 0, 10) or three waves (modal days of emergence: days 0, 10, 16) of follicular growth, each emerging about a day after a transient peak in serum concentrations of FSH. During the luteal phase both progesterone from

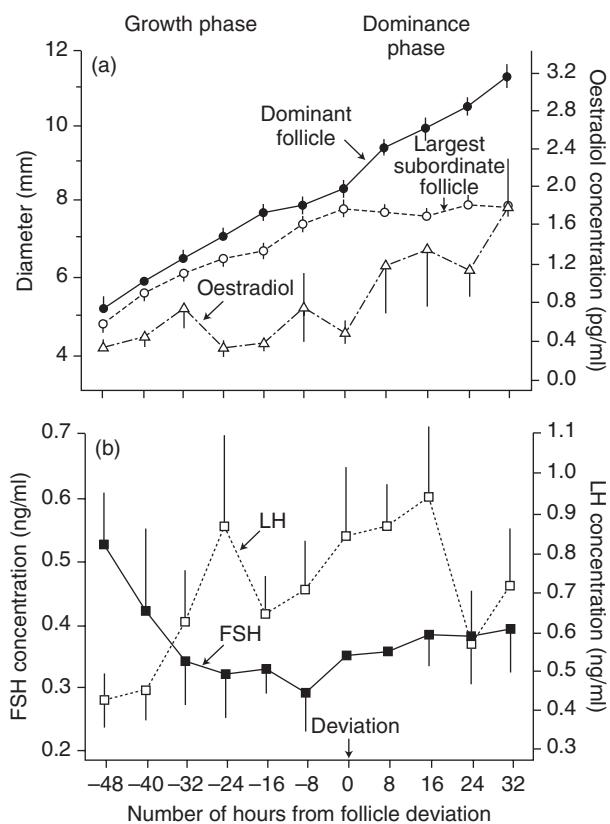

Fig. 33.28 The follicular wave has a growth phase and a dominance phase. the corpus luteum and oestrogen from the cohort of growing follicles ($>5\text{ mm}$) restrain the hypothalamic–pituitary axis by negative feedback. The frequency of the pulse generator is reduced to one pulse of GnRH every 4–8 hours and the concentrations of gonadotrophins in the peripheral circulation are insufficient to induce ovulation. As a result, neither of the dominant follicles in the first two waves can ovulate; all of the follicles in the two waves undergo atresia. Luteolysis, which is required to remove this inhibition, occurs spontaneously when the uterus, under the trophic influence of progesterone followed by oestrogen and oxytocin, produces sufficient prostaglandin $F_{2\alpha}$ ($\text{PGF}_{2\alpha}$) to kill the corpus luteum (see p. 495). The resultant fall in progesterone concentrations releases the GnRH pulse generator, which increases its frequency to one pulse every hour (approximately). The concentrations of FSH and LH rise in the peripheral circulation, stimulating the cohort of follicles that initiates the follicular phase of the cycle and from within

which the new dominant follicle goes on to ovulate approximately three days later (Fig. 33.28), by which time it has grown to 16–20 mm in diameter.

The phases of the oestrous cycle

Follicular phase: Each of the growing follicles has two populations of steroid-secreting cells: theca interna cells and granulosa cells (Fig. 33.29a). The cells of the theca interna have specific receptors for LH and they respond to this gonadotrophin by synthesizing androgens (androstenedione and testosterone) that diffuse across the basement membrane into the granulosa cell layer. During the early stages of folliculogenesis the granulosa cells have receptors for FSH and they respond to this gonadotrophin by converting the thecal androgens to oestrogen (Fig. 33.29b). As the follicles grow under the trophic influences of both FSH and oestrogen, the granulosa cells acquire increased numbers of FSH receptors and oestrogen receptors and they secrete increasing quantities of oestrogen-rich follicular fluid (Fig. 33.29c). Follicular oestrogen passes into the circulation and exerts negative feedback on the release of FSH from the pituitary gland: while the concentration of FSH is in decline, the dominant follicle is selected and the subordinate follicles regress (Figs 33.26, 33.27). The dominant follicle maintains FSH at low concentrations and becomes dependent on LH for continued growth and secretion of oestradiol (Fig. 33.30). LH stimulates the secretion of sufficient oestradiol to induce oestrus and to evoke the oestrogen surge that exerts a positive feedback on the hypothalamic–pituitary axis (Figs 33.30, 33.31). The frequency of the GnRH pulse generator increases, the sensitivity of the adenohypophysis to GnRH is increased by a self-priming action of the GnRH and the pituitary gland releases the preovulatory surge of LH. The response of the dominant follicle to LH is both morphological (growth, ovulation, formation of the corpus luteum) and secretory (oestrogen, progesterone).

Ovulation is critically dependent on the timing, frequency, and amplitude of the hormonal changes just described. For instance, an inappropriate pattern of LH secretion could lead to atresia or to undue persistence of the dominant follicle (with detrimental effects on the quality of the oocyte). The crucial hormonal event that initiates the ovulatory process is the switch from negative feedback by progesterone and oestrogen to positive feedback by oestrogen (Figs. 33.30, 33.31); again, the timing and rate of change of the oestrogen surge are critical: any significant deviation in either feature can result in delayed ovulation or anovulation.

Luteal phase: After ovulation, the basement membrane between the theca cells and the granulosa cells breaks down and the avascular granulosa cell layer is invaded

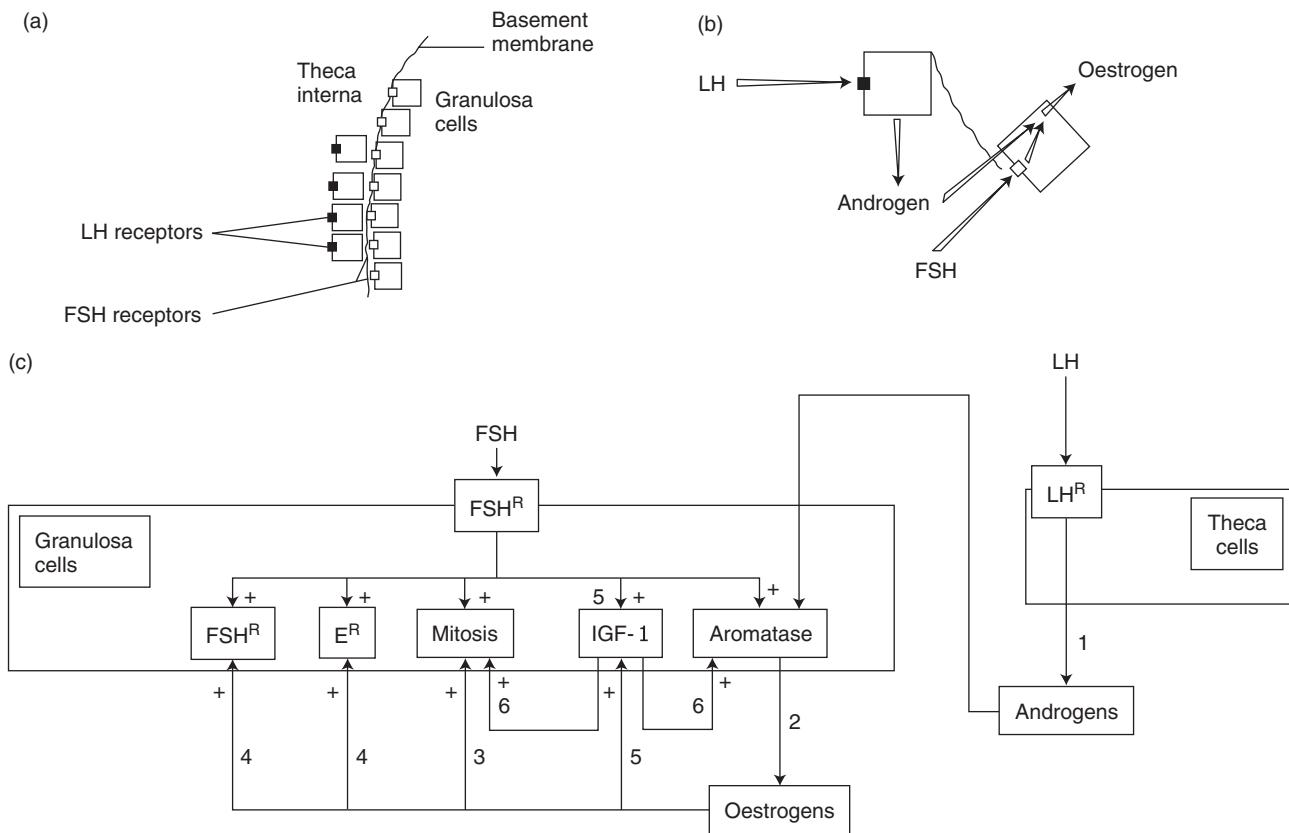

Fig. 33.29 Formation of oestrogen by ovarian follicles: (a) depicts the structure of the follicular wall; (b) illustrates the essential features of the production of oestrogen: LH stimulates the synthesis of androgens by the theca cells, FSH stimulates aromatases within the granulosa cells to convert the androgens to oestrogens; (c) depicts the biochemical events in the growing follicle between emergence and divergence: (1) LH stimulates theca cells to produce androgens; (2) FSH activates aromatase in granulosa cells to convert the androgens to oestrogen; In the granulosa cells, oestradiol (3) stimulates mitosis and (4) up-regulates receptors for FSH (FSH^R) and for oestradiol (E^R); (5) synthesis and secretion of IGF-1 by granulosa cells are stimulated by oestradiol and FSH; (6) IGF-1 further stimulates mitosis and aromatase activity in granulosa cells. Outcome: growth of the follicle and expansion of the antrum due to the combination of increased numbers of secretory granulosa cells with increased numbers of FSH and oestrogen receptors per cell.

by connective tissue septae that carry theca cells and blood vessels. The granulosa cells and the theca cells differentiate into luteal cells that secrete progesterone; they can also synthesize and secrete oestrogen, oxytocin and relaxin. The invading blood vessels undergo extensive branching and deliver a very large blood flow to support the very high metabolic rate of the mature corpus luteum; so rich does the vasculature become that endothelial cells comprise more than half of the constituent cells – in due course, these cells play a pivotal role in the process of luteolysis (see below).

Luteinizing hormone is the principal luteotrophin in the cow; under normal circumstances, tonic secretion of LH maintains the functional corpus luteum until PGF_{2α} from the uterus causes luteolysis at the end of the cycle. It is important to realize that ‘normal circumstances’ include the correct antecedent hormonal pattern:

specifically, serum progesterone at luteal phase concentrations for a few days before it subsides, followed by serum FSH at normal preovulatory concentrations. Failure of this sequence or inappropriate serum concentrations of either hormone seem to affect the lifespan of the corpus luteum (short luteal phase, prolonged luteal phase) and/or its capacity to secrete progesterone (inadequate luteal phase), phenomena that are common after the first ovulation at puberty or after calving. It is not known how the (prefollicular phase) progesterone exerts its influence on the activities of the next corpus luteum; it is possible that the FSH could do so through its role in the induction of LH receptors on the granulosa cells of the preovulatory follicle.

The corpus luteum grows progressively in size until days 16–18 of the oestrous cycle. Histologically, the mature corpus luteum is seen to contain two mor-

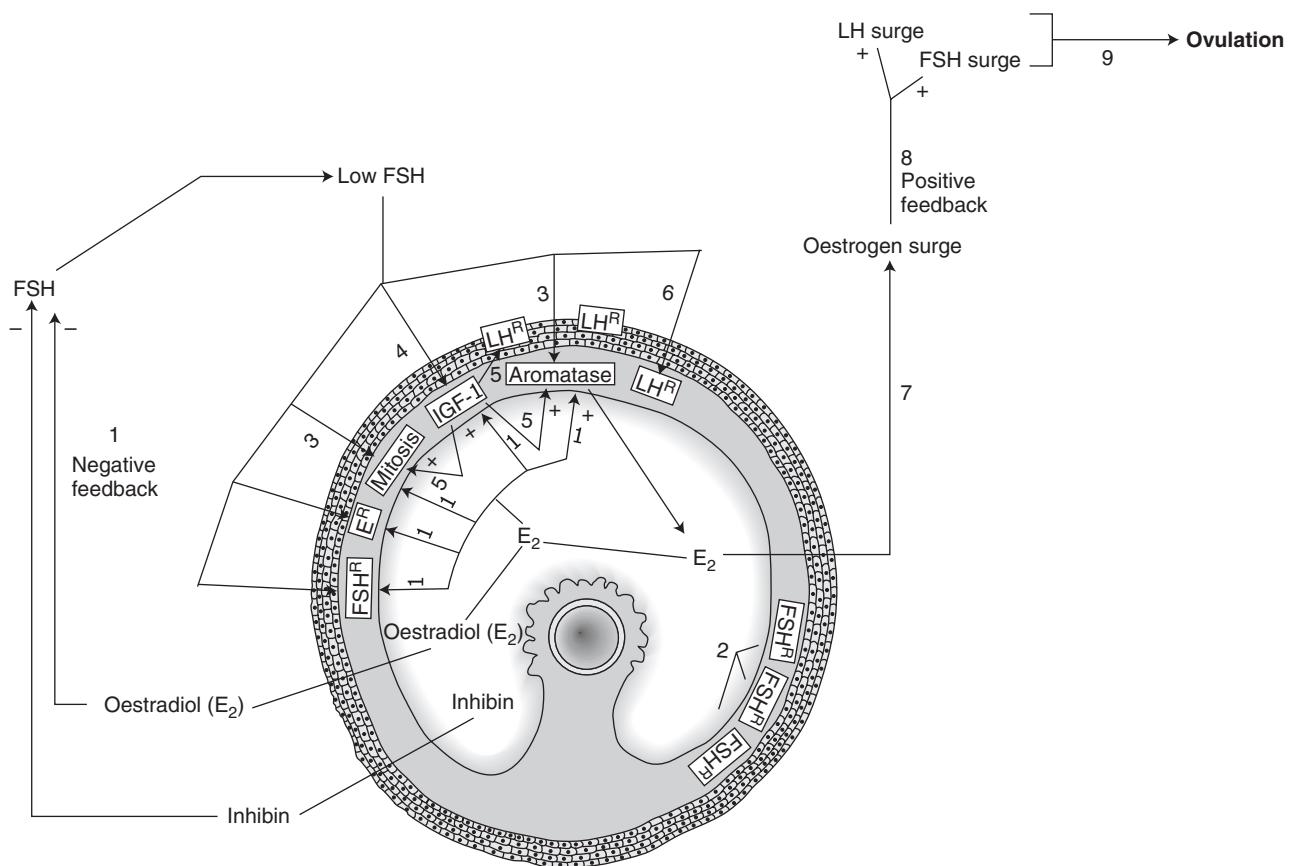

Fig. 33.30 Dominant follicle becomes the ovulatory follicle. When luteolysis occurs, the LH pulses attain the frequency that is required to progress the dominant follicle to ovulation. FSH induces mitosis and stimulates aromatase activity in granulosa cells and they secrete oestradiol and inhibin: within the follicle, oestradiol binds to receptors (E^R) in granulosa cells in which it (1) up-regulates E^R and receptors of FSH(FSH^R), stimulates aromatase activity, mitosis and secretion of IGF-1: systemically, both oestradiol and inhibin depress FSH secretion by the pituitary gland (negative feedback). (2) Granulosa cells have high number FSH^R [see (4) in Figure 30.29]. (3) The low levels of FSH continue to induce mitosis and to stimulate aromatase activity in granulosa cells (thus producing oestradiol and enlarging the antrum). FSH (4) and oestradiol (1) stimulate granulosa cells to secrete more IGF-1 – which, in turn, (5) enhances the steroidogenic and mitotic actions of FSH and oestradiol on granulosa cells, and enhances the steroidogenic action of LH on theca cells. FSH (6) increases the number of LH receptors (LH^R) on granulosa cell. The cell division and the secretory activity accelerate the expansion of the dominant follicle: it may be 16 to 18 mm in diameter at the preovulatory stage. The rapid increase in secretion of oestrogen induced by the activities of LH, FSH and IGF-1 leads to a surge of oestrogen (7) which evokes, by positive feedback (8), coincident surges of the gonadotrophins (large surge of LH, smaller surge of FSH) and, consequently, ovulation (9).

phologically distinct populations of parenchymal cells: small luteal cells ($10\text{--}20\mu\text{m}$) and large luteal cells ($20\text{--}35\mu\text{m}$). All of the small cells are derived from thecal cells and, until the sixth day of the oestrous cycle, nearly all of the large cells are derived from the granulosa cells. After day six, some small luteal cells differentiate into large luteal cells, so that the large cells are of mixed origin and the proportion of large cells increases as the corpus luteum matures (from less than 2 per cent at days 3 to 5 to almost 5 per cent at days 10 to 18).

It is significant for the clinical management of the oestrous cycle to realize that the small luteal cells and the large luteal cells differ in their abilities to respond

to the recognized luteotrophin (LH) and luteolysin ($\text{PGF}_{2\alpha}$). Receptors for LH are numerous on the small cells but they are scanty or absent on the large cells. Therefore, LH stimulates the small cells to secrete progesterone but it has no such effect on the large cells. Despite this and the numerical predominance of small luteal cells throughout the luteal phase, it is generally agreed that most of the progesterone is secreted by the large luteal cells. Progesterone is secreted as pulses at a frequency that is different from that for LH. This does not diminish the importance of LH as the principal luteotrophin in the cow: LH does not have direct control over the quantities of progesterone secreted by the large cells but it does exert an important indirect

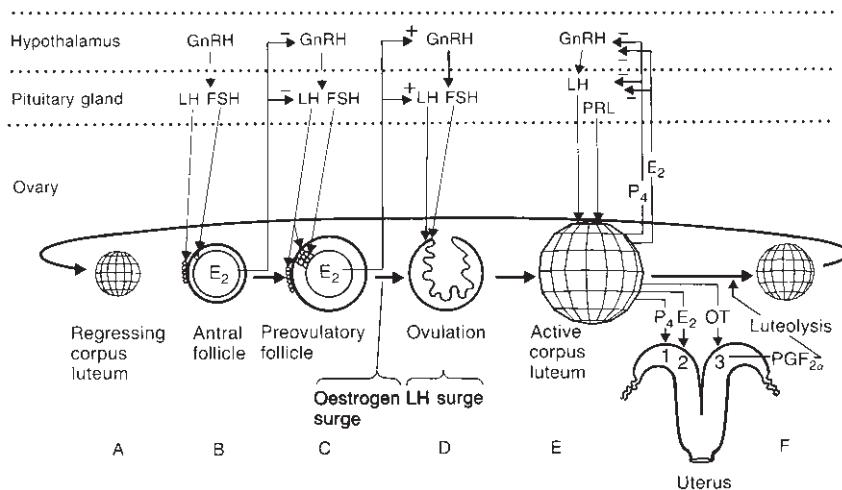

Fig. 33.31 Interrelationships between the hypothalamus, pituitary gland, ovary and uterus during the oestrous cycle. When the corpus luteum (CL) regresses at the end of a cycle (A), the hypothalamus and pituitary gland are released from the strong negative feedback exerted by progesterone (P_4) throughout the luteal phase of the cycle. FSH and LH stimulate the growth and secretory activity of a dominant ovarian follicle (B) that secretes increasing quantities of oestradiol (E_2). The initial low concentrations of E_2 have a negative feedback effect until the preovulatory follicle produces a surge of oestrogen (C) that exerts a positive feedback and results in a surge of LH that causes ovulation (D). A new CL develops under the trophic influence of both LH and, perhaps, prolactin (PRL). It secretes P_4 and E_2 that reassert a strong negative feedback effect on the hypothalamic–pituitary axis. In addition, the P_4 causes an accumulation of fatty acid precursors in the endometrium (1). After day 10, E_2 induces the synthesis of prostaglandin from the stored precursors (2). Finally, oxytocin (OT) causes the release of the $PGF_{2\alpha}$ (3), which is transferred from the uterus to the ipsilateral ovary by a counter-current mechanism (see Fig. 33.32) and induces luteolysis (F). (See Fig. 33.23 for changes in concentrations of the hormones in the peripheral plasma.)

control by regulating the differentiation of small cells into large luteal cells, a process during which the steroidogenic activities of the cells seem to be turned on fully and permanently. On the other hand, receptors for $PGF_{2\alpha}$ are numerous on large luteal cells but are absent from the small cells. Since the secretion of progesterone by the young corpus luteum (days 3 to 5) is invested almost entirely in the small cells, it is not surprising that it is refractory to the luteolytic action of $PGF_{2\alpha}$. The luteolysin becomes effective when the large luteal cells assume responsibility for most of the secretory activity.

It is well known that during the first four or six days of the oestrous cycle exogenous oxytocin can inhibit the growth of the corpus luteum and block its secretory activity. This is possible because the small luteal cells have specific receptors for oxytocin and interaction between the receptors and the peptide leads to inhibition of the LH-stimulated secretion of progesterone by the small cells. In the mature corpus luteum the large luteal cells synthesize oxytocin and it has been suggested that this peptide may play a significant role in local ‘large-cell-to-small-cell communication’ during prostaglandin-induced luteolysis.

Prostaglandin $F_{2\alpha}$ is formed in the endometrium. It leaves the uterus in the uterine vein and most of it is

transported in the venous blood to the lungs where approximately 65 per cent of it is degraded into its inactive metabolite, PGFM, in one passage. However, some $PGF_{2\alpha}$ is brought directly from the uterus to the adjacent ovary by means of a counter current mechanism (Fig. 33.32) that transfers the luteolytic agent from the uterine vein to the ovarian artery. Thus, in the cow, $PGF_{2\alpha}$ may act partly by the systemic route to augment the local counter-current transfer (McCracken *et al.*, 1999).

Prostaglandin $F_{2\alpha}$ is released from the uterus in pulses and there is evidence that the minimum requirement for normal regression of the corpus luteum at the end of the oestrous cycle (i.e. effective luteolysis by endogenous $PGF_{2\alpha}$) is a pulse lasting one hour repeated about every six hours over a period of 24–30 hours. (By contrast, after day 5 of the oestrous cycle the corpus luteum can be removed by a single injection of exogenous luteolysin, in an appropriate dose.)

The timing and magnitude of $PGF_{2\alpha}$ release from the uterus is determined by the sequential interactions of progesterone, oestradiol and oxytocin. The central and peripheral actions of oestradiol are critical for luteolysis to occur (Binelli *et al.*, 2001). During the early part of the oestrous cycle the endometrial cells have many receptors for progesterone and coupling of the steroid

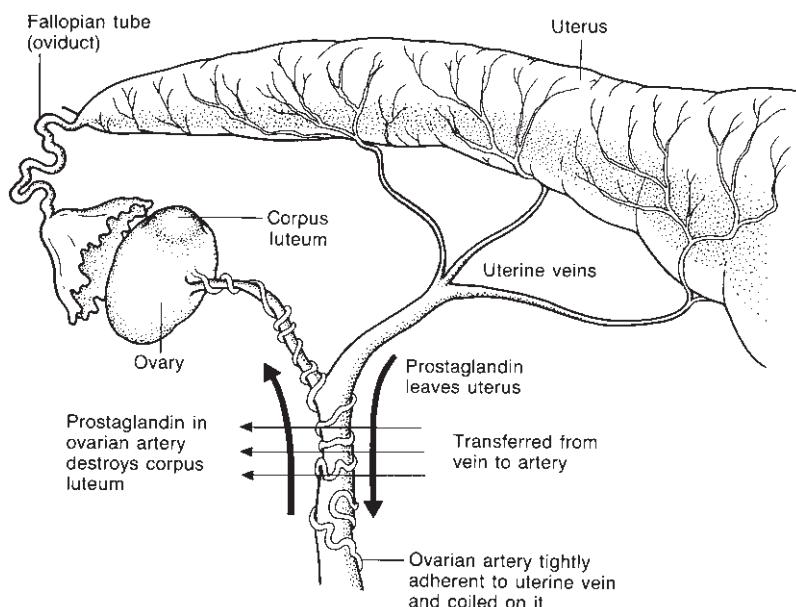

Fig. 33.32 The transfer of PGF_{2α} from the uterus to the ovary by a counter current mechanism.

with its receptors effectively blocks the production of PGF_{2α}; however, it causes an accumulation of fatty acid precursors in the endometrium. After about 10 days the action of progesterone on the hypothalamus and on the endometrium begins to decline (possibly due to progesterone-induced loss of its own receptor: 'down regulation'), permitting oestrogen to effect changes both centrally and peripherally. Centrally, oestradiol from developing ovarian follicles appears to alter the frequency of the hypothalamic oxytocin pulse generator, which produces a series of intermittent episodes of oxytocin secretion; peripherally, it promotes the formation of endometrial receptors for oestradiol and oxytocin. In the endometrium, coupling of oestradiol with its receptors increases the synthesis of PGF_{2α} from the fatty acid precursors, while coupling of oxytocin (from the hypothalamus and from the corpus luteum) with its receptors leads to immediate pulsatile secretion of PGF_{2α} (McCracken *et al.*, 1999). It is probable that the duration of the pulses is determined by the rapid down regulation of oxytocin receptors (within one hour) and that the frequency of the pulses reflects the regeneration time of the oxytocin receptors in response to oestradiol (six hours).

PGF_{2α} causes a significant reduction in luteal blood flow and it couples with specific receptors on the large luteal cells. However, the other steroidogenic cells, the small luteal cells, do not have receptors for PGF_{2α} and it has to be assumed that some type of intercellular communication between the large cells and the small cells is involved in terminating the LH-induced secre-

tion of progesterone by the small luteal cells. Oxytocin, which is formed in the large luteal cells and has specific receptors on the small luteal cells, is an obvious candidate messenger. Recent studies (Meiden *et al.*, 1999) assign the pivotal role to endothelin 1 (ET-1), a peptide synthesized and released by the resident endothelial cells. The proposal is that PGF_{2α} elicits the release of ET-1 from the endothelial cells and of oxytocin from the large luteal cells; ET-1 acts on the steroidogenic cells to reduce their progesterone output; both PGF_{2α} and ET-1 induce vasoconstriction and consequent hypoxic conditions; ET-1 secretion is enhanced both by hypoxia and by oxytocin (Fig. 33.33). For structural regression it is envisaged that ET-1 initiates a cascade of events leading to recruitment and activation of phagocytic cells that release cytokines responsible for programmed cell death.

It is obvious that the functional corpus luteum plays a primary role in the control of the oestrous cycle, a fact that is central to all regimes that aim to control the cycle. In the past, the practice was to remove it manually *per rectum*, a procedure to be condemned. The mature corpus luteum (CL) is a very vascular organ; manual expression causes haemorrhage which will give rise to local adhesions, if it is not fatal. The CL can be removed by administration of exogenous luteolytic agents. It is insensitive to exogenous PGF_{2α} during the first four days of the cycle, but between day 5 and day 16 the administration of PGF_{2α} or an analogue will cause rapid luteolysis followed, within a few days, by oestrus and ovulation.

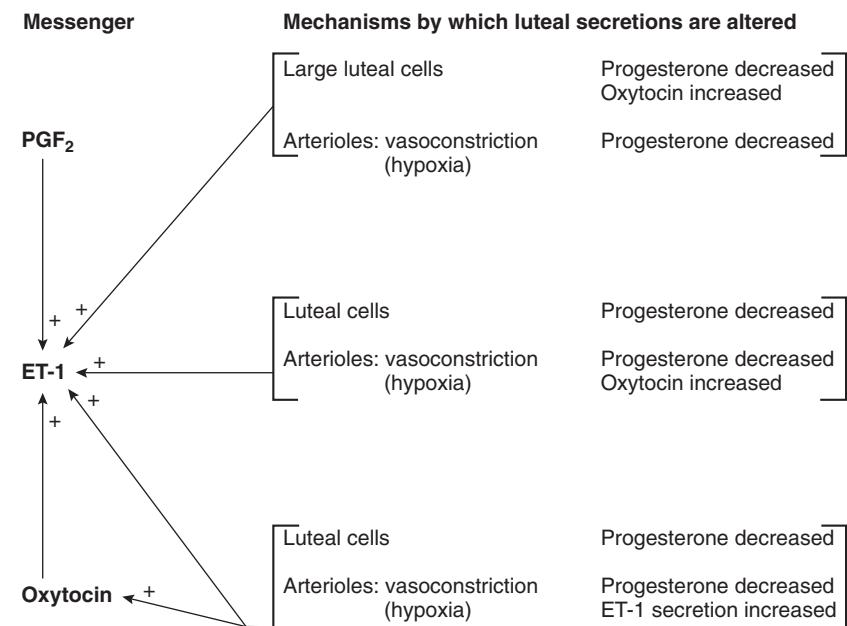

Fig. 33.33 Schematic representation of the putative role of endothelin-1 (ET-1) in functional luteolysis in cattle.

Pharmacological regulation of the oestrous cycle (see also Chapter 42)

The pharmaceutical industry has provided an array of natural and synthetic hormones – GnRH, gonadotrophins, steroids, prostaglandins – that can be used to regulate the oestrous cycle. The use of these agents for specific purposes will be described when we deal with the clinical conditions in which they have been found to be effective. Nevertheless, it is appropriate at this juncture to emphasize a few basic principles that should be borne in mind when the clinician is contemplating the use of reproductive hormones for therapeutic purposes.

The GnRH generator imposes a pulsatile mode of secretion on the hypothalamic–pituitary–ovarian axis. The component parts of the axis respond to hormonal signals that are encoded in the frequency and, to a lesser extent, the amplitude of the pulses. However, these target tissues may not be able to decode a hormonal stimulus that is either non-pulsatile or pulsatile at non-physiological frequencies. As an example, repeated small pulses of exogenous GnRH will induce pulsatile releases of gonadotrophins and these responses will be enhanced by the self-priming action of GnRH. On the other hand, continuous infusion of GnRH or intermittent infusions of GnRH at markedly non-physiological frequencies will soon lead to complete refractoriness of the pituitary gland to the continued stimulation (see p. 477). Therapeutic regimes should be planned with

due recognition of these observations. A single bolus of exogenous GnRH is likely to be effective only when a preovulatory follicle is present already.

During the luteal phase of the oestrous cycle the corpus luteum acts as an effective ‘brake’ on the pulse generator: pulse frequency is reduced so that circulating gonadotrophins are maintained at tonic concentrations and the dynamic surges required to cause ovulation cannot occur. Luteolysis removes the brake, the pulse frequency increases and ovulation occurs within four or five days. Hence, there are two methods by which control over the length of the cycle and ovulation can be achieved: the use of a luteolytic agent to kill the corpus luteum of the current cycle or the use of a progestogen to create an ‘artificial’ luteal phase, which will be followed by ovulation shortly after withdrawal of the progestogen. These methods can be used separately or in combination. Since prostaglandin does not kill the very young corpus luteum (less than five days after ovulation), the usual recommendation is to give two injections 11 days apart (see p. 682).

To date, neither of these methods has fully satisfied the requirements of the industry. Ideally, synchronization of oestrus should make it possible to achieve high rates of pregnancy to a single insemination at a predictable interval after treatment, without the need for detection of oestrus. Recent studies of the dynamics of follicular waves have revealed that the prime requirement is ‘to have a recently selected dominant follicle of short duration dominance at the end of a progestagen

or PGF_{2α} treatment regimen' (Roche *et al.*, 1999). Thus, the objective of current research efforts is to validate a regimen that will regulate both the luteal and follicular components of the periovulatory phase.

As mentioned, the response of the corpus luteum to an exogenous luteolysin depends on the stage of its development, and even when it is fully responsive the intervals from treatment to oestrus and ovulation can vary by some days depending on the stage of development of the dominant follicle at the time of treatment. For instance, if the current largest follicle is no longer functionally dominant, clinical response will be delayed until the dominant follicle of the next wave does the business up to a week later. Scientists have shown that it is possible to manipulate follicular waves to deliver ovulation within a time span that would satisfy the level of predictability required to make fixed-time insemination a viable proposition. However, the problem remains that some of the procedures that have been employed under 'laboratory conditions' do not lend themselves to ready application under field conditions. One such approach involved transvaginal ultrasound-guided ablation of all follicles greater than 5 mm (day 0) followed by PGF_{2α} (day 4) and LH or GnRH (day 5): all of 23 treated heifers ovulated within the same 24-hour period, 19 within the same 12-hour period (Bo *et al.*, 2002). Presumably, the next task is to replace surgical ablation by a pharmacological regimen that will selectively consign the current cohort of emerging follicles to immediate atresia, permitting the emergence of a new cohort, one of which then can be driven by exogenous hormones to ovulation within a predictable time span. It is known that the physiological activities of the follicle are modulated by a range of molecules produced locally within the follicle (growth factors, activins, inhibins, cytokines etc.: Box 33.2). The paracrine or autocrine actions of those molecules may hold the keys to precise manipulation of ovarian function.

Pregnancy

Transport of gametes in the female genital tract

Fertilization takes place in the oviduct, close to the junction of the isthmus and the ampulla (Fig. 33.34). Transport of the ovum from the ovary is achieved by muscular and ciliary activity and flow of fluids in the ovarian bursa and ampulla of the oviduct. After natural mating, spermatozoa have to traverse the cervix, the uterus and the uterotubal junction. Again, muscular activity and flow of fluids are largely responsible for the transport of the male gametes. The appropriate muscular activities, secretion and flow of fluids in the female genital tract are regulated by the ovarian hormones

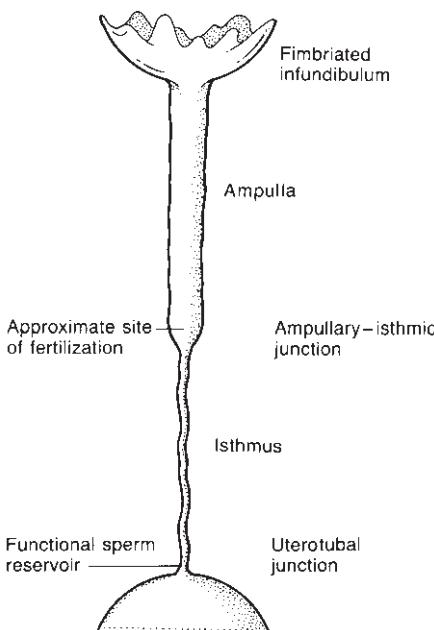

Fig. 33.34 Schematic diagram of the uterine tube (oviduct, Fallopian tube).

(oestrogens and progesterone) released in the correct concentrations and in the proper sequence. Therapeutic procedures that significantly alter the relative concentrations or sequence of the hormones can disrupt the transport mechanisms, which in some instances may cause the loss of gametes or of the conceptus.

The transport of spermatozoa is not an entirely passive process: the motility of the male gametes makes a significant contribution to the successful completion of the hazardous voyage from vagina to oviduct during which the vast majority of the spermatozoa are lost, partly as a result of phagocytosis but largely by expulsion to the exterior in cervical mucus. It appears from the literature that two distinct populations of spermatozoa arrive in the oviduct:

- Those that are transported rapidly but are incapable of fertilizing the ovum; and
- Those that are transported more slowly to the functional sperm reservoir, are viable and are capable of undergoing capacitation and the acrosome reaction, two processes that are essential if a spermatozoon is to acquire the capacity to fertilize an ovum.

Spermatozoa have been recovered from the ampulla of the oviduct within 3–5 minutes after mating. This rapid transport is due to muscular contractions in the female genital tract. During oestrus, the contractions begin at the cervix and move towards the oviduct; at the end of oestrus the direction of the contractions is

reversed. Most of the spermatozoa that reach the oviduct during the initial rapid transport phase are damaged or dead and they do not include the sperm that fertilizes the ovum. It has been suggested that these non-viable spermatozoa may play a significant physiological role, by releasing products that elicit local muscular and secretory responses that facilitate transport and sustenance of the gametes.

According to Hunter and Wilmot (1984), viable spermatozoa are transported more slowly: heifers mated early in oestrus took 8–12 hours to establish an adequate population of viable spermatozoa in the oviduct. Then the gametes were sequestered, in a relatively quiescent state, in the caudal 2 cm of the isthmus for a further 18–20 hours before they began a progressive migration towards the site of fertilization. Thus, the caudal isthmus served as the functional sperm reservoir, the immediate source of viable spermatozoa at the time of ovulation. It is known that both the temperature and the oxygen tension are lower in that segment of the isthmus than they are in the ampulla and it is thought that these factors may be responsible for the depressed motility of the spermatozoa in the reservoir up to the time of ovulation. At ovulation, the temperature and oxygen tension are elevated in the lumen of the caudal isthmus, the sequestered spermatozoa begin to exhibit activated motility (hyperactivation) and they migrate to the site of fertilization. Hyperactivation is in response to the 'pick-up' of follicular fluid and the ovum by the oviduct.

Capacitation and the acrosome reaction

The spermatozoa deposited in the female reproductive tract are not immediately capable of fertilizing an ovum. During transport through the tract they undergo physiological changes that make them competent to penetrate the zona pellucida and fuse with the ovum, i.e. they undergo capacitation. It is thought that during capacitation the spermatozoon loses some proteins it has acquired, by adsorption or incorporation into the plasma membrane, during exposure to epididymal fluid or seminal plasma. This does not cause any visible change in the morphology of the spermatozoon but it does alter the physical and chemical properties of the plasma membrane, permitting an influx of calcium ions required for the induction of the hyperactivated form of motility and for the acrosome reaction. The hyperactivated motility endows the capacitated spermatozoa with strong thrusting power that facilitates migration from the isthmus to the ampulla and subsequent passage through the zona pellucida. The acrosome reaction is an essential prerequisite for fertilization – a spermatozoon with an intact acrosome cannot penetrate the ovum.

The acrosome reaction (Fig. 33.20) involves multiple point fusions between the plasma membrane and the outer acrosomal membrane over the front half of the sperm head. The fusions give rise to a series of small vesicles formed by fragments of both membranes. The vesicles are separated by small pores through which the acrosomal enzymes escape. There is controversy as to whether or not the escaping enzymes aid the passage of the spermatozoa through the cumulus oophorus in the cow. As the reaction proceeds, the pores enlarge at the expense of the vesicles so that the vesicles have been lost by the time the sperm penetrates the zona pellucida. When one of the advancing spermatozoa reaches the perivitelline space, it fuses with the plasma membrane of the ovum and its genetic material is incorporated into the conceptus at fertilization.

The fusion of the egg and the sperm triggers a series of reactions that prevent polyspermy by making both the zona pellucida and the plasma membrane of the ovum impenetrable to other spermatozoa.

It is often stated that capacitation requires a 6-hour sojourn in the female tract. However, it is unlikely that the processes would be synchronized to ensure that all the surviving spermatozoa would have been capacitated at a fixed minimum time after deposition in the female tract. Asynchrony in the time to capacitation would appear to be more advantageous in that it would allow for small populations of potential fertilizing spermatozoa to be available sequentially over a period spanning several hours before and after ovulation. Indeed, there is evidence that only 10–20 per cent of bovine spermatozoa have undergone capacitation and the acrosome reaction within three hours of insemination, while other spermatozoa do so several hours later. Again, the inappropriate use of exogenous hormones may hamper capacitation and the acrosome reaction.

Maternal recognition of pregnancy

Normally, the conceptus enters the uterus about 72 hours after ovulation, at the 8–16 cells stage. The cells (blastomeres) form a solid mass (morula) still contained within the zona pellucida. By day 7 or 8, fluid secreted by the blastomeres accumulates in a central cavity (blastocoele) and the zygote is now called a blastocyst. The cells have been arranged into two distinct populations (Fig. 33.35):

- The flattened trophoblast cells that form the wall of the blastocyst and ultimately will form the chorion.
- A group of cells that form the inner cell mass at one pole beneath the trophoblast cells and is destined to form the fetus.

The blastocyst hatches from the zona pellucida on days 9 to 11 and on day 13 it begins to elongate so that

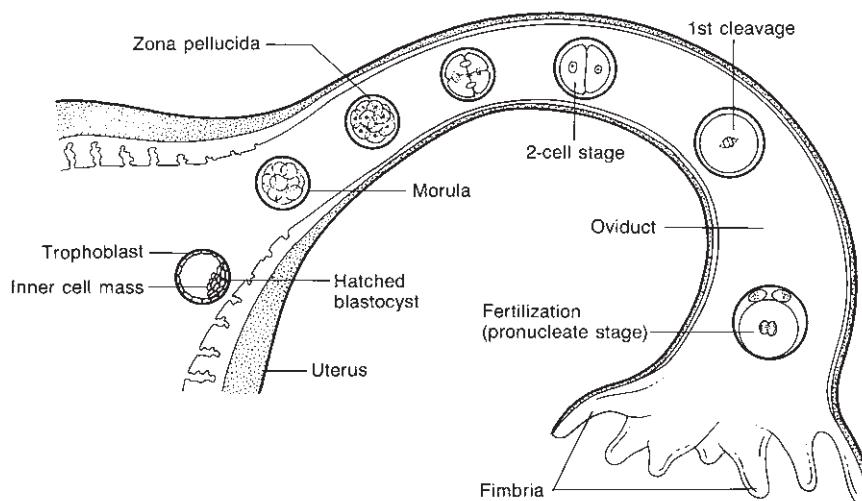

Fig. 33.35 Schematic diagram to illustrate the changes in the conceptus during transport down the uterine tube and into the uterine lumen (after McLaren, 1984).

during the third week it occupies most of the pregnant (ipsilateral) horn and a portion of the non-pregnant (contralateral) horn. The process of attachment begins at day 19 or 20 when there are definite areas of adhesion between the trophoblastic epithelium of the conceptus and the endometrial epithelium; implantation is completed between days 35 and 42. The conceptus plays an important role in prolonging the functional lifespan of the corpus luteum, an essential requirement for the maintenance of pregnancy. The critical period for the extension of the lifespan of the corpus luteum in the cow is between day 15 and day 17; if there is an elongated conceptus present at that time, the mother will 'recognize' that she is pregnant and the luteolytic pulsatile pattern of PGF_{2α} release from the endometrium will be attenuated or abolished.

Since maternal recognition of pregnancy precedes the physical attachment of the conceptus to the endometrium, it is evident that the utero-ovarian regulatory mechanisms that 'rescue' the corpus luteum are responding to a biochemical dialogue between the conceptus and the maternal tissue that is initiated by a variety of signal factors released into the uterine lumen by the preimplantation conceptus.

The bovine conceptus can synthesize a number of products (steroids, prostaglandins, peptides, proteins) that may interact with the maternal utero-ovarian axis. There is evidence to suggest that the conceptus releases different signal factors at different times and that the relative importance of each of these factors may change during these early days of pregnancy. A hypothesis consistent with current information is that the bovine conceptus initiates both antiluteolytic and luteotrophic activities. The main signal is the secretion of interferon-τ (IFN-τ) which reduces the secretion of PGF_{2α} by the

endometrium. The size of the blastodermic vesicle may be critical: a small conceptus may not secrete sufficient IFN-τ to prevent luteolysis. Putative luteotrophic factors include a lipid-like substance released by the conceptus between day 13 and day 18 of pregnancy and, possibly, PGE₂ from the endometrium.

Later in this text we shall pay serious attention to the effects of nutritional status on the resumption of normal ovarian and uterine functions after calving; therefore, it seems appropriate to mention at this juncture that the survival of the early conceptus may be put at jeopardy when the dam is fed excess protein in the diet. The resultant production of large quantities of ammonia in the rumen leads to elevated concentrations of urea in the blood which, in turn, so alters the ionic composition of uterine and tubal secretions that the pH is incompatible with the survival of the conceptus. Problems of embryonic loss are dealt with in Chapter 36.

Maintenance of pregnancy

Once the normal conceptus-endometrial-ovarian regulatory axis of pregnancy has been established, the uterus comes under long-term control by progesterone. In the cow, a fully functional corpus luteum is essential to maintain pregnancy up to day 235; thereafter, the adrenal glands seem to be able to secrete sufficient progesterone to maintain pregnancy in ovariectomized cows. The placenta contributes little to the circulating concentrations of progesterone at any time during pregnancy. The principal luteotrophin is LH; there is little evidence that prolactin plays any significant role (McCracken *et al.*, 1999). The corpus luteum maintains the plasma progesterone concentration above 10 ng/ml from the second week of gestation until term. Proges-

terone exercises a 'block' on the uterine muscle in that it depresses the amplitude of contractions, suppresses the reactivity to oxytocin and PGF_{2α} and prevents the development of synchronous coordinated contractions that might expel the fetus prematurely. It does not abolish the spontaneous contractility of the myometrial cells. Problems of fetal loss are dealt with in Chapter 37.

Parturition

Since parturition depends on coordinated rhythmic contractions of the myometrium as well as involuntary contractions of the abdominal muscles and 'softening' of the birth canal, the final preparation for delivery of the fetus must involve removal of the progesterone block. This is achieved by significant changes in the hormonal profile coupled with the acquisition of gap junctions by the myometrial cells.

The hormonal changes are initiated by the fetus, triggered by the recognition of 'stress' by the fetal hypothalamic–pituitary axis (Fig. 33.36). This results in the release of ACTH that stimulates the fetal adrenal to

release increased amounts of cortisol. The cortisol induces the placenta to release increased quantities of oestrogens into the maternal circulation, and both the cortisol and the oestrogens act on the endometrium to increase the output of PGF_{2α}, which causes luteolysis. Thus the oestrogen:progesterone ratio has been switched strongly in favour of oestrogen and the inhibitory effect of progesterone on the uterine muscle has been abolished. The oestrogens promote uterine contractility by stimulating the synthesis of contractile protein and of receptors for both oxytocin and PGF_{2α}, and by facilitating the formation of gap junctions between adjacent myometrial cells. Gap junctions are intercellular structures that link cells and allow them to exchange ions and electrical impulses. In the parturient uterus they provide the routes through which electrical activity is propagated; in other words, they provide the structural basis for a functional syncytium that permits synchronization of myometrial contractions. Thus, the switch to oestrogen domination at full term enables the uterine muscle to develop spontaneous rhythmical contractions. The transition of the myometrium from a quiescent state to an active state has been termed

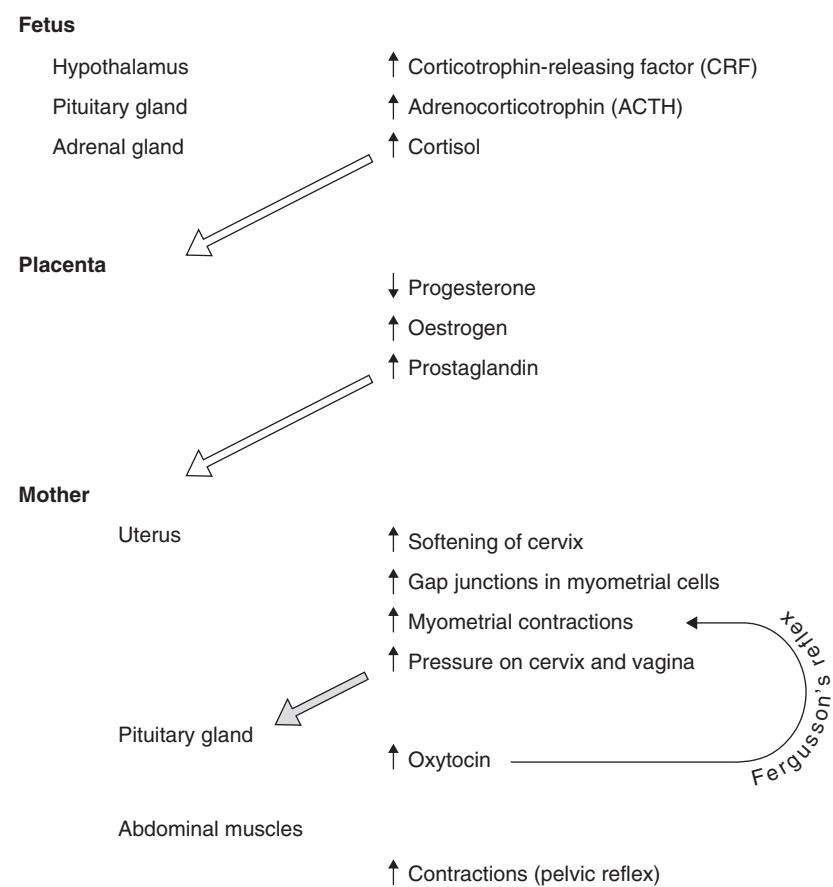

Fig. 33.36 Hormonal control of parturition. The hormonal changes are initiated when the fetal hypothalamic–pituitary–adrenal axis releases increased amounts of cortisol. The cortisol induces the placenta to release increased quantities of oestrogens. The oestrogen:progesterone ratio is switched strongly in favour of oestrogen and the inhibitory effect of progesterone on the uterine muscle ('progesterone block') is abolished. The oestrogens promote uterine contractility by stimulating the synthesis of contractile protein and of receptors for both oxytocin and PGF_{2α} and by facilitating the formation of gap junctions between adjacent myometrial cells. Gap junctions enable the uterine muscle to develop spontaneous rhythmical contractions. The more powerful contractions during parturition are generated in response to PGF_{2α}, augmented during the second stage of labour by oxytocin. (From Hartigan, 1995.)

'activation'; the activated myometrium is capable of generating high-frequency, high-amplitude contractions in response to mechanical or biochemical stimuli. The more powerful contractions during parturition are generated in response to PGF_{2α}, augmented during the second stage of labour by oxytocin. Both of these hormones influence smooth muscle activity by regulating the concentration of calcium ions in the myometrial cells. The concentration of free Ca²⁺ in myometrial cells increases about three-fold during contraction, through influx from extracellular sources and release from intracellular stores. A deficiency of calcium in a pregnant female at full term is associated with atony of the uterine muscle and a tendency to prolapse of the uterus.

Softening of the birth canal is achieved by the cascade of hormones: a rise in oestrogen concentrations followed by the activities of relaxin and PGF_{2α}. Parturition can be induced after about day 255 of gestation by a single injection of a synthetic glucocorticoid that simulates the effects of fetal cortisol, or after 270 days by PGF_{2α}. Retained placenta can be a problem with either method.

Tocolysis: Myometrial activity is inhibited by agents (such as β-adrenergic agonists and relaxin) that increase the intracellular levels of cAMP or cGMP, thus interfering with the interaction of free calcium ions with contractile protein.

Drugs that stimulate β₂-adrenoceptors of the myometrial cells have been used to relax the uterine muscle in non-pregnant cows undergoing embryo transfer and in pregnant cows at full term to delay parturition (tocolysis) or to facilitate obstetrical operations such as fetotomy, caesarean section or replacement of uterine prolapse. The duration of the tocolysis depends on the pharmacological effects of the agent and on the position of the fetus at the time of treatment. For instance, clenbuterol causes an outflow of calcium ions from the myometrial cells and that renders the cells unresponsive to oxytocin for some hours. When a single therapeutic dose of clenbuterol is given early in stage one of labour it can delay parturition for 5–8 hours, but if it is given in stage two after the cervix has been fully dilated the delay may be as short as an hour or two. It has been reported that when uterine contractility returns, the treated animal tends to have an 'easier' calving; it is suggested that this is due to greater widening and softening of the birth canal.

Physiology of the postpartum period

During pregnancy, the mechanisms for the synthesis and release of GnRH by the hypothalamus and those for the release of the gonadotrophins by the pituitary gland appear to remain intact and functional. The high

concentrations of progesterone and oestrogen in the circulation exert a prolonged negative feedback on the maternal hypothalamic–pituitary–ovarian axis. The principal long-term effect of this inhibition is a progressive decline in the amount of LH in the pituitary gland, accompanied by a greatly diminished response of the pituitary gland to GnRH, a low concentration of LH in the circulation and relatively quiescent ovaries. The inherent wave-like pattern of follicular growth is not lost: it is in train within a few days after parturition, with the intrinsic periodicity of seven to ten days. However, the selected dominant follicle may not be able to trigger the neuroendocrine process that leads to oestrus and ovulation. Hence, immediately after calving, the cow has a period of anoestrus, the length of which can be influenced by age, season, nutritional status, dystokia, milk yield, suckling, uterine pathology or subclinical disease.

Re-activation of the hypothalamic–pituitary–ovarian axis

The primary objective of the neuroendocrine adjustments in the early postpartum period is to reinstate the ovaries as fully functional components of the hypothalamic–pituitary axis and to restore the pituitary stores of LH to their normal levels so that the pituitary gland can respond to pulses of GnRH by releasing pulses of LH of sufficient frequency and amplitude to stimulate follicular maturation; in general, this is achieved by day 10 postpartum. In addition, the cow has to cope with the myriad of endogenous and exogenous stressors that might interfere with her ability to progress the dominant follicle to its physiological destiny as a preovulatory follicle. The fate of the first-wave dominant follicle has a significant impact on the duration of the interval to first ovulation: for instance, Beam and Butler (1999) reported the interval as 20 days for those that ovulated (46 per cent of their cows), 51 days for those that regressed (31 per cent of cows) and 48 days for those that formed follicular cysts (23 per cent of cows).

Metabolic factors play key roles in the resumption of reproductive activity (Fig. 33.37). Following parturition, the high producing dairy cow is unable to increase dry matter intake as fast as is necessary to meet the increased nutrient demands for lactation; body reserves of fat and protein are mobilized to meet the deficit; in the circulation, the concentrations of non-esterified fatty acids and triglycerides are elevated, while the concentrations of glucose, insulin, and IGF-1 are diminished (Fig. 33.37) and the interval to first ovulation is extended. According to Beam and Butler (1999), the interval from calving to the nadir of negative energy balance has just as much significance for fertility as does

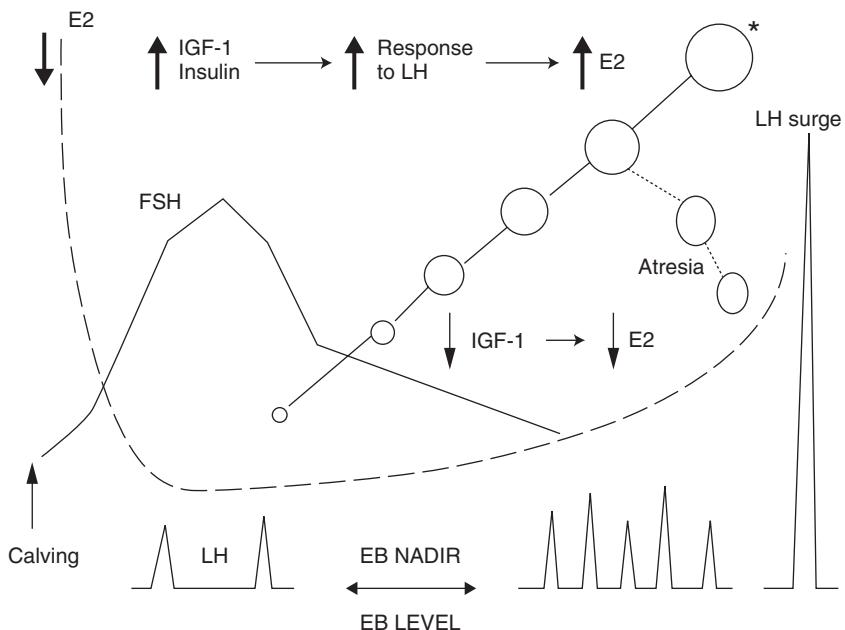

Fig. 33.37 A schematic model describing dominant follicle development (circles) and function in relation to changing metabolic and reproductive hormones, and energy balance (EB), during the first follicular wave postpartum in dairy cows. The first-wave follicle either ovulates (*) or undergoes atresia. LH pulse frequency is modulated by the day of the EB nadir and, to a lesser extent, the level of EB. The large upward arrows indicate increased insulin-like growth factor-1 (IGF-1) and insulin leading to improved responsiveness to LH and greater oestradiol (E_2) production by the dominant follicle. (From Beam & Butler, 1999, reproduced with permission of the Society for Reproduction and Fertility.)

the depth of the nadir. Available evidence seems to confirm that the modal interval to first ovulation has become longer in recent years.

It is suspected that the negative energy balance may be a factor in the pathogenesis of abnormal cycles (short luteal phase, prolonged luteal phase, follicular cysts) in cows that have returned to oestrus. The mechanisms by which the negative energy balance can inhibit ovarian activity are complex. For instance, there is some evidence that it may suppress LH pulse frequency; the low levels of insulin and IGF-1 may retard the growth of the dominant follicle; the steroidogenic activity of the dominant follicle may be so reduced that it is incapable of exerting the positive feedback on the hypothalamus and the pituitary gland that is required for ovulation; if the follicles that ovulate are small, they may form small corpora lutea that are incapable of secreting optimal concentrations of progesterone. It has been reported that cows that experienced deep negative energy balance over the first 10 days postpartum subsequently had subnormal progesterone concentrations in their third oestrous cycles.

Oestrous cycles in postpartum cows

The first ovulation may or may not be associated with oestrus; estimates of silent ovulation range from 40 to 70 per cent. Frequently, oestrus is not observed until the end of the first full-length interovulatory period. The first preovulatory surge of LH may be followed in some cows by a complete cycle with a normal luteal phase. However, other cows may have an initial cycle of

normal duration but with reduced concentrations of progesterone. Another group that may constitute approximately 50 per cent of either the dairy herd or the beef herd has been reported to have a short luteal phase of five to ten days' duration during which the corpus luteum secretes reduced amounts of progesterone (Lamming *et al.*, 1981). These corpora lutea are not killed by the usual luteolytic process: their ability to synthesize progesterone is lost prematurely. The transient low levels of progesterone after the first ovulation may have a significant (but, as yet, unidentified) effect on hypothalamic function and they almost certainly play a role in ensuring that oestrus is expressed before the second ovulation.

As mentioned above, a variety of factors can delay the onset of oestrous cycles. Although the events leading to normal stores of LH in the pituitary gland are relatively independent of the suckling stimulus and environmental stressors, the events leading to an increased frequency of LH pulses are susceptible to inhibition by such factors.

In general, milked dairy cows ovulate earlier in the postpartum period than do suckling dairy cows or beef cows. For instance, Lamming's group at Nottingham has reported that milk progesterone profiles on 505 milked dairy cows indicated a mean calving-to-first-ovulation interval of 24 days compared with approximately 60 days for 365 suckled beef cows. Suckling depresses the frequency of LH pulses, probably because it induces a release of endogenous opioids that inhibit the normal pulsatility of the hypothalamic–pituitary axis. There are high concentrations of prolactin in the circulation of

lactating cows but, according to Lamming *et al.* (1981), there is no evidence that hyperprolactinaemia plays a significant role in the suckling-induced inhibition of ovarian activity. The potency of the suckling stimulus declines with time after parturition. The duration of the period of inhibition can be influenced by other environmental factors, such as poor nutrition (e.g. when cows lose one unit or more in body condition score in early lactation) or season at calving (photoperiod?). For instance, cows that calved during January to June took significantly longer to resume ovarian activity than did those that calved during July to December (Lamming *et al.*, 1981).

Uterine involution

It should be emphasized that the uterus exercises some control over the activities of the ovaries by way of a local utero-ovarian axis and that uterine pathology can put a brake on the ovarian contribution to the larger neuroendocrine axis. Synthesis and metabolism of PGF_{2α} are elevated in the bovine uterus during the early postpartum period and this is reflected in the presence of a major metabolite (PGFM) in the blood at that time. There is accumulating evidence that ovarian function does not resume until the concentration of this metabolite has fallen below a critical threshold. There appears to be a significant negative correlation between the duration of elevated concentrations of PGFM after calving and the time required for completion of uterine involution (Lindell & Kindahl, 1983). Persistent uterine infections prolong the period of high concentrations of PGFM and the time to uterine involution. A problem may arise in the infected cow that ovulates very early in the postpartum period because these continuously elevated concentrations of prostaglandin are not sufficient to induce luteolysis and a mutual interdependence between the infection and the corpus luteum may be established, thus rendering the cow liable to develop pyometra. However, the majority of cows do not ovulate until after the microbial population of the uterus has been reduced to transient contaminants, a process that may be enhanced by the fluctuating levels of oestrogens released from the follicles that begin to grow in the ovaries as early as the first week postpartum and at intervals of seven to ten days thereafter.

During the second week after parturition the pool of antral follicles in the ovaries is increased both in dairy cows and in beef cows; the increase in numbers is largely due to the development of medium-size follicles (4–8 mm in diameter), particularly evident in the ovary contralateral to the previous pregnancy. This predominance of the contralateral ovary seems to persist for about four weeks, with the result that the majority of first ovulations are from the contralateral ovary. It has

been suggested that a very early ovulation from the ipsilateral ovary in an infected cow may increase the risk of development of pyometra (Hartigan *et al.*, 1974).

It is perfectly 'normal' for bacteria to invade the bovine uterus during the first few days after parturition. Bacteriological studies have revealed that a very wide range of micro-organisms, both pathogens and commensals, gain entry but repetitive sampling showed that when parturition was uncomplicated the contamination of the uterus was transient and that the isolates varied from one sample to the next. At the end of the fourth week postpartum only 30 per cent of the cows had bacteria in the uterus, mostly non-pathogens (Griffin *et al.*, 1974). Under optimal conditions, most cows have eliminated the pathogenic contaminants before cyclic ovarian activity begins. On the other hand, cows that experience dystokia, traumatic damage to the endometrium or retention of placental membranes are less efficient in dealing with pathogens. There is a significant reduction in the efficiency of phagocytic cells in the endometrium and uterine lumen and, as a result, potential pathogens may persist and induce endometritis or metritis. Again, in the majority of cows the endometritis tends to be short-lived; the combination of phagocytosis, local antibody production and myometrial contractions that are normal features of the involutionary period effect clearance of the micro-organisms and resolution of the endometritis. However, it is important to stress that infusion of irritants (antibiotics, iodine) that inhibit phagocytosis, extensive intra-uterine manipulation that damages the endometrium or an early ovulation that causes the onset of a precocious luteal phase may permit a pathogenic micro-organism to become established within the uterus, particularly if the concentration of PGFM is still high. In such circumstances the prostaglandin produced by the uterus is inadequate to cause luteolysis. The result is that the defence mechanisms of the host are depressed by the progesterone from the corpus luteum and the pathogens cause continuing damage to the endometrium, thus preventing the release of a luteolytic dose of prostaglandin. At this stage, the pathogen and the corpus luteum have established a mutual interdependence that predisposes to the development of pyometra. The vicious circle can be broken by exogenous prostaglandin. The important point is that inappropriate medication early in the post-partum period can interfere with the physiological progress of involution and induce long-term pathological consequences.

If a cow enters the second week postpartum without clinical evidence of an active inflammatory response, it is unnecessary – and it may be unwise – to resort to intrauterine antibacterial therapy: the drug may cause physical damage to the regenerating mucosa and – perhaps just as important – it may dampen the local

immune response to micro-organisms that may challenge that system later, when the cow is inseminated.

If purulent endometritis/metritis develops it does not abolish ovarian activity immediately and totally. Initially, it causes prolonged cycles, usually with silent ovulations for some months before anoestrus supervenes. Obviously, the best prospects of full recovery to fertility will depend on diagnosis and treatment before the link between the hypothalamic–pituitary axis and the ovaries has been severed.

For problems seen in the postpartum period consult Chapter 34.

Uterine environment after resumption of cyclic ovarian activity

The quality of the luminal microenvironment of the female genital tract has a significant impact on fertility. The fluids secreted by the oviducts and by the uterus are the media in which the gametes are transported and sustained; the spermatozoa are capacitated, hyperactivated and acrosome-reacted, the ovum is fertilized and the conceptus is transported and sustained while it develops into the elongated blastodermic vesicle that implants in the uterus. The appropriate secretions, muscular activity and flow of fluids are governed by oestrogen and progesterone released from the ovaries in the correct concentrations, at the correct times and in a specific sequence. Therefore, any factor that alters the delicate balance of ovarian hormones during the oestrous cycle is a potential hazard to pregnancy, even when a normal fertile cow is bred to a highly fertile bull.

The composition of the tubal and uterine fluids changes on regional and temporal bases – specifically to meet the needs of the gametes and of the conceptus: in particular, the changing needs of the conceptus as it progresses from a single cell zygote to an elongated vesicle. It follows that the preimplantation conceptus is vulnerable to damage by anything that disrupts the hormonal balance or otherwise alters the secretions. However, it is not easy to disentangle the complex interrelationships between the various actions of the hormones, the secretory and muscular responses of the tubular tract, and the viability and developmental competence of the oocyte. For instance, there are several highly sensitive junctures at which short-term acute stress might interfere with the maturation of the oocyte, fertilization, embryogenesis or implantation; it would be virtually impossible to ascertain whether the pregnancy wastage was due primarily to low developmental competence of the zygote or to an inappropriate uterine microenvironment that was unable to sustain a fully competent conceptus. Frequently, it would be just as difficult to identify the cause of the acute stress. A similar cause-and-effect conundrum attaches to the

reports of long-term (up to the third cycle) deleterious effects on embryo survival in cows that experienced deep negative energy balance during the first 10 days after calving. Were the carry-over effects due to a loss of developmental competence that resulted in embryo mortality and suboptimal luteotrophic stimuli, or were they due primarily to deficient luteal function that made the uterine microenvironment suboptimal for the conceptus?

We have mentioned that ingestion of excess protein leads to elevated blood urea levels, lower pH of uterine fluids and lower fertility. The pregnancy wastage has been attributed to the deleterious effect of acidic uterine fluid on embryos (Butler, 2000) but O'Callaghan and Boland (1999) took a different view: on the basis of experiments involving reciprocal embryo transfers, they suggested that the effects on embryo quality are due to alterations in the tubal microenvironment or in the follicle rather than in the uterus.

The iatrogenic introduction of micro-organisms can seriously diminish the quality of the uterine microenvironment during the breeding season. The uterus has a higher degree of susceptibility to bacterial infection during the luteal phase than it has during oestrus. This is because the migration of neutrophils into and through the endometrium is inhibited by progesterone, which also depresses the phagocytic activity of the cells once they have arrived in the endometrium. Therefore, the clinician should exercise great care to avoid the introduction of contaminated or irritant material into the uterus during the luteal phase. For the same reason, cows should not be inseminated at mid-cycle or after conception. Persisting bacterial endometritis in a cyclic cow could induce embryo loss because (i) it damages the endometrium so that it is not possible to establish an efficient interface for the transfer of nutrients; (ii) it induces embryo mortality or retards expansion of the blastocyst which then fails to secrete enough IFN- τ to maintain the corpus luteum and/or (iii) it releases sufficient PGF_{2 α} to induce premature luteolysis.

Problems of the postpartum period are dealt with in Chapter 34, with endometritis being discussed from p. 521.

Take-home concepts for the clinician

Readers must be aware that this overview of the basic elements of reproductive physiology in cattle is a simplified account of some highly complex phenomena; the aspiration has been to provide the broad concepts that ought to inform the diagnostic and therapeutic efforts of the clinician. So, what is the conceptual framework for the major themes presented here?

Overall control of reproductive activities is vested in the HPG axis, within which the dominant role is played by the hypothalamus, literally the nerve centre that coordinates and responds to the relevant neural, endocrine and immunological inputs. It exercises control through the actions of a pulse generator that is responsible for the pulsatile release of GnRH which, in turn, regulates the release of the gonadotrophins that determine the nature, intensity and timing of events in the genital tract. For instance, it is the frequency and, to a lesser extent, the amplitude of LH pulses that regulate the timing of ovulation. The *pulsatility* is modulated by *feedback*, by *energy balance* and by *stress*; to take a practical example, it is likely that ovulation will be suppressed when an animal is in negative energy balance and/or is stressed by other environmental challenges.

During the transition period the high-producing cow is exposed to a plethora of stressors (both intrinsic and extrinsic), is relatively immunosuppressed and, once lactation begins, is in significant negative energy balance; in such circumstances, reproduction has a relatively low priority in the *partitioning of energy* and it is likely that the resumption of cyclic ovarian activity will be delayed. Of course, the deleterious effect of the energy deficit on LH pulses is a major factor in the suppression of oestrus and ovulation, and in the low pregnancy rates to first service; however, the fact that approximately half of the mated cows calve to first service should convince us that there are other contributing factors that tip the balance away from a satisfactory level of herd fertility. Thus, management of the breeding programme demands attention to hygiene and the physical facilities, to body condition score, to feeding practices and to veterinary care throughout both the transition period and the breeding season. The prime objective is to minimize the *allostatic load* so that functions of HPG axis are not put at hazard by the coping strategies of an overburdened cow (see Chapter 67).

If there is a need to induce ovulation, the relevant conceptual framework derives from the inherent pattern of *follicular waves* that makes a cohort of newly recruited follicles available every seven to ten days. Treatment should be administered at the appropriate stage in a current wave or, as has been done by investigators pursuing the aspiration to eliminate the need for detection of oestrus after induced ovulation, in a new wave that has emerged after surgical ablation of the current wave (Bo *et al.*, 2002). The latter experiment is an exciting application of basic physiological information but it does prompt a rhetorical question: if an effective pharmacological regimen capable of chemical ablation of cohorts of recruited follicles is devised and is then used widely on a whole-herd basis, how is the consumer likely to respond to the news that milk on

sale in the local store has been produced by cows that are 'hormone-laden'?

Introduction

The postpartum period is the time during which the genital tract recovers after parturition, and returns to a normal state ready for the next pregnancy. Despite a trend for extended lactation for higher genetic merit dairy cows producing high milk yields, the majority of farmers still select an earliest service date, or voluntary waiting period, between 40 and 60 days after calving. Similarly, in seasonally calved herds, a short period for recovery following pregnancy is often essential for those animals that calve during the later part of the season. Monitoring the uterus and ovaries in the postpartum period is important because delayed uterine involution, the presence of postpartum uterine infec-

tion or abnormal ovarian function causes subfertility which results in substantial economic loss for the cattle industry. Retained fetal membranes, endometritis and cystic ovarian disease, for example, delayed conception by 25, 31 and 64 days, respectively compared with cows with a normal postpartum period (Borsberry & Dobson, 1989).

The events that comprise the postpartum period are uterine involution, regeneration of the endometrium, elimination of bacterial contamination of the uterus and the return of ovarian cyclical activity. The initial stimulus for these changes to occur is the expulsion of the fetus along with the associated membranes and fluids at calving.

Uterine involution

Uterine involution is the return of the genital tract after calving to normal non-pregnant dimensions. This involves physical shrinkage, necrosis and sloughing of caruncles, and the regeneration of the endometrium. There is considerable loss of tissue, with the mean weight of the uterus decreasing from about 13 kg before parturition to about 1 kg during a 30-day period (Kaidi *et al.*, 1991). The uterus and cervix contract rapidly immediately after calving and it is often difficult to insert a hand through the cervix 24 hours postpartum; the cervix only admits two fingers by 96 hours postpartum. Uterine involution occurs in a decreasing logarithmic scale with the greatest change during the first few days after parturition (Fig. 34.1). By 10 to 14 days postpartum the entire genital tract is palpable *per rectum* in normal animals, although the previously gravid horn can still be identified because it is longer and has a greater diameter than the contralateral horn. Although the time required for complete involution is 40 to 50 days, the changes in uterine diameter are almost imperceptible after 20 days postpartum. Involution is delayed by postpartum disease including milk fever, retained fetal membranes and uterine infection.

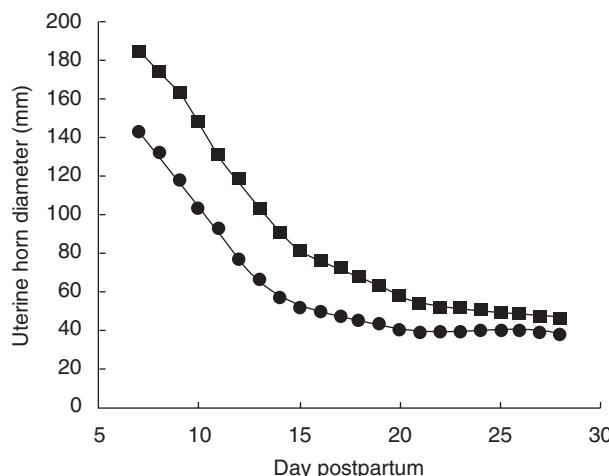

Fig. 34.1 The mean external diameter of the previously gravid (■) and non-gravid (●) uterine horns between 7 and 28 days postpartum.

Regeneration of the uterine epithelium

Following the loss of the allantochorion there is necrosis of the uterine caruncle and this has usually sloughed by day 12 postpartum. Sloughing of the uterine caruncles contributes significantly to the rapid reduction in weight of the involuting postpartum uterus because the caruncles account for over half of the weight of the uterus. The sloughed caruncles form the lochial discharge, along with the remains of fetal fluids and blood from the ruptured umbilicus. The lochia is usually a yellow to brown, viscous fluid without an unpleasant odour. The uterus of normal animals contains one to two litres of lochia immediately postpartum and the greatest discharge is in the first two to three days; it has virtually disappeared by 14 to 18 days after calving.

There is initially regeneration of the endometrium in the intercaruncular areas and then by centripetal growth of the cells over the caruncle. Epithelial regeneration is complete by about day 25 postpartum, but the deeper layers of tissues are not fully restored until 6 to 8 weeks postpartum. Whilst these epithelial changes are taking place the caruncles are shrinking. By 40 to 60 days postpartum the caruncles are only 4 to 8 mm diameter and 4 to 6 mm high, compared with 40 to 70 mm diameter and 25 mm high at calving.

Elimination of bacterial contamination

At calving, the vulva is relaxed and the cervix dilated, allowing bacteria to gain entry to the vagina and the

Box 34.1. Uterine defence mechanisms.

- Intrauterine neutrophils
- Physical barriers of the vulva and cervix
- Persistent uterine contractions and involution
- Caruncular sloughing (to expel adherent bacteria)
- Secretory immunoglobulins
- Cell mediated immunity
- Intrauterine pH (rises at oestrus to 7.0, from 6.4 during dioestrus, which reduces bacterial growth)
- Resident vaginal bacterial flora

uterus. The postpartum environment of the uterine lumen supports the growth of a variety of aerobic and anaerobic bacteria. Many of these bacteria are simple contaminants in the uterine lumen and are removed by a range of uterine defence mechanisms (Box 34.1). In one study, 93 per cent of the uteri obtained at an abattoir within 15 days of calving yielded bacteria on aerobic and anaerobic culture of luminal swabs and endometrial tissue (Elliot *et al.*, 1968). The number of uteri from which bacteria were isolated had declined to 78 per cent by 16 to 30 days, 50 per cent at 31 to 45 days and 9 per cent by 46 to 60 days postpartum. In the live animal, there is a constantly fluctuating bacterial flora in the first 7 weeks postpartum due to spontaneous contamination, clearance and recontamination. However, uterine infection is commonly associated with *Escherichia coli*, *Arcanobacterium pyogenes*, *Fusobacterium necrophorum* and *Prevotella* (formerly *Bacteroides*) species. Indeed, *A. pyogenes*, *F. necrophorum* and *Prevotella* species have been shown to act synergistically to enhance the likelihood of uterine disease and increase the risk of clinical endometritis and its severity.

Return of ovarian cyclicity

During the bovine oestrous cycle, ovarian follicular development occurs in a wave pattern starting with the emergence and recruitment of two to six follicles of 4 to 6 mm diameter (Savio *et al.*, 1988). One of these follicles is selected to continue to grow and become the dominant follicle, whilst the remaining follicles become atretic and regress (Fig. 34.2). Each follicular wave is preceded by an increase in circulating FSH concentration (Adams *et al.*, 1992). Selection of the dominant follicle results in oestradiol production, and negative feedback on FSH, with the follicle subsequently becoming LH dependent (Ginther *et al.*, 1996). Early luteal phase progesterone secretion, however, suppresses LH pulse frequency and the first dominant follicle under-

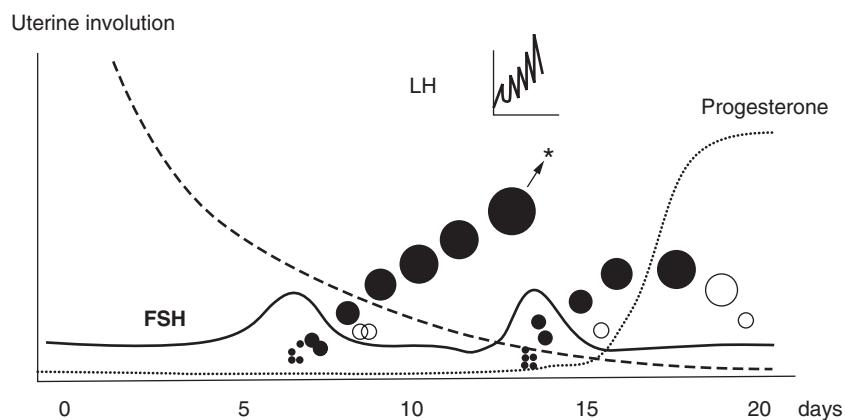

Fig. 34.2 Cartoon of resumption of ovarian cyclical activity in a dairy cow during the first 20 days postpartum. As uterine involution (--) progresses, there is a transient increase in plasma FSH concentration (—), followed by the emergence of several follicles > 4 mm diameter (●), with subsequent selection of a dominant follicle (●) and atresia of the subordinate follicles (○). The fate of the first dominant follicle is dependent on LH pulse frequency, which in the present case is sufficient to cause ovulation (*), and the subsequent formation of a corpus luteum secreting progesterone (...), heralding the return of ovarian cyclical activity.

goes atresia. Conversely, at the other end of the cycle, after luteolysis the LH pulse frequency increases, stimulating growth of another dominant follicle that increases plasma oestradiol concentrations, which subsequently stimulate an LH surge and ovulation.

Throughout pregnancy, regular periodic emergence of anovulatory follicular waves occurs in response to recurrent FSH surges, except for the last 21 days of pregnancy due to very high plasma progesterone and oestrogen concentrations. After parturition steroid hormone concentrations decrease to basal values, there is an increase in plasma FSH concentration within days of calving and that stimulates the emergence of the first postpartum follicular wave. Subsequently, the first dominant follicle is selected around day 10 to 12 postpartum (Savio *et al.*, 1990; Beam & Butler, 1997). These events occur in all postpartum cows irrespective of periparturient disease, environment or dietary deficiencies. However, the first dominant follicle has three possible fates: ovulation and formation of the first postpartum corpus luteum (return of ovarian cyclical activity), atresia with the emergence of one or more follicular waves without ovulation (anoestrus) or formation of an ovarian follicular cyst (Beam & Butler, 1997). In Europe, 70–80 per cent of first dominant follicles are ovulated in dairy cattle fed an appropriate diet whereas in the beef suckler cow ovulation of the early postpartum dominant follicles is less frequent (Roche & Boland, 1991). The prolonged interval to return of ovarian cyclicity in beef suckler cows is an expression of their failure to ovulate, rather than a failure to develop, dominant follicles. The principal factor determining the fate of the dominant follicles is LH pulse frequency;

frequency; ovulation generally occurs once the LH pulse frequency is one per hour. Therefore, factors that suppress LH pulse frequency in the postpartum period can delay the return of ovarian cyclical activity. Those factors causing anoestrus tend to be more common in the beef suckler cow, and include suckling or the maternal bond, low body condition score and inadequate nutrition. The principal factor causing anoestrus in dairy cattle is negative energy balance.

An interesting feature of ovarian follicular growth within 4 weeks of parturition is that there are fewer dominant follicles or corpora lutea in the ovary ipsilateral to the previously gravid uterine horn, compared with the contralateral ovary (Sheldon *et al.*, 2000). However, the presence of a dominant follicle in the ipsilateral ovary, although less frequent, is a positive marker of subsequent fertility.

Early return of cyclical ovarian activity is generally accepted to be beneficial for subsequent fertility (Darwash *et al.*, 1997); however, others have reported the converse (Smith & Wallace, 1998). Furthermore, it is suggested that an early postpartum first ovulation in the presence of uterine infection can lead to pyometra with persistence of a CL in the presence of pus within the uterine lumen (Olson *et al.*, 1984).

Farmers rarely observe oestrus at the time of the first postpartum ovulation in cattle, and in a significant number of animals the first luteal phase is relatively short. Using continuous observation, oestrus is detectable at the time of about 50 per cent of first and 95 per cent of second ovulations. It is suggested that a period of progesterone dominance prior to ovulation is important for oestrous expression.

Monitoring the postpartum period

Herd records

Recording the basic fertility parameters including the date of calving, dates of observed oestrus and service dates is invaluable for analysis to determine whether a herd is achieving its fertility targets (see also Chapter 41 (b)). The importance of efficient and accurate heat detection cannot be stressed too often to farmers. In addition, the recording of calving ease, the occurrence of retained fetal membranes, abnormal vulval discharge and other peripartum problems identify those herds, and animals within a herd, that warrant particular attention during the postpartum period.

Individual clinical cases

In many cows presented immediately after calving, diagnosis of postpartum problems is quite simple, for example retained fetal membranes or prolapse of the uterus. However, a cow that is acutely ill could be suffering from a variety of conditions and, therefore, a systematic approach to diagnosis is necessary both for differential diagnosis and to ascertain the severity of the condition. Investigation of the individual cow should include the history, a thorough physical examination and further investigations as indicated.

History

Questions should be asked to ascertain whether the cow was ill before calving and whether the illness was related to reproduction or was a condition that is obviously related, such as a pathological vaginal discharge. Information about previous feeding and management should be gathered, particularly relating to the transition period, with the object of determining whether the diet could have predisposed to metabolic diseases. Details of other postpartum problems in the herd in this and previous breeding seasons should also be obtained.

The place where the cow calved should be inspected to assess the level of environmental hygiene during calving. The farmer should be asked if the calving was assisted and, if so, how much and what help was given, by whom and what hygienic precautions were taken. It is also important to determine whether the client has given any treatment already.

Clinical examination

A thorough clinical examination must be undertaken, although the optimum time after calving for examination is debatable. Most often in outwardly healthy

animals an examination is made three to five weeks postpartum to identify abnormalities of the puerperium that might lead to subsequent infertility. This may include the following procedures.

Physical examination

Body condition scoring of cows at drying-off, at calving, at routine postpartum examinations and at the time of insemination is an effective method to assess the adequacy of nutrition in a herd and to monitor energy balance. Indeed, changes in body condition score reflect the effect of negative energy balance on fertility as well as other markers of energy balance such as plasma concentrations of insulin-like growth factor 1 (IGF-1) and β -OH butyrate (BHB). In addition, the presence of ketosis can be established by analysis of urine, milk or serum, and is associated with postpartum uterine infection (Markusfeld, 1984). The use of milk analysis as a method of assessing the nutrition of dairy cattle and their metabolic status is discussed further in Chapter 47 (see p. 807).

Palpation *per rectum* of the genital tract is the predominant method of assessing uterine involution and the return of ovarian cyclicity. Uterine involution may be considered to be complete when the genital tract has contracted such that the uterine horns are of equal diameter and length and the uterus has returned to lie within the pelvic cavity. Return of ovarian cyclicity is usually determined by the palpation of a corpus luteum in the ovary; palpation of follicles in the ovary does not indicate return of ovarian cyclicity. Anoestrus cows may have ovarian follicles up to 18mm diameter, but there is no corpus luteum. Palpation of ovarian structures more than 25mm in diameter may indicate the presence of a follicular or luteal cyst. However, a substantial proportion of cystic structures identified before day 30 postpartum will spontaneously regress (Chapter 35).

Palpation *per rectum* alone is not sufficient to determine the adequacy of uterine involution and elimination of bacterial contamination. A vaginal examination is essential for the assessment of the presence or absence of postpartum uterine bacterial infection. Generally, a manual examination of the vagina is performed by inserting a lubricated, clean, gloved hand between clean vulval lips. During the examination, vaginal and cervical os lacerations and abnormalities are noted and a sample of vaginal mucus withdrawn and examined for character, volume and smell. The combination of a vaginal examination and a rectal palpation can be used to score the severity of endometritis, which is a prognostic indicator of the success rate of treatment for endometritis (Sheldon & Noakes, 1998). Observation of the vagina, vaginal mucus and the cervix with a specu-

lum may provide additional information; sterile, disposable specula are available.

Ultrasonography

Real-time B-mode ultrasonography using a linear array transrectal probe has revolutionized the veterinarian's ability to monitor the return of ovarian cyclical activity and uterine involution. Visualization of the genital tract before day 10 postpartum is difficult, particularly in older animals, and a 5MHz probe is more appropriate for examination of the enlarged uterus at this time. However, a 7.5MHz probe is superior for examination of the ovaries. Ultrasonography is particularly useful for identifying ovarian follicles; a dominant follicle is usually defined as a follicle ≥ 9 mm diameter in the absence of other large growing follicles. However, caution has to be exerted when considering structure and function; the detection of a large follicle or follicular cyst alone does not indicate that it is endocrinologically active (Beam & Butler, 1997).

Use of the ultrasound machine's internal callipers allows measurement of the diameter of the uterus and ovarian structures and comparison with the expected normal values determined by sequential measurement of uterine horn diameter during the process of involution. In addition, abnormal contents of the uterine lumen are readily detected. The entire length of both uterine horns should be scanned, because often pus is localized within a limited section of the genital tract. However, the use of transrectal ultrasonography does not negate the value of performing a manual or specular examination of the vagina before examining the remainder of the genital tract.

Progesterone analysis

Estimation of plasma or milk progesterone by enzyme-linked immunosorbent assay (ELISA) or radioimmunoassay (RIA), collected two to three times per week after calving is adequate to determine the first postpartum luteal activity and abnormal patterns of ovarian activity. Milk samples are more practicable in the field because of the ease of collection. Samples of 10 ml of milk can be stored for at least a month in containers with a potassium dichromate tablet as a preservative (Lactab Mk III, Thompson & Capper, Runcorn) and refrigerated at 4°C.

Endometrial biopsy

Histological examination of endometrial biopsies has not been used as frequently in cattle as in mares. However, endometrial biopsies are valuable indicators of subsequent reproductive performance. Unfortu-

nately, the cost of collection and evaluation for the individual animal precludes the widespread use of the technique in cattle.

Bacterial culture

Guarded transcervical swabs can be used to collect samples of intrauterine fluid for bacterial culture and identification. It is essential that both anaerobic and aerobic cultures are used, which requires the use of a transport medium and specialized microbiological techniques. The predominant pathogens associated with endometritis are *A. pyogenes*, *E. coli*, *F. necrophorum* and *Prevotella melaninogenicus*. Sensitivity tests for selection of an appropriate antibiotic might be of value for herds with a high incidence of endometritis.

Principal factors affecting the postpartum period

There are a variety of factors than can influence the duration of the postpartum period. For convenience, we have already considered the various components of this period as separate entities; however, this does not reflect the normal situation. Uterine involution, bacterial infection and the return of ovarian cyclicity are all closely linked.

Abnormalities of the puerperium such as dystokia, retained fetal membranes, stillbirths, abortions and twins delay uterine involution and the return of ovarian cyclicity. In addition, these problems are associated with an increased risk of metritis and/or endometritis. Conversely, early postpartum ovulation prior to the elimination of bacterial contamination may predispose to pyometra if uterine infection persists in the presence of a corpus luteum.

Suckling has been widely reported to delay the return of ovarian cyclicity. It is interesting to compare studies using milk progesterone estimation to determine the mean time to postpartum resumption of ovarian cycles in dairy (Bulman & Lamming, 1978) and beef cows (Peters & Riley, 1982), which were 24.0 ± 0.6 and 59.9 ± 2.5 days, respectively. It would appear that this inhibitory influence, mediated by reduced LH secretion, is a function of the maternal bond attributable to the dam's own calf, rather than simply an effect of suckling or milk yield (Williams & Griffith, 1995). It has also been suggested that higher milk yields are associated with longer acyclic periods, although it is difficult to separate the effects of milk yield and confounding factors such as nutrition.

Inadequate nutrition, and particularly a diet deficient in energy, is the most important cause of postpartum anoestrus. Body condition score (BCS), particularly in

beef suckler cattle, is an important factor affecting the resumption of ovarian cyclicity and cows with a body condition score less than 2.5 are likely to have a significant delay (see p. 10). In dairy cows, changes in BCS after calving are more important than BCS at calving.

Enhancement of the postpartum period

Shortening the postpartum period would increase the opportunity for rebreeding cattle after calving. Unfortunately, most practical attempts to advance uterine involution have been disappointing; a variety of therapeutic agents have been used in the early postpartum period with no significant effect.

A number of therapeutic agents have been used to try to induce ovulation in the early postpartum period and, therefore, shorten the interval to return of ovarian cyclicity; these agents include GnRH, progesterone and eCG (see p. 678). However, results are inconsistent and often of little long-term benefit to the fertility of the herd.

In the absence of consistently effective pharmacological methods of shortening the postpartum period, it is particularly important for the veterinary surgeon to be familiar with the management factors affecting this period and to give appropriate advice to clients to avoid their negative effects. For example, veterinarians should use condition score targets for key points in the management cycle such as at calving and drying off, in dairy cattle, or weaning, in beef suckler cows. In addition, it is important to ensure the cows are fed an appropriate diet, paying particular attention to the energy density of the ration.

Postpartum lesions of the genital tract

Traumatic injuries to the genital tract, bony pelvis and nerves of the pelvis sometimes occur during normal parturition. However, they are more common following dystokia. Postpartum problems include traumatic injuries such as penetrating wounds and tears of the uterus or vagina, tearing of the cervix or vulva, rectovaginal fistula formation, haemorrhage and haematoma, as well as other conditions such as retention of the fetal membranes and prolapse of the uterus (Noakes, 2001a).

Lacerations and haemorrhage

There is usually, but not always, a history of a protracted or particularly difficult *per vaginam* delivery of the calf.

The first action of the obstetrician after the delivery and resuscitation of a calf should always be to check the dam for trauma. If haemorrhage is apparent its severity should be assessed and appropriate action taken; severe haemorrhage involving a large artery can be rapidly fatal.

Traumatic and post-traumatic lesions are treated according to general principles of wound management. If the calf has been delivered without the use of epidural analgesia, but surgical intervention is required to control haemorrhage, then the use of an epidural should be considered. In order to prolong the duration of analgesia obtained by this method it may be advantageous to include xylazine in the epidural (Ko *et al.*, 1989; Holden, 1998). When a vaginal vessel is bleeding severely, an attempt must be made to clamp the traumatized vessel with artery forceps which can then be left in place for 24 hours. Ligation and the suturing of lacerations would also be indicated in some cases, although it is often impractical due to the inability to gain adequate access to the site. If bleeding vaginal vessels cannot be clamped or ligated the only other option is to apply pressure using materials such as clean towels or bedsheets or a pressure pad containing ice in an attempt to bring about constriction of the bleeding vessels and promote blood clotting.

Where haemorrhage is occurring from uterine lacerations, oxytocin may also be used to promote contraction of the uterus. In cases of uterine rupture, laparotomy and surgical repair may be the only alternative to emergency slaughter. Following severe haemorrhage a blood transfusion may be indicated as a life saving procedure.

In less severe cases the bleeding may stop spontaneously, although lacerations, severe bruising and tissue trauma may result in the later development of necrotic vaginitis. Where perivaginal fat prolapses through vaginal lacerations and becomes necrotic, this may have to be removed to allow closure of the vaginal tear. Infection with *F. necrophorum* or *Clostridium* species may result in a locally severe reaction and serious systemic illness or death.

In the case of necrotic vaginitis emollient fluids and antiseptics are applied locally along with an appropriate systemic antibiotic such as a cephalosporin or potentiated amoxycillin. Following any difficult parturition with associated trauma to the reproductive tract the cow is likely to benefit from the administration of systemic non-steroidal anti-inflammatory drugs (NSAIDs) (Chapter 62).

The response to treatment of many vaginal lesions is good and the clinical signs will disappear within about 10 days. In these cases there is no interference with future reproduction. In a few cases infection spreads and affects the uterus, with resultant poor prognosis for

fertility. Scar tissue may cause narrowing of the birth canal and interference with the next calving.

For further information on nerve damage, the reader should consult Chapter 32.

Uterine prolapse

Uterine prolapse is a relatively common complication of third stage labour in the bovine, with the uterus prolapsing within hours of the calf being delivered and prior to the cervix contracting (Noakes, 2001b). The usual presentation is of a complete inversion of the gravid uterine horn. While prolapse of the uterus may follow a dystokia with a high degree of traction, it is also commonly seen as a sequel to a normal or unassisted second stage labour. Plenderleith (1986) reports that the condition is recorded in 0.5 per cent of assisted calvings and 0.3 per cent of all calvings, while Correa *et al.* (1992) report the condition in 0.6 per cent of calvings. The main predisposing factor in the aetiology of this condition is considered to be uterine inertia immediately postpartum. Hypocalcaemia (milk fever) (see p. 781), which results in a reduction of smooth muscle tone in the uterus, and elsewhere, has been shown to increase the risk of uterine prolapse threefold, while dystokia increased the risk fivefold (Correa *et al.*, 1992). The increased risk of hypocalcaemia in older cows may explain why multigravidae are more commonly affected than primigravidae. Factors that are considered to predispose to prolapse of the uterus are summarized in Box 34.2.

Box 34.2. Possible predisposing factors for uterine prolapse.

- Fetal oversize and maternal/fetal disproportion
- Prolonged dystokia
- Fetal traction
- Hypocalcaemia
- Retained fetal membranes
- Chronic disease, particularly cattle in very poor body condition

When notified of a case of uterine prolapse, the veterinarian should inform the client to wrap the prolapse in a clean sheet to prevent further trauma and contamination and reduce heat loss.

When faced with a case of uterine prolapse in a cow with overt clinical signs of hypocalcaemia, treatment of the hypocalcaemia should probably be carried out prior to replacing the uterus, in case regurgitation and aspiration of rumen contents occurs or the cow succumbs to the hypocalcaemia. However, a non-life-threatening hypocalcaemia which maintains a cow in recumbency

with reduced abdominal straining may actually aid replacement of the prolapsed organ if the procedure can be undertaken swiftly and treatment with calcium borogluconate is not delayed too long.

The replacement of the uterus is aided by the correct positioning of the cow. If the cow is standing the uterus may be lifted on a sheet with the aid of two assistants and replaced from that position. However, if the cow is recumbent she should be placed in sternal recumbence in the frog-leg position as described by Plenderleith (1986) (Fig. 34.3) and if possible positioned facing down hill. This positioning of the cow is achieved by rolling her onto one side and pulling the opposite leg straight back, before rolling her to the other side and repeating the process. If necessary, ropes can be used to hold the cow in this position until the uterus has been replaced. Replacement of the uterus is greatly aided by the administration of an epidural anaesthetic, possibly including xylazine (Ko *et al.*, 1989; Holden, 1998); this also reduces postoperative straining and improves pain relief for the cow. Before replacing the uterus it must be carefully checked for trauma and cleaned as much as possible using a warm, non-irritant, antiseptic solution or normal saline; lacerations of the uterus may require suturing. There is no absolute need to remove the placenta, but often the most effective way of cleaning the organ is to remove the heavily contaminated fetal membranes. However, if the placentomes are still intact and the fetal membranes are not removed easily they should be left in place.

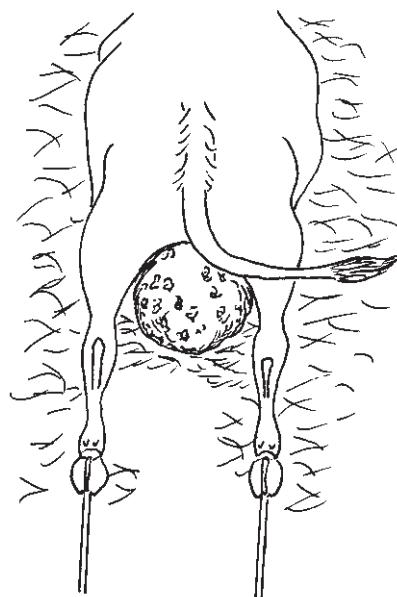

Fig. 34.3 Recumbent cow in the 'frog-leg' position for replacement of a uterine prolapse. Reproduced from Plenderleith (1986) with permission.

The weight of the uterus is best supported by an assistant on either side of the cow while the surgeon replaces the uterus little by little starting at the vulval lips. Gentle but continuous pressure is applied with a clenched fist or the open palm of the hand as portions of the uterus are pushed back into the vagina. Care must be taken to ensure that fingers are not pushed through the often friable uterine wall. Once the uterus begins to be replaced it is best to maintain momentum, as a single abdominal contraction from the cow while the uterus is not held can result in the entire uterus once again becoming prolapsed. As the uterus disappears within the vulval lips the veterinarian should continue to press it forward to the full length of his/her arm. It is important that the whole of the uterus passes through the cervix and that the total length of the uterine horn is fully replaced and any remaining inversion of the tip of the uterine horn reduced. This can be achieved using something to extend the veterinarian's reach such as a clean smooth-ended bottle. Alternatively a volume (5–10 litres) of warm clean water, normal saline or dilute antiseptic solution can be instilled into the uterus and then the majority can be siphoned back out. This has the added advantage that it also has a cleansing action, and any fluid remaining in the tip of the uterine horn may act to hold the uterus in place until the recurrence of normal uterine contractions results in its expulsion.

There is debate within the profession as to whether there is a need to suture the vulval lips closed after replacing a uterine prolapse. If suturing is considered necessary it is best to use Buhner's technique with obstetrical tape, although many other techniques are available (Hooper *et al.*, 1999). Following replacement of the uterus every effort must be made to restore uterine tone and promote involution and closure of the cervix. To this end hypocalcaemia must be treated and oxytocin may be administered; parenteral antibiotics and analgesics are also indicated. Some uterine prolapse cases prove fatal due to trauma and haemorrhage including rupture of the uterine and/or ovarian blood vessels, shock or the often concurrent hypocalcaemia. However, the prognosis depends largely on the following:

- The time lapse between the development of the prolapse occurring and professional treatments being undertaken.
- The degree of trauma that has taken place to the uterus.
- Associated periparturient conditions such as hypocalcaemia and haemorrhage.

There are few published reports looking at success rates for uterine prolapse cases. However, a study undertaken in New Zealand (Oakley, 1992) showed that 19 per cent of cows died within 24 hours of treatment and a further 16 per cent died or were lost to the

study before the end of the next breeding season. Of those cows that were subsequently mated, 78 per cent were found to be pregnant, although 9 per cent subsequently aborted. This indicates that prompt attention to uterine prolapse gives a reasonable survival rate and acceptable subsequent conception rates. Possible complications following uterine prolapse are listed in Box 34.3.

Box 34.3. Possible complications of uterine prolapse.

- Hypocalcaemia
- Haemorrhage
- Metritis
- Endometritis
- Peritonitis
- Toxaemia/septicaemia
- Necrosis of devitalized tissue in longstanding cases
- Uterine rupture

Retained fetal membranes

Introduction

Retained fetal membranes (RFM) is a common condition that is defined as non-separation of the fetal membranes by 12 hours after calving (some authors extend this period to 24 hours before they consider the placental retention to be pathological). The incidence varies from study to study but tends to be about 5–10 per cent (Kossaibati & Esslemont, 1995; Parkinson, 2001); in a survey of >160 000 calvings in the Netherlands the average incidence was 6.6 per cent (Joosten *et al.*, 1988). In problem herds the incidence may be much higher. The year of calving, season of calving, parity of dam, calf mortality, calving difficulty and fetal presentation have all been shown to affect the incidence of RFM (Mee, 1991).

Diagnosis and consequences of retained fetal membranes

The diagnosis of RFM is self-apparent, the major variable being the effect of the condition on the cow's health. In many cases health is unaffected. However, the majority of cows have mild disturbances of appetite and body temperature. In a small number of cows, acute metritis develops causing severe illness, with typical signs of toxæmia and septæmia. Without effective treatment this condition can be fatal. Some of the effects of RFM are summarized in Box 34.4. Economically, RFM represents one of the most significant postpartum abnormalities with each case reported to have a direct cost of approximately £85, mainly due to a reduction in milk yield and/or milk sales. When the effects on subsequent poor fertility are also considered

Box 34.4. Some of the effects of retained fetal membranes.

- Reduced dry matter intake
- Withholding of milk from the food chain and possibly a lowered milk production
- Increased incidence of postpartum metritis, endometritis and pyometra
- Increased time to first service
- Reduced conception rates/increased services per conception
- Increased days open
- Longer calving interval
- Predisposition of cows to other conditions such as left-displaced abomasum and laminitis
- Mortality

the cost is estimated to be around £300 per case (Kossaibati & Esslemont, 1997).

Aetiology

The specific pathogenesis of RFM still remains uncertain due in part to our poor understanding of normal placental separation in the bovine. However in simple terms there are considered to be two main ways in which fetal membrane retention occurs:

- (1) Interference with the separation of the fetal villi from the maternal caruncles. This may be associated with the following:
 - (a) Premature calving (induced or spontaneous) without the normal maturation of the placentome involving hormonal and structural changes in preparation for separation. This maturation involves changes in the molecular structure of collagen within the placentome and alteration in binucleate cell numbers in the trophectoderm. Spontaneous premature calvings will include many twin births as well as abortions.
 - (b) Prolonged gestation may result in excessive growth of the dam's caruncles.
 - (c) Trauma with oedema of the villi, which occurs after Caesarean section, torsion of the uterus and other dystokias.
 - (d) Infectious conditions (with or without abortion) result in inflammatory changes that bind together the maternal and fetal tissue in the placentome.
 - (e) Hyperaemia of the placentomes.
 - (f) Necrosis of the villi.
- (2) Observations on uterine contractions after calving suggest that in many cases of retained fetal membranes, their frequency and amplitude are greater

than in cows that released the membranes normally. However, on some occasions retention is associated with uterine atony: for instance, after overextension of the myometrium as in cases of hydrops allantois, or prolonged labour or in hypocalcaemic cows. It is unlikely, however, that uterine atony in the absence of some disturbance of the process of caruncle/cotyledon separation would result in RFM.

In addition to the above mechanisms, nutritional problems such as vitamin E/selenium, iodine and vitamin A deficiency have been reported to be associated with an increased incidence of RFM in some herds, although individual cows are not normally considered to develop RFM due to nutritional deficiencies.

Laven and Peters (1996) have reviewed the aetiology and pathogenesis of fetal membrane retention in detail.

Treatment

Over time the natural sloughing of the maternal caruncles and uterine involution contributes to the loss of the membranes. If left untreated, freeing of the fetal villi from the maternal caruncles eventually occurs as a result of bacterial putrefaction and autolysis over several days. The toxic products of this putrefaction accumulate within the uterus, causing a fetid odour that taints the milk making it unfit for human consumption.

Moller *et al.* (1967) describe a large clinical trial in which the results of a wide variety of treatments were studied. They pointed out that cows that are ill and cows with metritis must be treated, but they concluded that the evidence did not indicate a need to treat cases of uncomplicated placental retention. In fact it appeared that any type of drug therapy for this condition tended to depress subsequent pregnancy rates, whereas cows that were not treated (that is, membranes not removed, no drug therapy administered) had pregnancy rates that were not significantly different from those achieved by cows that passed the membranes at the proper time. In cows that remain healthy, treatment may therefore not be indicated. However, in a small proportion severe metritis and toxæmia may develop, which may be fatal if left untreated.

Manual removal of fetal membranes: Veterinarians have been arguing for decades over the need for manual removal of retained fetal membranes. It should be borne in mind that although the results of many field trials tend to favour non-removal, the arguments in favour of manual removal are said to include the following:

- (1) It removes a major source of infection and putrefying protein.
- (2) It removes the unpleasant smell, which can taint the milk, and physical presence of the retained membranes.
- (3) The cow may be less likely to develop systemic illness.
- (4) The cow may be less likely to have disturbed fertility later.
- (5) The cow may be less likely to suffer from reduced milk yield.
- (6) A small number of conservatively treated cows become very ill and require life-saving treatment.

These points are not necessarily sufficient justification for manual removal of RFM, as point 2 is a benefit to the farmer rather than the cow and points 3, 4 and 5 have been contradicted by many published trials. Points 1 and 6 are true, although there is little evidence that toxæmia occurs because the placenta has not been removed. Toxæmia can occur after removal of the placenta (Peters & Laven, 1996).

Those in favour of manual removal claim that the danger of reproductive or general disease is greatly reduced with gentle handling, a willingness to stop manual removal where the attachment is firm, and the concurrent use of local or systemic antibiotics. If manual removal is to be used this should not be attempted until a minimum of 96 hours after calving and in many cases it is necessary to leave for a longer time period than this. Manipulation should be confined to gentle traction on the membranes and not involve the manual breaking down of each individual placenteome as this results in significant trauma to the endometrium.

The arguments used against manual removal of the retained fetal membranes include the following:

- (1) Just after calving the cow is ready to deal with the large amount of infected material and decomposing necrotic caruncles that are sloughed off into the uterus in the normal course of events; the need to get rid of fetal membranes as well presents no insurmountable problem to most cows.
- (2) Intrauterine manual intervention should be avoided because it interferes with the natural defence mechanism by reducing phagocytosis for several days.
- (3) Manual removal of the membranes is never complete and numerous villi and remnants of placenta are left attached.
- (4) Manual removal causes trauma and adds to the likelihood of local infection persisting.
- (5) If the cow is ill, systemic treatment is sufficient to deal with the problem and manual removal may worsen the cow's condition.

Advocates of conservative treatment may intervene only if the animal develops signs of systemic disease, in which cases the treatment is systemic administration of a broad-spectrum antibiotic. Other veterinarians simply cut off the part of the membranes that is visible to reduce the smell and only apply other treatment in those (few) cases that become systemically ill.

It would seem that current practice in the field is often at odds with research findings regarding treatment of RFM. Laven (1995) undertook a survey of the methods used by British veterinarians for treating RFM and found that manual removal was used in some cases by at least 92.5 per cent of respondents. Ecbolic agents including prostaglandin F_{2α} (or analogues of PGF_{2α}) and oxytocin were sometimes used by 84.2 per cent, with 15.7 per cent using oestradiol (no longer permitted in many countries) in an attempt to potentiate the effects of oxytocin. Most veterinarians reserved the use of antibiotics for cows that were systemically ill, but 18 per cent used them in animals with no overt illness. Only 1.6 per cent of respondents routinely left cases of RFM untreated.

At the present time it is difficult to say categorically that cows should or should not be treated by manual removal of the membranes, or which cows would benefit from manual removal rather than other medical or conservative treatment. However, it is in conditions such as RFM, where we need evidence-based medicine most, that treatment decisions of this type should be based on sound scientific and economic analysis to provide decision support rather than individual arbitrary decisions.

Ecbolic drugs: Prostaglandin F_{2α} or analogues have been administered systemically to encourage the removal of fetal membranes. Stevens *et al.* (1995) evaluated the use of an intrauterine infusion of oxytocin, subcutaneous injections of fenprostalene or a combination of both. They concluded that the interval from parturition to expulsion of the fetal membranes was unaffected by treatment, as was the frequency of subsequent displaced abomasum, ketosis and mastitis. However, Stocker and Waelchli (1993) found that the administration of PGF_{2α} after Caesarean section decreased the risk of retention of fetal membranes.

Similarly, oxytocin used up to 36 hours after calving may increase myometrial contractions and hasten expulsion of the membranes. Trial results have been variable regarding the use of oxytocin (Stevens & Dinsmore, 1997), however its administration may be of some benefit to counteract the effects of uterine relaxants used during obstetrical procedures or Caesarean sections. Oestrogen alone has also been used (but is probably contraindicated and is no longer available for use in food producing species in some countries). In

short, ecbolic drugs are unlikely to be effective after a diagnosis of RFM has been made, but they may reduce the incidence of RFM in certain groups of cows if administered very soon after the delivery of the calf.

Collagenase: Eiler and Hopkins (1993) reported using collagenase as an infusion into the umbilical artery; a dose of 200 000 iu of collagenase was dissolved in 1 litre of saline and infused between 24 and 72 hours after parturition. The technique was reported to give an 85 per cent success rate in cases of spontaneous RFM. However, no further reports of this technique have appeared in the literature and it has not been accepted and taken up widely. This author has no personal experience of this technique and feels that there is a need for further research before it could be recommended.

Intrauterine medication: Various intrauterine medications have been advocated over the years including intrauterine infusions of oxytetracycline (Stevens *et al.*, 1995). Brooks (2001) compared two different intrauterine pessaries administered after manual removal of RFM, one containing penicillin, streptomycin and formosulphathiazole and another made up of 8 per cent iodoform in a vegetable gelatine base. He was unable to detect any difference in the efficacy of the two products as determined by subsequent fertility, but did not compare the treatment groups with negative controls.

Intrauterine antimicrobial and antiseptic treatments are probably best reserved for the treatment of the sequels of RFM, including endometritis (see p. 521), rather than being seen as a treatment for RFM itself. There is even a school of thought that advocates not suppressing bacterial putrefaction of the membranes by administering local intrauterine antimicrobials as this slows the release of the membranes. Some intrauterine medications may also interfere with the local immune response within the uterus.

Other treatments: Other treatments such as intravenous calcium borogluconate, corticosteroids, multivitamins (Laven, 1995) and oral calcium chloride gel (Hernandez *et al.*, 1999) are advocated by some. However, their use is controversial and like the more established treatment options there is a lack of evidence to support their use. In some cases these treatments may actually be detrimental and thus contraindicated.

It should perhaps also be borne in mind that other treatments administered to the postpartum cow such as NSAIDs (e.g. flunixin meglumine) may even induce RFM (Waelchli *et al.*, 1999).

In summary, there is little scientific evidence to support anything other than conservative treatment of

RFM, with close monitoring of the cow so that supportive therapy can be instigated rapidly in the small number of cases that develop systemic illness. Veterinary efforts should be concentrated on preventing the high incidence of RFM at the herd level and minimizing the reproductive and economic consequences of the condition.

Prevention of retained fetal membranes

General preventive measures for postpartum disease problems including RFM are discussed at the end of this chapter (p. 526). With specific reference to RFM, attempts at prevention by routine treatment of all cows at calving are generally ineffective and impractical because of the relatively low incidence and morbidity of the condition. However, incidence of retention is increased greatly when parturition is induced with corticosteroids and there is some evidence that PGF_{2α} can be an effective therapeutic agent in such cases. Gross *et al.* (1986) used dexamethasone to induce parturition in 66 cows; they injected PGF_{2α} into 40 cows within one hour of delivery and treated 26 cows with saline (controls). The incidence of retention in the PGF_{2α}-treated cows was 8.8 per cent compared with 90.5 per cent in the controls. This approach to prevention is supported by findings that suggest that cows which subsequently develop RFM have lower levels of endogenous PGF_{2α} at the time of calving than those without RFM (Wischral *et al.*, 2001).

Effects of retained fetal membranes

The effect of retained fetal membranes on subsequent fertility depends on whether acute metritis, endometritis or pyometra develops or not. While there is argument about the best treatment at the time of retention, there is general agreement that it is important to monitor cases closely until the membranes are lost. They should also be examined again about 18–30 days after calving to identify and treat those cows that have developed endometritis or pyometra (see pp. 521, 524).

In an extensive field study with cows that retained the placenta for at least 48 hours, Leslie *et al.* (1984) reported that 14 per cent of the cows developed pyometra and 15 per cent developed chronic endometritis. In four herds in which a conservative approach to treatment was employed, metritis developed in 40 of 73 cases of retained fetal membranes (Sandals *et al.*, 1979). From a study of days to service, days to conception and services per conception these authors concluded that the condition of retained fetal membranes alone has little effect on subsequent fertility. In a large field study (Halpern *et al.*, 1985) 45 per cent and 41 per cent of

primiparous and pluriparous cows with retained fetal membranes developed metritis. In the heifers there was no significant adverse effect of retained fetal membranes on fertility. In adult cows with no subsequent metritis, retention for five or more days caused lower pregnancy rates than controls. Retention for more than seven days caused a long calving-to-service interval and low pregnancy rate. Borsberry and Dobson (1989), working in the UK, reported that RFM alone extended the calving interval by 25 days, but when it was associated with a subsequent endometritis this increased to 51 days. McDougall (2001) also reported that cows with RFM have lower pregnancy rates and take longer to conceive than unaffected herd-mates under New Zealand management systems. Rowlands and Lucey (1986) reported that the lactation yield following retained fetal membranes was 7 per cent lower than expected (Box 34.4).

Pneumovagina and urovagina

Pneumovagina may be caused by damage to the vulva during parturition or inadequate closure of an episiotomy incision. However, often there is no specific cause of pneumovagina or urovagina evident on presentation. Both conditions are often associated with a history of dystokia or delivery of a large calf; the affected cow frequently has a BCS < 2. Pneumovagina and urovagina may be unobserved until a genital tract examination or artificial insemination (AI) is performed. Occasionally, the herdsperson will observe a persistent dribble of urine from the vulva or hear air being sucked through the vulval lips.

The treatment of pneumovagina is to perform a Caslick's operation. Briefly, under epidural anaesthesia, the lips of the vulva are scarified along a 1 cm wide strip from the dorsal commissure to the level of the ischial arch, leaving 2.5–3.0 cm at the ventral commissure to permit urination. The lips of the vagina are sutured with a non-absorbable material. Concurrent vaginal and/or uterine infection is treated appropriately. Sutures are removed in 10 to 14 days and the animal artificially inseminated at the next oestrus.

There are a number of treatments for urovagina. Some cases will respond spontaneously, particularly those cases identified before 4 to 6 weeks postpartum and in animals that increase BCS. The return of ovarian cyclical activity, or possibly administration of PGF_{2α} to induce oestrus, may help resolution in some cases. The use of AI can be successful even in the presence of urovagina, in other cases. In severe or long-standing cases surgical intervention may be necessary. A caudal extension to the distal urethra can be constructed using the ventral vaginal wall or a transverse

ventral shelf of tissue can be formed cranial to the urethral orifice.

Vaginitis

Vaginitis is often associated with a more extensive infection of the genital tract. However, inflammation may also be associated with pneumovagina, urovagina or following trauma during parturition. In addition, infectious causes of vaginitis are reported especially where natural service is practised. Infectious pustular vulvovaginitis caused by bovine herpes virus-1 (BHV-1) is probably the most common. However, other potential pathogens such as *Ureaplasma diversum*, *Mycoplasma bovigenitalium*, *Haemophilus somnus* and BHV-4 have also been implicated as causes of a mild granular vulvovaginitis (Cook, 1998).

The presenting sign of vaginitis is usually tenesmus; there may also be an abnormal vaginal or vulval discharge and changes in the mucosa, varying from hyperaemia through necrosis to gangrene in rare cases. Occasionally there is a more extensive retroperitonitis and septicaemia. A mild vaginitis has little effect on subsequent fertility unless accompanied by endometritis, pneumovagina or urovagina. However, severe cases of vaginitis may cause extensive scarring leading to infertility or in some instances to dystokia at the subsequent parturition.

Treatment should be based on the severity of the lesions and correction of predisposing factors. The vagina should be gently douched with normal saline or a mild antiseptic solution, following administration of an epidural anaesthetic. The duration of activity of the epidural anaesthesia can be extended by the addition of xylazine to the anaesthetic solution (Caron & Le Blanc, 1989). Douching of the vagina may be repeated on several occasions. In addition, infection of deeper tissues should be treated using systemic antibiotics. Inflammation can be reduced and analgesia provided using NSAIDs.

Acute puerperal metritis

Microbial contamination of the uterine lumen at parturition is a normal event (Elliot *et al.*, 1968) (see p. 509), and in most cows this contamination is eliminated and does not result in severe infection. For this reason acute puerperal metritis is relatively uncommon. However, in those cases where it does occur acute inflammatory changes are seen in the endometrial, myometrial and peritoneal layers of the uterus within ten days of calving. Pathogenic bacteria produce toxins and result in the development of septicaemia, toxæmia

and possibly also pyaemia. Cows with acute puerperal metritis have a very serious life-threatening condition that requires intensive treatment.

Diagnosis

A foetid, reddish to brown discharge flows from the vulva and abdominal straining is noted. Affected cows also commonly exhibit pyrexia, tachypnoea, tachycardia, anorexia, rumen stasis and dehydration. Severe cases may have a toxæmia-induced diarrhoea and develop signs of shock including a subnormal rectal temperature. The infection may extend through the uterine wall causing a localized or generalized peritonitis. Therefore internal examination of suspected cases of acute metritis must be undertaken with extreme care. The uterus is often friable and liable to trauma, and therefore uterine exploration should be minimized in the acute stages of the condition. Vaginal or rectal exploration of cases of metritis often results in acute discomfort and may be followed by persistent straining.

It is probable that in the future the diagnosis and monitoring of response to treatment of acute infections such as metritis will be aided by the use of acute phase protein estimations going some way towards removing the need for internal examinations (Eckersall, 2000; Sheldon *et al.*, 2001).

Aetiology

The physiology of the response to normal postpartum infection suggests that there are two main factors that lead to a pathological result.

- (1) The uterus is exposed to an unusually high polymicrobial challenge that includes some of the more pathogenic organisms such as *A. pyogenes*, coliforms and anaerobes such as *F. necrophorum* and *Prevotella melaninogenicus*. In rare cases *Clostridium* spp. may cause severe disease and rapid death. The risk of postpartum intrauterine infection may be increased by:
 - (a) Dystokia with resultant trauma inside the uterus;
 - (b) The use of dirty equipment and dirty calving boxes;
 - (c) The delivery of an emphysematous calf, resulting in the uterus being heavily infected with anaerobic organisms;
 - (d) Retained fetal membranes;
 - (e) Synergistic action between infectious agents, such as *A. pyogenes* and anaerobic organisms (*F. necrophorum* and *Prevotella melaninogenicus*).

- (2) The natural defence mechanisms are less effective than normal. Factors that may cause this include the following:
 - (a) Dystokia;
 - (b) Manipulation within the uterus after calving, such as inappropriate and rough attempts to remove RFMs;
 - (c) Uterine inertia;
 - (d) Concomitant infection with immunosuppressant agents such as bovine virus diarrhoea virus.

The effect of diet before calving is unresolved; it is possible that dietary energy intakes that result in fatty infiltration of the liver, insufficient protein and micromineral deficiency may also impair uterine defence mechanisms.

Treatment and prognosis

Good nursing is vitally important. The cow should be placed in a well-bedded, comfortable warm box and encouraged to eat and drink. Systemic broad-spectrum antibiotic treatment applied in the correct dose, and maintained for a minimum of 5 days, is essential. Suitable antimicrobials include cephalosporins, potentiated amoxycillin or possibly tetracyclines. However, for good genital tract penetration postpartum oxytetracycline should be prescribed at a dose of 10 to 15 mg/kg b.i.d. This 'off-label' use is above the normal recommended dose and would require additional precautions to be taken to prevent problems with milk or meat residues. See also the section on antimicrobial treatment of endometritis (p. 522) for a fuller explanation of the efficacy of antimicrobials in the treatment of intrauterine infections.

Severely affected cows should also be treated aggressively with intravenous fluid therapy using either high volumes (20–30 litres or more) of isotonic fluid or low volumes of hypertonic fluid (3 litres of 7.2 per cent saline) to combat the effects of the toxæmia and to reduce the development of shock. Non-steroidal anti-inflammatory drugs (NSAIDs) such as flunixin meglumine are also indicated both to provide analgesia and to reduce the effects of endotoxins (see p. 1050). It might be expected that the administration of flunixin meglumine would inhibit normal uterine involution in cows with metritis, due to reduced biosynthesis of PGF_{2α}. However, at least one study suggests that the administration of flunixin meglumine to cows with metritis accelerates uterine involution and shortens the calving to first oestrus interval (Amiridis *et al.*, 2001).

If the cow is continually straining, caudal epidural anaesthesia can be used; it may be advantageous to

include xylazine in the epidural in order to prolong its duration of action (Ko *et al.*, 1989; Holden, 1998).

Any manipulation of the uterus should be avoided while the cow is systemically ill. However, after the acute phase of the disease a technique of gentle flushing and fluid withdrawal reduces the quantity of infected material in the uterus and may facilitate myometrial contractions and uterine involution. This can be done using a wide diameter smooth ended tube, such as a stomach tube attached to a funnel. The operator (taking extreme care not to traumatize the uterus) passes the tube through the cervix and pours in several litres of a flushing solution made up of warm sterile normal saline. The funnel is then lowered below the level of the uterus and the fluid along with debris from within the uterus is siphoned out. This procedure can be repeated several times to remove as much as possible of the uterine contents (Parkinson, 2001). While removal of the uterine contents in this way seems logical, and has been undertaken many times by these authors, it should be noted that controlled studies to evaluate this form of therapy are lacking. Flushing the uterus in this way also has inherent risks: the uterus may be punctured or damaged and irrigation fluid may flow in a retrograde direction up the oviducts, resulting in salpingitis and adhesions of the ovarian bursae.

Many clinicians introduce antibiotics into the uterus once the cow has responded to parenteral treatment, but the points discussed regarding the use of intrauterine antibiotics for the treatment of endometritis (see p. 522) should be borne in mind.

With acute metritis the prognosis refers to the possibility of death, adverse effect on health, milk yield and future reproductive function. Most cases make a fairly slow recovery as regards body condition, milk yield and return to cyclicity and pregnancy. In the worst affected cases, if the cow survives the acute metritis episode treatment can be considered a reasonable success.

Consequences of metritis

A small proportion of metritis cases develop embolic pneumonia, polyarthritis or endocarditis (see p. 726) as a consequence of a bacteraemia or laminitis following the toxæmia. In those cases that do respond to treatment, after recovery there may be adhesions affecting the uterus, the oviducts and ovarian bursae, resulting in reduced fertility. The majority of cases of acute metritis will also progress to endometritis.

In a meta-analysis of papers published since 1960, metritis was shown to be associated with a seven-day increase in time to first service and a 20 per cent reduction in conception rate to first service, resulting in a delay to conception of 19 days (Fourichon *et al.*, 2000).

Endometritis

Introduction

Endometritis is defined histologically as an inflammation of the endometrium. However, it is normally characterized clinically by the presence of a mucopurulent vaginal discharge, 21 days or more after calving, and associated with delayed uterine involution. The incidence of endometritis is about 10 per cent in dairy cattle, although the incidence in beef herds is less clear. However, there is wide variation in the incidence of endometritis between herds, ranging from a few cases to more than 40 per cent of the herd affected. Endometritis causes considerable subfertility and infertility. The presence of uterine bacterial contamination disrupts the delicate hormonal milieu of the hypothalamic–pituitary–ovarian axis (see p. 489; Chapter 67) and disrupts follicular growth and development. Uterine infection has been reported to be associated with an increased incidence of cystic ovarian disease. Furthermore, the presence and persistence of pathogenic organisms causing endometritis is assumed to preclude the establishment of pregnancy. Thus, endometritis has a detrimental effect on fertility, extending the calving to conception interval, and increasing the number of services per conception and the proportion of culls for failure to conceive.

The economic cost of endometritis depends on the detrimental effect on fertility, increased culling rate and, to a lesser extent, the cost of treatment. The estimated direct cost of a case of vulval discharge was £71 for treatment and a 300 litre reduction in milk yield (Kossaibati & Esslemont, 1997). However, the total cost was £160, including an increased calving interval of 18 days and an increase of 0.3 services per conception.

Aetiology

It is assumed that the uterus and its contents are sterile during a normal pregnancy and prior to parturition. Then at the time of parturition or just afterwards the uterine lumen becomes contaminated by micro-organisms from the animal's environment, skin and faeces, through the relaxed perineum, vulva and dilated cervix.

There are a variety of predisposing factors for endometritis (Box 34.5). Cows with a uterine infection associated with *A. pyogenes* more than 21 days post-partum develop a severe endometritis and are almost invariably subfertile to the first service. In addition, there is synergism between *A. pyogenes*, *F. necrophorum* and *Prevotella melaninogenicus*, causing more severe cases of endometritis. Interference with uterine defence mechanisms such as uterine involution or neutrophil function will delay the elimination of bacterial contamination. Dystokia, the delivery of twins or a

Box 34.5. Predisposing factors for endometritis.

- Stillbirths
- Induced parturition
- Dirty calving environment
- Postpartum ovarian inactivity
- Diet—possibly vitamin E/selenium deficiency

dead calf and assistance at calving increase the opportunity for faecal contamination of the genital tract. Retained fetal membranes are a predisposing factor for endometritis and are associated with an increase in severity of endometritis (Sheldon & Noakes, 1998).

Uterine infection has a seasonal incidence, being highest during the housed period, presumably because of environmental contamination. A dirty calving environment may increase the risk of endometritis. Noakes *et al.* (1991) described two hygienically contrasting farms: on one with a relatively clean environment the incidence of endometritis was 2–3 per cent, compared with an incidence of 15 per cent for one with a dirty environment. However, there was no difference in the quantitative or qualitative uterine bacterial flora in cows calved on either farm.

A delay in the return of cyclical ovarian activity after calving appears to predispose to endometritis. Conversely, if the interval from calving to first ovulation is too short, it has been suggested that pyometra could occur because *A. pyogenes* and Gram-negative anaerobic bacteria would remain within the uterus after ovulation, allowing bacterial growth to continue following corpus luteum formation (Olson *et al.*, 1984).

Diagnosis and assessment

Clinically, endometritis is characterized by the presence of a mucopurulent discharge in the vagina, associated with delayed uterine involution. The definitive diagnosis of endometritis would be made based on histological examination of endometrial biopsies. However, under field conditions, examination of the vagina and palpation of the genital tract *per rectum* are the most useful techniques for the diagnosis of endometritis. Visual or manual examination of the vagina for an abnormal uterine discharge is essential for the diagnosis of endometritis, although the contents of the vagina do not always reflect the contents of the uterus. Flakes of pus in the vagina could come from the uterus, cervix or vagina and slightly cloudy mucus is often regarded as normal. A number of scoring systems have been used

to assess the degree of uterine and cervical involution, and the nature of the vaginal discharge. The majority of systems use a combination of uterine horn and cervical diameter and a score for the contents of the vagina (Fig. 34.4) (Sheldon & Noakes, 1998).

Treatment

The treatment of endometritis has caused considerable debate and has been reviewed extensively in the literature (Bretzlaff, 1987; Sheldon, 1999). The value of treatment of clinical cases has not been accepted by all clinicians, despite evidence that cows administered a placebo, rather than an accepted therapy, had longer intervals from calving to conception and higher culling rates (Steffan *et al.*, 1984). Treatment success rates are higher for mild cases of endometritis compared with severe cases and the success rate is reduced if the vaginal discharge has a foetid odour.

The three treatments most often used are parenteral PGF_{2α} or analogues (see p. 524), oestrogen (see p. 523) and intrauterine antibiotic. There are a limited number of products licensed for endometritis; in addition, a nil milk withholding period is usually demanded in dairy cattle.

Antimicrobial treatment: A number of antimicrobial selection criteria have been suggested for endometritis including efficacy against the causal organism in the uterine environment, but without inhibiting natural uterine defence mechanisms. Fluid and tissue debris reduce the effect of sulphonamides, aminoglycosides and nitrofurazones, and aminoglycosides are ineffective in an anaerobic environment, such as the uterine lumen. The chosen antibiotic must reach appropriate concentrations at the site of infection and persist a sufficient length of time to eliminate the infection. At less than 30 days postpartum, mixed bacterial infections may render intrauterine infusion of penicillin ineffective, due to penicillinase produced by bacteria. In contrast, oxytetracycline and cephalosporins are broad spectrum, and are effective in the uterine lumen in the presence of pus and reduced oxygen tension. In addition, pharmaceutical preparations of oxytetracycline and cephalosporins produce effective antimicrobial concentrations in the endometrium, but with minimal concentrations in milk. Any milk withdrawal period would make a treatment for endometritis unattractive under practice conditions; for example, parenteral tylosin gave effective concentrations in genital tract tissues and the uterine lumen, but has a significant milk withdrawal period (Cester *et al.*, 1993). Metronidazole and chloramphenicol are prohibited in food producing animals in the UK. The use of the intrauterine route of administration has prevailed for many years and the pharma-

| Clinical sign | | | | Point score |
|---|-----------|---------------|---------------|-------------|
| Vaginal discharge | Smell | Foul | | 3 |

ceutical industry continues to develop antibiotic products administered by this route, despite the widespread use of systemic antibiotics for treatment of other bacterial infections in cattle.

Hormones: The hormonal treatment of endometritis is based upon observations that the genital tract is more susceptible to infection when under progesterone dominance and more resistant under the influence of oestrogens (Rowson *et al.*, 1953).

Oestrogens: Rowson *et al.* (1953) demonstrated that the bovine uterus was more resistant to infection with

A. pyogenes when either endogenous or exogenous oestrogen was present compared to during dioestrus, and suggested that exogenous oestrogen may be used therapeutically. Despite the potential of oestrogens for the treatment of endometritis, results have been equivocal and vary with the pharmaceutical preparation and dose administered. The treatment-to-conception interval was longer for cases of endometritis treated with a single intramuscular injection of 3 mg oestradiol benzoate per 500 kg body weight, compared with those treated using prostaglandin or intrauterine oxytetracycline (Sheldon & Noakes, 1998). Furthermore, regula-

tory authorities have prohibited the use of oestrogens in several countries.

Prostaglandins: The parenteral application of PGF_{2α}, or its analogues, has been used widely for the treatment of endometritis. The majority of authors report that the presence of an active corpus luteum is required for optimal results when using prostaglandin to treat endometritis, which supports the hypothesis that the subsequent induced oestrus increases the uterine resistance to bacteria (Jackson, 1977; Sheldon & Noakes, 1998). Conversely, Pepper and Dobson (1987) reported that the efficacy of prostaglandin therapy for endometritis did not depend on the presence of an active CL, as determined by measuring milk progesterone concentrations. An alternative hypothesis for the mechanism of action of prostaglandin as a treatment for endometritis is a direct myometrial effect, with physical expulsion of uterine detritus.

A number of clinical trials have studied the possibility of using the direct myometrial effect of prostaglandin therapy, to reduce the incidence of endometritis and improve subsequent fertility. A routine injection of prostaglandin shortened the calving-to-conception interval in normal cows compared with control animals (Etherington *et al.*, 1988). However, a number of subsequent trials gave conflicting results. Meta-analysis of 24 trials where PGF_{2α} was administered to cattle within 40 days of calving reported no beneficial effect on first-service pregnancy rate, although there was a small reduction in days open for treated cows (Burton & Lean, 1995).

Other treatments: A variety of antiseptics have been administered by intrauterine infusion for the treatment of endometritis including solutions of Lugol's iodine, polyvinyl pyrrolidine iodine, povidone-iodine, chlorhexidine and metakresol sulphonic acid. Many of these solutions cause a necrotic endometritis within 24 hours of infusion that may stimulate release of PGF_{2α} in addition to possible direct effects on pathogenic organisms. However, despite clinical resolution of the endometritis using antiseptic solutions, the effect on fertility may not be beneficial. Nakao *et al.* (1988) administered a 2 per cent polyvinyl pyrrolidine iodine intrauterine infusion and reported that treated cows, particularly those with a purulent discharge, had an increased calving-to-conception interval compared with controls. In addition, some of these antiseptic products are not licensed for use in food producing animals.

Pyometra

Pyometra is associated with the accumulation of pus in the uterus and by the persistence of functional luteal tissue on one or both ovaries. Affected cows do not

appear ill; however, they are anoestrus and may be presented to the veterinarian as 'not-seen-bulling' or for pregnancy diagnosis.

Pyometra may be a sequel to the conditions discussed earlier in this chapter and therefore those factors that predispose a cow to RFM, metritis and endometritis can also be considered to predispose to pyometra. In addition pyometra may also be seen in cows after service (either natural or by AI).

In most cases pyometra is a sequel to chronic endometritis as the uterus ceases to release the endogenous luteolysin PGF_{2α}. Research has shown that the persistence of the CL in cows with pyometra is not due to an insufficiency in the synthesis of uterine PGF_{2α} but is associated with inadequate secretion of luteal oxytocin (Vighio *et al.*, 1991). The result is that the dioestrus CL persists and the genital tract remains under the influence of progesterone. The infection is thus not eliminated and the cervix remains closed, resulting in the accumulation of large quantities of purulent exudate in the uterine lumen. Occasionally there will be slight leakage through the cervix, resulting in a small amount of pus accumulating in the anterior vagina and an intermittent purulent vaginal discharge. In a small number of cases the persistent luteal tissue is a progesterone secreting (luteal) cyst rather than a persistent CL. In some instances the introduction of infection during dioestrus, such as occurs when a cow is artificially inseminated at an incorrect time, results in pyometra. Pyometra may also occur secondary to the death of a fetus, either caused by, or followed by, bacterial invasion by *A. pyogenes* and persistence of the CL of pregnancy. Infection with *Tritrichomonas fetus* also causes embryonic death and pyometra formation (Bon-Durant, 1997).

When examined *per rectum*, cases of pyometra have enlarged uterine horns and must be accurately differentiated from a normal pregnancy before treatment can be administered. There are a number of distinguishing points:

- The uterus feels 'doughy' and the uterine wall is thicker than during pregnancy.
- It is not possible to palpate the amniotic vesicle or 'slip' the allantochorion membranes.
- Placentomes are not palpable or visible on ultrasound examination, although the caruncles of the previous pregnancy are occasionally detected.
- Ultrasonography will demonstrate the absence of a fetus and the presence of pus rather than normal fetal fluids.

The best and most appropriate treatment of pyometra is to bring about luteolysis with PGF_{2α} or PGF_{2α} analogues. However, this treatment should never be administered if there is any suspicion that the cow

may be pregnant, as it will cause abortion in early pregnancy.

The administration of PGF_{2α} to cases of pyometra usually results in dilation of the cervix and expulsion of the purulent uterine contents, with oestrus occurring three to five days later. There is evidence to suggest that treatment of pyometra is improved by the administration of two doses of PGF_{2α} 8 hours apart (Archbald *et al.*, 1993). This is probably due to the fact that a single dose of exogenous PGF_{2α} has only a very short duration of action, as the inadequate release of ovarian oxytocin from the CL in these cases is insufficient to maintain the normal positive feedback loop that brings about luteolysis by the release of further endogenous PGF_{2α}.

Many cases of pyometra go on to become pregnant, despite having a prolonged first luteal phase and a prolonged calving to pregnancy interval of 125 days compared to 74.8 days (Etherington *et al.*, 1991). However, longstanding cases are associated with endometrial degeneration, which may increase the rate of late embryonic and early fetal losses. Comparison between pregnancy rates at first pregnancy diagnosis 33 to 70 days postservice and a subsequent diagnosis 120 to 150 days postservice have shown that attrition rates are 2.6 times higher in cows with previous pyometra than in cows without the condition (López-Gatius *et al.*, 1996).

Postpartum anoestrus

Introduction

Postpartum anoestrus is a greater problem for beef cattle than dairy cows, and it is often evident in specific herds.

Aetiology

The two main predisposing factors are inadequate nutrition, specifically energy deficiency, and suckling or the maternal bond. Other associated factors are that it is more common during late winter, in the absence of a bull and following dystokia. Rarely, anoestrus may be associated with pituitary or ovarian damage.

Negative energy balance (NEB) is common to most postpartum cows and is the difference between the dietary intake of metabolizable energy and the expenditure for maintenance and lactation (see p. 103). Consequentially, the balance between milk yield and feeding (including diet composition, feed supply and appetite) is an important determinant of the severity of NEB. However, in first lactation an animal's metabolizable energy may also have to contribute to continued growth. The effect of NEB is most easily identified by monitoring body condition score (BCS). Cows that lose

>1.0 BCS points during the first 30 days after calving take longer to the first postpartum ovulation than those losing less than one unit (Beam & Butler, 1999). However, monitoring BCS over periods greater than 6 weeks postpartum often has a less clear association with the length of the anoestrus period. The pituitary secretion of FSH appears to be insensitive to NEB. Thus, successive waves of follicular growth start within 10 days of calving. However, in the anoestrus cows, dominant follicles fail to ovulate because of inadequate LH pulse frequency. Insulin-like growth factor-1 (IGF-1) is a likely hormonal mediator between nutrition and fertility. However, the precise mechanisms and how they may be modulated are not yet clear. Shortening the postpartum interval to the NEB nadir is a more tangible management objective to reduce the incidence of anoestrus in a herd.

The suckling calf inhibits the release of GnRH from the dam's hypothalamus, so suppressing LH pulse frequency. However, this inhibitory influence occurs as a consequence of the maternal bond between cow and calf, and it is not dependent upon sensory innervation of the udder (Williams & Griffith, 1995). The frequency and duration of suckling by a single calf are unrelated to the period of anoestrus, although suckling following adoption of an additional calf will delay the return of ovarian cyclicity. If the single calf is removed from its dam there is a corresponding increase in the frequency of LH pulses within two to six days. The inhibition of GnRH release is dependent on the cow being suckled by her 'own' calf, which she identifies by sight and smell. The mechanisms underlying this effect are unclear; in part, they may involve increased opioid tone within the brain.

Diagnosis

At least two examinations, 10–14 days apart, are required to make a clinical diagnosis of anoestrus. Both ovaries are small and there is no CL detectable at either of the examinations; however, follicles up to 18mm diameter may be identified. An alternative or additional method of diagnosis is to use milk progesterone analysis; two low values, at 10–14-day intervals, is indicative of anoestrus.

Treatment

The most important consideration when presented with an anoestrus animal is to correct the underlying causes, in particular dietary deficiencies. The quantity and quality of feed supplied to the animal in relation to its milk yield should be determined. In addition, dry-cow management should be examined, paying particular attention to the transitional period. Monitoring BCS

during the dry period and early lactation will help to quantify the severity of dietary energy deficiency. Two groups of pharmaceutical products may be used to treat anoestrus: GnRH and analogues, and progestagens.

GnRH: The pituitary LH content and responsiveness to GnRH are complete by day 10 postpartum and so exogenous GnRH administered to the anoestrus cow will induce a transient LH and FSH release. However, the response to treatment depends on the stage of ovarian follicular wave. If there is a dominant follicle present, ovulation will occur. So, when daily ultrasound monitoring was used to identify a suitable dominant follicle, administration of GnRH consistently induced ovulation (Roche *et al.*, 1992). However, the majority of animals did not express oestrous and had short luteal phases after ovulation. Gonadotrophin releasing hormone administered in the absence of a dominant follicle is ineffective, so overall blind-treatment success rates are variable.

Progesterone: Administration of progesterone, using an intravaginal device or norgestomet by injection and implantation, is an alternative treatment for the anoestrus cow. In the absence of severe NEB, once the progesterone treatment is removed, there is an induced ovulation and such treatment overcomes the absence of behavioural oestrous that often occurs at the first post-partum ovulation. However, if the NEB is severe, progesterone treatment requires supplementation with 400–700iu equine chorionic gonadotrophin (eCG) by intramuscular injection at the time of implant removal. An alternative to eCG is the administration of 1mg oestradiol benzoate 24 hours after a seven-day progesterone treatment which increased oestrus expression and ovulation (MacMillan *et al.*, 1995).

Cystic ovarian disease

Cystic ovarian disease can be a major problem in the postpartum dairy cow resulting in an increase of 6 to 11 days to first service and an increase in the calving-to-conception interval of 20–30 days (Fourichon *et al.*, 2000). However, this subject is dealt with elsewhere in this book in Chapters 35 and 36.

Prevention of postpartum disease problems

The key to controlling postpartum disease problems is to recognize that they are interlinked (Peeler *et al.*, 1994) and that their control is related to breeding management, nutrition, the management of the transition cow and management at and immediately after calving.

Control of these conditions is not simply a matter of good management at the time of calving.

Breeding decisions and the management of the pregnant and periparturient cow

The most important way of reducing puerperal problems is to avoid dystokia. Where dystokia does occur it is essential that it is dealt with correctly at an early stage and that any developing problems observed after calving are also treated as soon as possible. Attention to all aspects of hygiene is also a basic requirement.

If it were purely a veterinary matter it would be relatively simple to reduce the incidence of dystokia in the majority of herds. However, the measures required may not be acceptable to the farmer. Simple modifications such as improved supervision of calving and better housing may be judged to be too expensive. Selecting an easy calving breed of bull or individual bull within a breed may not produce calves with the desired conformation or genetic potential.

The consequences of several synergistic adverse effects tend to be particularly serious. Therefore, if a client chooses to use a bull that is liable to produce a high rate of dystokia it is particularly important to avoid any other factor that predisposes to dystokia.

Application of the following precautions will reduce the incidence of dystokia in a herd.

- (1) Selection of sires that produce calves of suitable size and conformation for the dams concerned. This refers to the breed and to the individual bull within the breed. Special care is needed for heifers (see Chapter 5).
- (2) Induction of premature calving, if the fetus is likely to be too large at full term for a normal calving (see p. 687).
- (3) Control of energy intake and avoidance of macromineral and trace element imbalances.
 - (a) Do not let the dams get too fat, as the perirectal and perivaginal fat will narrow the birth canal, the dam may be less capable of forceful labour and the calf may also be larger. This is also an important way of avoiding necrotic vaginitis and other damage to the vagina. At calving a condition score of 2.5 (see p. 10) is advised.
 - (b) Avoid undernutrition as cows in very poor condition also have problems of dystokia.
 - (c) Regular body condition scoring and careful attention to the late lactation, dry period and particularly the transition period ration are required. This may be aided by the use of

- metabolic profiles (see Chapter 47). Specific dietary manipulations such as the use of salts to manipulate the dietary cation–anion balance (DCAB) of the transition cow ration may also be useful in reducing the incidence of periparturient problems (see p. 787).
- (4) Provision of a suitable environment, especially for cows that calve inside or in a restricted area. This should be clean, well bedded, with a good water supply, properly lit and with enough space to get at the cow if need be and to allow observation without disturbance. There also need to be facilities to safely restrain the cow.
 - (5) Avoid stress and disturbance of the calving cow (Hindson, 1976).
 - (6) Suitable supervision and timely intervention at calving will reduce the severity of those cases of dystokia that do occur (Hodge *et al.*, 1982).
 - (7) Proper training of the farmer and stockworkers in how to assist at calving should be supplied by the veterinarian.
 - (8) When veterinary assistance is needed, the farmer and his staff must decide at an early stage to call for help. It is important that the veterinarian and the farmer should agree before the start of the calving season how these problems will be dealt with and at what stage the farmer will call for professional help.

Therapy immediately postpartum

In addition to specific therapies such as those described above for uterine prolapse, cows that have had obstetrical interventions at calving may benefit from a course of systemic antibiotic.

Metabolic diseases, such as milk fever, should be dealt with appropriately and if these cases are common, investigation into their causes is essential. This aspect of bovine medicine is dealt with elsewhere in this book (Chapter 46).

The routine administration of agents such as PGF_{2α} (see p. 524) and oxytocin (see p. 517) to postpartum cows is not justified by improvements in subsequent fertility; reports of the benefits in the published literature are inconsistent. Their use postpartum should therefore be restricted to animals where a specific indication exists, as described earlier in this chapter.

Conclusions

The key to good fertility in multiparous cattle is to maintain a high level of stockmanship at all times, and to manage cattle in such a way as to minimize postpar-

tum problems. The preparation of cattle for breeding begins well before the expected service date. Preparing the cow for parturition and particularly dry cow and transition cow management in the previous gestation period are crucial stages in this preparation. However, parturition is the key event, and it must be managed to minimize the development of abnormalities of the genital tract in the postpartum period, which may lead to problems of subsequent oestrous cyclicity, depression in conception rates, increased embryonic loss and subfertility.

Chapter 35

Problems Associated with Oestrous Cyclicity

H. Boyd, D.C. Barrett and M. Mihm

| | |
|----------------------------|-----|
| Manifestation | 530 |
| Aetiology | 532 |
| Diagnosis | 535 |
| Treatment | 541 |
| Prognosis | 542 |
| Long interservice interval | 544 |
| Prevention | 544 |

Manifestation

Normal oestrous cycles, clear oestrous expression and efficient and accurate detection of oestrus with a predictable interval to ovulation are still essential for the successful management of reproduction in cattle. Failure to observe oestrus or lack of oestrus adversely affects the efficiency of production and profitability by interfering with the reproductive markers shown in Box 35.1 (see also Chapter 41 (b) page 678). Inaccurate oestrous detection, i.e. identification of a cow as being in oestrus when she is not, leads to cows being inseminated when fertilization is not possible because there is no ovulation at the expected time after insemination, and to pregnancies being lost when already pregnant cows are inseminated using artificial insemination (AI).

Missed heats that result in longer than planned intervals from calving to first service cause considerable economic loss. A missed oestrus will cause a delay of about 21 days until the next chance for service and this loss in milk production time and delay in producing a calf results in a loss of income. Assessment of the real loss (litres of milk/year; calves/100 cows per year) and the economic loss is complex. Where possible, herd-specific economic estimates should be undertaken to determine the cost–benefit of alterations in the various elements of herd fertility (Dijkhuizen *et al.*, 1997). However, in herds with a conventional breeding strategy it may be useful to consider a rule-of-thumb value to estimate losses occasioned with every day the calving interval is extended beyond the target of 365 days. A figure that has remained remarkably constant over the last decade (to 2002) is £2.50 to £3.00/day for every day over the planned calving interval. In beef suckler cows, delay in achieving preg-

nancy causing very prolonged calving seasons results in a similar loss; this is partly due to management problems, such as loss of the seasonal calving pattern, but also because at weaning the calf is younger and therefore weighs less. The marketing advantage of being able to sell uniform batches of calves may also be lost if the calving season is extended much beyond nine weeks.

Clients may present individual cases of cows that have not been seen in oestrus when due or overdue for service, but mostly the problem is seen on regular fertility visits when post service anoestrus is also detected in animals diagnosed not pregnant. It is important to differentiate as far as possible those cows that have not been in oestrus from those that have simply not been seen in oestrus either because of poor expression of heat or poor oestrous observation. This may require an assessment to be made of the efficiency of oestrous detection in the herd and careful examination of ‘anoestrus’ cows on more than one occasion. Regular milk progesterone assays may also be useful when attempting to determine whether an individual cow is undergoing oestrous cyclicity or is truly anoestrus. Suckler cows running with the bull may be presented as failure to conceive towards the end of the breeding season. The problem of abnormal oestrous cyclicity, which is most serious when it occurs on a herd or group basis, is often picked up retrospectively on herd record analysis.

Heifers

Delayed puberty may affect targets for breeding age or date. It occurs mainly as a group problem because heifers are handled and fed in groups and the cause of anoestrus is nearly always related to the environment or to the management, particularly feeding (Webb *et al.*, 1997). Occasionally, anoestrus is manifested in a group of heifers after natural service, which the farmer erroneously thought was successful because of lack of returns to service.

Cows after calving

An extended interval between calving and first service, calculated on a herd basis, is the most important

Box 35.1 Aspects of reproduction affected by failure to observe, or lack of, oestrus.

| | |
|---|--|
| Heifers | |
| Age at first calving | |
| Season of first calving | |
| Cows | |
| Interval from calving to first service (and thus calving to conception) | |
| Timely observation of returns to service | |

Table 35.1 Percentage of cows with various calving-to-first-service intervals in days, based on 1595 cows in 15 herds.

| | Calving-to-first-service interval (days) | | | |
|-----------------------|--|-----------------|-------|------|
| | 0–55 | Target 56–77 | 78–99 | >100 |
| Percentage of cows | 15.9 | 32.2 | 24.7 | 27.1 |
| Cumulative percentage | 15.9 | 48.1 | 72.8 | 99.9 |

manifestation of dysfunction of cyclicity and oestrus or oestrous detection. A farmer with a serious problem may not be aware of it because of poor records or good ones that are not used properly. In the example given in Table 35.1, in 15 herds that were not in fertility control programmes, the target for calving interval was 12 months and to achieve this target, cows should have had their first services 56–76 days after calving. The distribution of days from calving to first service for the 1595 cows served in these herds shows that about half of the cows were first served after the target date (Boyd & Munro, 1980). Recent data from the National Milk Records (NMR) representing approximately 1 million dairy cows shows that between January 1997 and September 2000 the mean calving to first service interval rose from 84 to 88 days (Barrett, 2001), therefore the majority of cows are probably now served after the target 56–76-day window (assuming a target calving index of 365 days). However, the voluntary waiting period, i.e. the number of days postpartum waited until first service, may be deliberately increased in high-yielding cows, where the decision is taken to extend their lactation for economic and welfare reasons (Knight & Sorensen, 1998). On the best farm illustrated in Table 35.1, 67 per cent of the cows were served within 77 days of calving and on the worst farm only 21 per cent of cows reached that target.

The situation in this group of herds is quite typical of the results obtained in many surveys carried out in

different countries and demonstrates the seriousness of the problem. Within herds the incidence of the problem is quite variable at different times and there may be periods of four to six weeks during the year when a high proportion of cows appear to stop cycling or exhibit poor oestrous signs. This may be a direct seasonal effect in certain climates, but in temperate regions is probably largely a nutritional effect (Butler, 1999).

The number of cows treated by veterinarians for anoestrus and suboestrus was reported to be low in the 1980s. Saloniemi *et al.* (1986) gave the incidence as 5.2 per cent of cows, falling from first calvers (6.3 per cent) to older cows (3.7 per cent). Markusfeld (1987) diagnosed inactive ovaries after two rectal examinations in 8.5 per cent of 7751 lactations. However, more recently 20 per cent of high-yielding cows have been shown to exhibit a delayed interval to first ovulation postpartum based on progesterone profiles (Opsomer *et al.*, 1996).

Another manifestation of absence of oestrus is the cow that starts cycling and then stops, a situation recorded in 5.2 per cent of cases in a survey based on progesterone assays by Bulman and Lamming (1978). In a similar study (Kassa *et al.*, 1986), cyclicity started and then stopped in four (3.2 per cent) of 125 lactations. Once again this situation seems to have worsened over time; in a recent Dutch study, true return to anoestrus was seen in only 3 per cent of high-yielding cows, however, 20 per cent of cows showed a prolonged first luteal phase of more than 20 days based on their progesterone profiles (Opsomer *et al.*, 1996). Royal *et al.* (2000) have shown an increase in the proportion of animals with one or more atypical ovarian hormone patterns from 32 per cent of cows in the period 1975–82 to 44 per cent in the period 1995–98. During the same period pregnancy rate to first service declined from 55.6 per cent to 39.7 per cent, again suggesting that fertility in dairy cattle has declined over time.

Cows after service

Analysis of data from approximately 35 000 cows in 255 British herds (Warren, 1984) showed that 26 per cent of interservice intervals were greater than 48 days, i.e. more than two cycles (Table 35.2). These results are similar to the results obtained in other surveys. For example, in the 15 herds discussed above (Table 35.1), 25 per cent of the returns to service were after a delay greater than 48 days and in Boyd and Reed's (1961) study in smaller herds at a time when management was less intensive, 23 per cent of returns were greater than 48 days.

In Warren's (1984) report the average interservice interval was 39 days, possibly due to a delay in the return to service of 39–21 days = 18 days. In some other surveys there were rather fewer very long intervals,

Table 35.2 Percentage of cows with various intervals between services in days
(Warren, 1984)

| | Interservice interval (days) | | | | | |
|--------------------|------------------------------|-------|-------|-------|-------|-----|
| | 1–17 | 18–24 | 25–35 | 36–48 | 49–90 | 91+ |
| Percentage of cows | 6 | 37 | 13 | 18 | 18 | 8 |

possibly due to different culling patterns or more efficient heat detection. In New Zealand, Moller *et al.* (1986) reported that only 8.6 per cent of return-to-service intervals were greater than 36 days. Nowadays in New Zealand and other locations where dairy farming is highly seasonal, repeats are often resynchronized which increases the submission rates for the first and second repeat cycles of the breeding season.

While survey data do not explain why a cow has not been served, discussion with farmers makes it clear that in the majority of cases the reason is that the cow has not been seen in heat. In conclusion, failure to have cows served because they have not been seen in season is a widespread and important problem.

Aetiology

The aetiology of anoestrus in the cow and heifer is complex because as presented to the veterinarian it includes several different conditions, as shown in Box 35.2. Because there is a wide range of types of anoestrus there is also a wide range of causes, some unknown. Moreover, a variety of management and environmental factors contribute to poor oestrous detection rates.

Physiological anoestrus

It is important to bear in mind that during certain phases of the reproductive cycle, the absence of oestrus is physiological. These phases are prior to puberty, during pregnancy and for at least two weeks after calving. It is not uncommon for a cow that is pregnant to be presented to the veterinarian as a case of anoestrus. This occurs if there is unknown access to a bull, or unrecorded insemination or misidentification of the cow inseminated.

In dairy cows, from which the calves are removed a day or so after birth, ovulation rarely occurs earlier than 15 days after calving; in general first postpartum ovulation occurs 17–21 days after calving in medium-yielding dairy cows calving in appropriate body condition and experiencing no major loss in body condition subsequently (Savio *et al.*, 1990). This postpartum interval to

Box 35.2 Aetiology of anoestrus.

- Physiological anoestrus: prepuberty, pregnancy, puerperium
- True anoestrus: no oestrous cycle and no ovulation or blocked cycle (prolonged luteal phase, such as with pyometra)
- Silent oestrus: better termed silent ovulation, i.e. ovarian cycles occur but no oestrous behaviour is detected
- Weak oestrus: poor oestrous expression (reduced length or intensity)
- Unobserved oestrus: oestrus normal, human error

first ovulation may be prolonged to 60 days in high-yielding cows (Opsomer *et al.*, 1996). In cows that are suckling, usually beef cows, the duration of non-cyclicity may be extended from 25 to beyond 100 days, depending on body condition score at calving and post-partum nutrition (Stagg *et al.*, 1995). The effect of suckling of one or more calves is to inhibit the return to cyclicity via neurohormonal routes, which can be modified by nutritional factors. This is demonstrated by the observation that some well-fed, well-managed beef suckler herds achieve a tight calving pattern at the same time each year, which requires an early return to cyclicity while the cows are still suckling their calves. For a list of factors that affect the onset of puberty, see Chapter 5.

True anoestrus

The major causes of true anoestrus characterized by lack of ovulation are summarized in Box 35.3.

- (1) In heifers, bilateral gonadal aplasia, which causes permanent anoestrus and sterility, occurs in the common condition of freemartinism, found in the majority of female calves that are cotwins with males. It is also observed in bilateral ovarian hypoplasia, a rare inherited condition, in which the genes are passed on through fertile individuals with unilateral gonadal hypoplasia. Poor nutrition is important and discussed below.

Box 35.3 Major causes of true anoestrus.**Heifers**

- Freemartinism
- Ovarian hypoplasia
- Inactive ovaries (poor nutrition)

Cows

- Dystokia and postpartum problems
- Delayed involution (inactive ovaries)
- Pyometra (persistent corpus luteum)
- Cystic ovarian disease
- Poor nutrition prepartum, severe energy deficit postpartum, especially first calvers
- Age-related factors

(2) In cows a variety of abnormalities at or around calving, such as dystokia, retained fetal membranes, hypocalcaemia, metritis, endometritis and other postpartum abnormalities may result in delayed return to cyclicity (for a full discussion of this see also Chapter 34).

(3) Ovarian cysts, traditionally defined as fluid-filled structures >25 mm in diameter and present for more than 10 days in the absence of a corpus luteum (CL), are quite commonly recorded in cases of anoestrus and in fact the majority of cows with cystic ovarian disease exhibit anoestrus. This traditional definition implied that cysts were static structures; however, this is now known not to be the case, and cysts should be considered dynamic both in structure and function (Cook *et al.*, 1990). The likely hormonal mechanism of cystic ovarian disease is failure of the preovulatory luteinizing hormone (LH) surge. In some cases there may be failure of the ovary to respond to LH at the start of oestrus (Brown *et al.*, 1986). Cystic ovarian disease is a very complex condition and in many cases the cyst produces a mixture of steroids, which are variably absorbed into the general circulation.

In the postpartum period, particularly during the first six weeks, some cows (approximately 20–25 per cent) experience ovulation failure followed by the development of palpable but functionally transient cystic structures that may not interfere with subsequent cyclicity. Towards the end of this period many farmers become concerned about lack of oestrus and so the cow is presented for veterinary examination. Cystic ovaries were associated with 6 to 11 more days to first service and with 20 to 30 more days to conception in a meta-analysis of papers published between January 1987 and January 1999 (Fourichon *et al.*, 2000). By about six weeks after calving an ovarian cystic structure should be regarded as pathological. Cysts are often classified as either follicular (about 70 per cent; single large cyst or multiple smaller cystic structures) or luteal and it is

easy to understand why the cow with the luteal cyst, which is predominantly progesterone producing, does not exhibit oestrus, though it is less clear why she fails to cycle. However, follicular cysts with oestrogen production are also found in cases of anoestrus. This may be due to the low level of the steroid produced in some cases, while in other cases it may result from the negative effect on the behavioural centre of high levels of oestrogen circulating more or less continuously. Another explanation for the lack of oestrus in cows with follicular cysts is that the behavioural centres in the brain, which control the expression of oestrus, respond better to oestrogens if they have been primed by progesterone.

Garverick (1997) in the USA and Dobson *et al.* (2001a) in the UK have both reviewed cystic ovarian disease. Factors associated with the occurrence of cystic ovarian disease are discussed further in Chapter 36.

(4) The role of nutritional deficiencies in anoestrus is relatively straightforward in heifers but is complex in adult dairy cows.

(a) In heifers it has been shown in many field trials that low energy intake that causes slow growth rate is associated with delayed puberty. Onset of puberty tends to be related to body weight rather than age. The mechanism is discussed in Chapter 5.

(b) In adult lactating dairy cows it is not clear how feeding affects return to cyclicity after calving, even when only energy is considered; however, evidence is growing to suggest that the effect may, at least in part, be mediated by insulin-like growth factor-1 (IGF-1) levels (Taylor *et al.*, 2001). It is clear that dairy cows experience a metabolic crisis early postpartum, as energy loss cannot be compensated for by energy intake and stored energy is utilized. Factors that exacerbate the negative energy balance including the feeding levels before and after calving, particularly the energy density of the ration, excessive energy loss due to high milk yield and increased body condition loss after calving (body condition score loss of more than 0.5) will prolong the interval to first ovulation, as will associated metabolic or other diseases postpartum. A clear relationship has been shown between the timing of the negative energy balance nadir (the lowest point of the negative energy balance postpartum) and the interval to first ovulation, the LH pulse frequency and the LH-dependent fate of the first dominant follicle selected postpartum (Canfield & Butler, 1990; Beam & Butler, 1997). First ovulation occurs 7–14 days after the energy balance nadir; thus, if the lowest point of the negative energy balance is reached between the first to second week postpartum, cows can be expected to ovulate by 21–30 days postpartum. However, in cows in

which body condition score loss exceeds 1, the interval to first ovulation may be prolonged to 60 days and beyond. One method to try to take into account these many interacting factors is regularly to measure the body condition score of cows (Anon, 1984); particularly important times include drying off, calving and service times.

(c) In the beef suckler cow, prepartum nutritional deficits leading to reduced body condition at calving delay the interval to first ovulation by more than 40 days to 90 days and beyond (Stagg *et al.*, 1995, 1998). The delay in resumption of ovulatory activity is associated with continued atresia of recurrently selected dominant follicles; instead of ovulation of the 2nd to 4th dominant follicle postpartum, it is on average the 9th dominant follicle which eventually secretes sufficient oestradiol to induce the gonadotrophin surge and ovulation. As circulatory concentrations of FSH are not affected by pre- or postpartum diet, the detrimental effects of low body condition score at calving on the fate of dominant follicles selected early postpartum are attributed to reduced LH secretion, which reduces dominant follicle oestradiol production.

The relationship between nutrition and fertility is a complex one which is still not fully understood. There is a vast body of literature on this subject which is too extensive to review here. However, the reader may find the following reviews of interest: Britt (1995); Webb *et al.* (1997, 1999); Wathes *et al.* (1998); O'Callaghan and Boland (1999); Garnsworthy and Webb (2000) and O'Callaghan *et al.* (2000).

Several studies have shown that cows in their first lactation exhibit a disproportionately high incidence of true anoestrus, with lack of ovulation. A variety of explanations for this have been put forward, in particular the inhibitory effects of lactation and growth on the recovery of the LH pulse frequency early postpartum, preventing dominant follicle maturation and ovulation. Another suggestion is that this is mainly the result of the high incidence of dystokia that occurs in first calvers.

However, the high incidence of anoestrus in first calvers is often attributed to nutritional and environmental factors. Excessive weight loss and very poor body condition result in cessation of ovulation and cyclicity, presumably through hypothalamic–pituitary dysfunction (see Chapter 67). Cows continue to grow until their second or third lactation and therefore young animals have to carry out the tasks of milk production, growth and reproduction simultaneously, at a time when adult dentition has not been fully developed. In dairy cows it is also the time when the young, smaller cow is introduced to the highly competitive environment of a herd, which, particularly during the housing period, makes it difficult for small animals to compete

for food. It is also presumably a stressful experience being low within the herd hierarchy.

(d) In many cases first calvers may exhibit a high incidence of lameness. Lameness (see Chapters 31 and 32) is a cause of weight loss that can result in true anoestrus and also, because of the associated pain, can cause poor oestrous expression in animals that are cycling. Various other forms of stress such as surgery, changes in social grouping, transport and heat stress may all affect fertility, thus stress on breeding cattle should be minimized whenever possible (Dobson *et al.*, 2001b).

(5) Among miscellaneous causes of persistent corpus luteum is the rare condition of uterus unicornis, in which one horn of the uterus is absent. Ovulation on the side without a uterine horn results in a corpus luteum that is not exposed to locally produced prostaglandin and therefore does not regress after 16 or 17 days.

Silent ovulation and unobserved oestrus

First ovulation postpartum is generally silent (80 per cent), but once cycles have been established, silent oestrus is not a common phenomenon, as was clearly demonstrated by Williamson *et al.* (1972), who carried out continuous observation of 107 cows for 21 days and concluded that four demonstrated silent oestrus. This has been confirmed by others in field trials in herds in which silent oestrus was thought to be a problem. Generally, when oestrous detection methods are improved, there is a corresponding reduction in the number of cases regarded as silent oestrus. Many cases previously diagnosed as silent oestrus are in fact unobserved oestrus.

Incidence figures for silent ovulation are most reliable when based on serial progesterone assays, as in the study of 1400 cows by Ball and Jackson (1984) in which 21 per cent of the cows had ovulated but had not been seen in oestrus. This level of non-detected oestrus is in agreement with other studies. McLeod *et al.* (1991) reported 78 per cent of ovulations in their study were correctly identified by conventional oestrous detection, confirming that approximately 20 per cent of those cows ovulating are not seen in oestrus.

To what extent delayed return to service is due to unobserved oestrus is not clear, but Humbolt (1982), using milk progesterone assays, calculated that only 29 per cent of delayed returns were due to embryonic death and that 73 per cent were due to anoestrus (including true, silent and unobserved oestrus).

However, ovulation without the accompanying signs of oestrus (that is, silent oestrus) does occur. The best documented situation relates to the first ovulation after

Box 35.4 Causes of silent and weakly expressed oestrus.

calving, particularly if it occurs within the first 20 days. Otherwise it is almost impossible to distinguish between silent and unobserved oestrus. Some instances of oestrus are so weak or last for such a short time that detection by conventional observation is a matter of chance.

Standing oestrus lasts for about 8–12 hours in cows and 6–8 hours in maiden heifers. However, 20 per cent of heats last less than 6 hours (Esslemont *et al.*, 1985). Increasing herd sizes and decreasing availability of skilled manpower on many farms is probably exacerbating the problem of poor oestrous detection. It may also be the case that high-genetic-merit, high-yielding modern dairy cattle exhibit oestrous behaviour either less intensely or for a shorter duration, making oestrous detection more difficult.

The causes of silent oestrus, weak oestrus and short oestrus are not well understood, but those considered to be the main factors are presented in Box 35.4.

(1) Social factors within the group of cows, the size of the group and the reproductive status of the rest of the group all play a role in oestrous behaviour and in the frequency of mounting (Britt, 1987). Mounting requires that there is both a cow in oestrus and a cow that is willing to mount.

Cows that are usually bullied or are low in the pecking order are less likely to stand to be ridden when they are in oestrus than more dominant cows. A small group of cows, say fewer than four or five, may be less effective at stimulating mounting behaviour than a larger group of sexually active cows. Cows at different stages of the reproductive cycle vary in their likelihood of trying to mount a cow in oestrus. The most likely to jump are those in or near oestrus, followed by non-pregnant cows in the early luteal phase followed by pregnant cows. At the end of an intensive breeding season when most cows are pregnant the remaining cows to be served may be more difficult to detect because of the absence of cows willing to mount. In the main, oestrous detection is therefore easier in tight seasonally calving herds, where a large number of cows are eligible for service within a given time period, than in a herd with a wide calving spread and fewer non-pregnant cows in the herd at any one time.

The presence of a bull inhibits cow-to-cow interaction, but this may be made up for by the bull's own

sexual monitoring of the herd. However, a bull may not choose to serve all cows in oestrus if several are in season at the same time.

(2) Pain and fear. As oestrus is a behavioural phenomenon that is subject to psychological influences, it can be inhibited by discomfort, pain or fear. Severe adverse weather conditions such as driving rain and cold reduce cows' interest in sexual behaviour. Slippery flooring produces fear of falling and may inhibit oestrous behaviour. The pain caused by lameness inhibits oestrous expression.

(3) Weight loss. It has been suggested that weight loss is associated with an increase in silent heats.

(4) Genetic factors are almost certainly involved. The subjective nature of the measurement of oestrous expression makes it difficult to gather enough reliable data to evaluate the hereditary influence. Reports from progeny testing stations, where large groups of daughters from bulls under test were kept, showed that different daughter groups exhibited oestrus in characteristic ways. There may also be differences between breeds in expression of oestrus. Currently, there is much anecdotal evidence to suggest that the modern high-genetic-merit Holstein exhibits oestrus less well than the traditional British Friesian, or some other dairy breeds.

(5) Presence of calf and suckling. The presence of a suckling calf may reduce expression of oestrous behaviour in some cows as well as affect oestrous cyclicity.

Epidemiological data

In a study of 70 775 lactations in Finnish Ayrshire cows in which only cases treated by veterinarians were analysed (Saloniemi *et al.*, 1986) it was noted that the chance of a cow being presented to the veterinarian as anoestrus was affected by parity (highest risk in first calvers), calving season (highest risk in cows that calved from September to February), herd milk yield (highest incidence in high-yielding herds) and the occurrence of metritis (Chapter 34), mastitis (Chapter 23) and ketosis (Chapter 46).

Diagnosis

A systematic approach to diagnosis is essential and the clinician should follow the steps outlined in Box 35.5.

If the anoestrous cow is in a herd in which the veterinarian is running a fertility control programme involving regular visits, diagnosis will be both easier and more reliable because there will be historical informa-

Box 35.5 The diagnosis of anoestrus.

- History (including records)
- General clinical examination (including condition score)
- Special examination of the reproductive system
- Rectal palpation and transrectal ultrasound examination
- Vaginal specular examination
- Laboratory tests, e.g. progesterone assays

**Fig. 35.1** Cyclic CL with lacunae on right ovary.

tion available and it will be simpler to introduce routine sampling where this is indicated.

There are two separate but overlapping aspects of diagnosis:

- *Stage 1:* assessment of ovarian status to determine whether the case is true anoestrus, in which there is no ovulatory activity, or in which cyclicity is prevented by a persistent corpus luteum or other progesterone producing structure; or silent or unobserved oestrus, in which ovarian cycles are taking place.
- *Stage 2:* assessment of the causes of the condition.

Stage 1: assessment of ovarian status

Since the word 'cycle' implies repetition, theory would dictate that assessment of whether or not a cow is cycling necessitates repeated examinations over an interval that should allow the observation of two oestrous periods. Under practical conditions it is usually assumed that the animal is cycling if it is possible to prove that ovulation has recently taken place. Another common assumption concerns a group of animals. It is usually considered that the group as a whole is cycling if two-thirds of the cows are in the luteal phase, i.e. the same fraction of the oestrous cycle that the luteal phase occupies. Furthermore, the description of the 'luteal phase' given in Chapter 33 presents some difficulties in connection with diagnosis. This is because a corpus luteum is unlikely to be palpable until approximately seven days after oestrus, but

**Fig. 35.2** Cyclic solid CL.**Fig. 35.3** Dominant follicle on right ovary bordering the CL.**Fig. 35.4** Two corpora lutea in a 6-week pregnancy.

may be functional before that time. However, positive detection of a functional corpus luteum via ultrasound examination (size and echogenicity, Figs 35.1–35.4) is usually closely related to its progesterone secretion. Progesterone assay of milk or plasma will only produce a definite, recognizable rise after a similar delay; to confirm cyclicity a sequence of progesterone assays two or three days apart showing a pattern consistent with a luteal phase followed by a period of low progesterone level and another luteal phase should be seen.

Accordingly, for clinical purposes 'luteal phase' is defined as from day 5 to day 17 and the normal 'period

Box 35.6 History taking for anoestrus cows.

- Are there other cows in the herd with similar problems?

of low progesterone' is expected to be from day 18 through oestrus (day 0) to day 4. This definition applies to the majority of cows in a normal population and is needed to form a basis for rational diagnosis, but its use should be tempered by the realization that no definition will fit all cases (Bloomfield *et al.*, 1986).

The first step is to take a history of the case. Relevant information, required for both stages of diagnosis, is shown in Box 35.6.

The next step is to find out if there is functional luteal tissue present in the ovaries. The traditional way to do this is to palpate the ovaries per rectum, but there are now several choices. One is to carry out a single or a series of milk progesterone assays, which gives a quick, reliable result. Another is ultrasound scanning, which allows the user to observe functional luteal tissue in the ovary (Figs 35.1–35.4) (Omran *et al.*, 1988; Boyd & Omran 1991).

The choice of method will depend on circumstances as each method has advantages and disadvantages. Rectal palpation is immediate, simple, requires little restraint of the cow and, if part of a regular visit, is relatively cheap. It also allows other observations to be made on other parts of the reproductive tract and on the animal's general condition. There is minimal risk of misidentification of the animal, a danger always present when samples are taken for analysis. On the other hand, it is a less accurate indicator of luteal function than a progesterone assay. Real-time ultrasound scanning is a valuable tool that, in experienced hands, is capable of giving a very accurate picture of ovaries and uterus (Figs 35.1–35.13).

Rectal palpation alone, when undertaken by an experienced clinician, can be relatively accurate. For example, Dawson (1975) compared the findings made by rectal palpation shortly before slaughter with post-mortem observations. He identified accurately 125 (89 per cent) of 141 ovaries with corpora lutea. The errors were mainly in cows with small corpora lutea and also some with cysts or follicles. However, others have suggested that rectal examinations alone are less accurate. On the basis of milk progesterone assays (which were assumed to be correct) Ott *et al.* (1986) summarized their own and other workers' results, as shown in Table 35.3.

Table 35.3 The accuracy of corpora lutea detection by rectal palpation based on comparison with milk progesterone assay.

The use of progesterone assays has the advantage that they can be incorporated into a fertility control programme and used prior to a visit, so that the clinician has information available before the examination of the animal. They can also be used after the visit to give extra information about the case. There may be slight problems in deciding the level of circulating progesterone that can be taken as indicative of luteal function and caution needs to be exercised in interpretation of absolute values, as these may change depending on time from milking (Waldmann *et al.*, 1999).

The accuracy of ultrasound scanning was investigated by Pieterse *et al.* (1990), who examined the ovaries of 59 cows by rectal palpation, ultrasound scanning (5MHz linear array transducer) and dissection on the day of slaughter, and concluded that for the detection of a mid-cycle corpus luteum the sensitivity of rectal palpation was 83 per cent and for ultrasonography the sensitivity was 80 per cent. For the detection of follicles, ultrasonography was considered to be significantly better than rectal palpation, with ultrasonography detecting 95 per cent of follicles over 10mm in

diameter whereas rectal palpation only detected 71 per cent. These results obviously reflect in part the quality of the ultrasound equipment used and the skill of the clinician palpating the ovaries and interpreting the ultrasound images. In another study comparing the use of ultrasound and rectal palpation (Fishwick, 1993), the accuracy of palpation and ultrasonography in detection of luteal tissue was compared to contemporaneous plasma progesterone concentrations. In this study the overall accuracy of manual palpation was 62 per cent compared with 83 per cent for ultrasound examination. In cows with high progesterone status, manual palpation (60 per cent) was significantly less accurate than ultrasound imaging (94 per cent), whilst in cows with a low progesterone status manual palpation (65 per cent) and ultrasound imaging (70 per cent) were both equally accurate.

In general it would be expected that imaging of the ovaries using modern ultrasound equipment, for example using a 7.5MHz transducer, would be more accurate than manual palpation. However, individuals highly skilled in rectal palpation may be able to detect luteal tissue with an accuracy comparable to ultrasound, but will not be able to palpate small follicles that are readily detected by ultrasound scanning. Reduced cost of equipment and improved image quality combined with practice and much increased use within veterinary medicine have made transrectal real-time ultrasound examination of the bovine reproductive organs the examination of choice in regular fertility visits.

If there is evidence of functional luteal tissue, the possibilities shown in Box 35.7 exist.

The simplest way to decide whether the animal is pregnant or has a pathological condition is to carry out rectal palpation or ultrasound examination of the ovaries and genital tract, plus in some cases a vaginal examination. This will, however, fail to reveal very early pregnancy before 25–28 days after service using ultrasound and below 35–40 days using manual palpation. Figures 35.10 to 35.12 show examples of ultrasound images of early pregnancy. Figure 35.13 shows an image of fetal sexing in a three-month-old fetus. The most common finding is that ovaries and uterus appear to be normal and these cases are usually regarded as normal cycling cows that have simply not been seen in oestrus.

Box 35.7. Likely reasons for the presence of functional luteal tissue.

- Cycling (days 5–17 inclusive)
- Pregnancy
- Ovarian pathology (luteal cyst)
- Uterine pathology (pyometra with persisting corpus luteum)

Box 35.8 Likely reasons for no luteal tissue being present.

- True anoestrus
- Cycling (day 18 through oestrus to day 4)
- Ovarian pathology
 - Freemartin: heifer
 - Cystic ovarian disease

Booth (1988) has investigated the accuracy of diagnosis of luteal cysts using rectal palpation, and the clinical finding of luteal cysts was confirmed by progesterone assay in only 54 per cent of cases. This accuracy can be improved by transrectal ultrasound scanning. For example, Douthwaite and Dobson (2000) reported that diagnostic criteria for follicular cysts using ultrasound examination and plasma progesterone assays agreed in 92 per cent of cases; a similar comparison for luteal cyst diagnosis gave a 74 per cent agreement. The rapid on-farm diagnostic method of choice should thus be transrectal ultrasonography, supported by milk progesterone assay where required.

If initial examination shows there is no functional luteal tissue, there are also the various possibilities shown in Box 35.8.

When the initial examination reveals no luteal function and apparently normal ovaries and tract, and no evidence of mucus or mucohaemorrhagic discharge on the tail to indicate recent oestrus or ovulation, the cow's ovarian status is unresolved. If she is cycling normally and in the low progesterone phase of the cycle, a corpus luteum will become palpable and visible by ultrasound examination in the ovary within approximately 7 days from the first examination. A second examination at 7–10 days after the first will detect this corpus luteum. This second examination must not be delayed too long, as some cows (those at day 5) will go into the low progesterone phase again in about 12 days after the first examination. These calculations can be upset by the considerable variations in cycle lengths and progesterone patterns that occur in a normal population of cows, as detailed by Bloomfield *et al.* (1986). It is also very useful to carry out a vaginal examination at the time of the first examination, as the presence of copious, clear mucus is strongly indicative of the peri-oestral stage of the cycle. In this way vaginal examination may allow a diagnosis to be made without the need for a second progesterone assay or a second rectal palpation.

If a second examination or sampling is required it is best done 7–10 days after the first. It is even better if serial sampling for progesterone assays can be arranged. It is necessary to work out a satisfactory regimen of sampling. This involves making a compromise between the biological ideal, which might be daily

samples, and what is acceptable to the farmer because of the cost, labour and interference with the milking routine. For example, a sampling regimen of two to three samples per week, which will give a useful picture of the oestrous cycle but is not frequent enough to time oestrus exactly, may be unacceptably frequent for a farmer. This situation may change in future if accurate and reliable automated systems to assess the cows' physiological state using biosensors can be developed (Koelsch *et al.*, 1994; Mottram, 1997; Scully *et al.*, 2000). New developments in this area of technology may allow automatic milk progesterone assays, and other assays, to be performed while cows are being milked, allowing the timing of ovulation to be accurately predicted and removing the need for oestrous detection.

Detection of antral follicles in the ovary, the observation of uterine tone and assays for oestrogens are all of limited value because they do not give clear indication of exact timing of oestrus to predict ovulation. There are a number of aids to detection of oestrus that can aid diagnosis (Boyd, 1984).

The veterinarian now knows whether the cow or group of cows is exhibiting true anoestrus or is undergoing ovarian cycles. If a conclusion of anoestrus has been reached an important question is whether (i) the cow is in 'deep' anoestrus, which means that she is not likely to start cycling soon and may revert to an anoestrus state following treatment, or (ii) whether she is in 'shallow' anoestrus and liable to begin cycling soon and be responsive to therapy. Unfortunately, it is almost impossible to predict accurately the 'depth' of anoestrus. However, if the cow is in extremely poor condition and if she has small hard ovaries she is probably in deep anoestrus and may require a combination of treatments to induce first ovulation, with the possibility of subsequently reverting to an anoestrus state.

Detection of the LH pulses that occur in the cow about to start cycling and are absent in those in deep anoestrus requires a series of samples taken at short intervals. At present (2003) LH assays cannot be done in a practice laboratory but are routinely carried out in affiliated research laboratories.

Stage 2: assessment of the cause of anoestrus or silent ovulation

This section deals with the difficult question of how to find out what has caused the abnormal ovarian status or the problem of oestrous expression or detection.

To some extent procedures followed for diagnosis of ovarian status also give the clinician an understanding of the causes of the ovarian dysfunction. Examples of these are listed in Box 35.9. Three of the causes of inactive ovaries: nutritional deficiency causing metabolic stress and severe negative energy balance, delayed

Box 35.9 Causes of dysfunction of the ovarian cycle.

- Freemartinism (congenital)
- Ovarian hypoplasia (inherited)
- Uterus unicornis (congenital)
- Pyometra (periparturient problems)
- Some cases of inactive ovaries
- Nutritional and metabolic stress
- Systemic disease
- Delayed involution

involution and concomitant disease, present some problems in diagnosis.

In cases of delayed involution, the enlarged uterus and particularly the enlarged cervix, which involutes more slowly, usually make the diagnosis of the immediate cause easy. However, on some occasions, by the time the cow is examined the uterus may well have returned to normal size and the veterinarian will have to depend on a history of periparturient problems and possibly of abnormal vaginal discharges noted by the farmer (see Chapter 34 page 523 for details of an involution scoring system).

The clinician should look for any other disease condition in the cow examined for anoestrus. Especially important is any disease that causes loss of body condition or pain.

There is a complicated series of factors, such as actual and potential milk yield, feeding before and after calving and weight change after calving, which are very difficult to assess. Body condition of the cow should be noted at the time of examination for anoestrus, but this deals with only part of the problem (Anon., 1984). If body condition is poor or loss of body condition score has been extreme, or if there are many cases of inactive ovaries, feeding should be investigated. Feeding analysis and metabolic profiles are discussed elsewhere in this book (see Chapters 9 and 47).

On occasion there is no clear reason for the occurrence of inactive ovaries, either in the individual cow or when the condition affects a group of animals.

When investigating silent oestrus and unobserved oestrus, the veterinarian should find out about the following:

- Organization of oestrous detection.
- Ease of cow identification.
- Method of recording.
- Layout of the buildings.
- State of the floors and levels of lighting.
- The way the cows are handled, moved around and assigned to groups.
- Amount of knowledge of oestrus and the oestrous cycle among the people who are detecting oestrus.
- Motivation for oestrous detection.

- Time made available for oestrous detection.
- Personalities of the people involved.

Treatment (see also Chapter 42)

When using proprietary products, the clinician should consult the data sheets, produced by the manufacturers, for details of use, contraindications and other guidance. Successful treatment, leading to oestrus, service and pregnancy, depends not only on veterinary therapy but on husbandry and breeding management, some aspects of which are described in the data sheets and also on page 525. Different manufacturers of apparently similar products often give slightly different advice about their use and users should be aware of the major differences between some of these products. Some of the therapeutics, for example Prostaglandin F_{2α} (PGF_{2α}) are dangerous for humans and could cause return to service and abortion in cows, and therefore the veterinarian must handle them responsibly and with care.

Where drugs that result in oestrus are used, efficiency of oestrous detection will be enhanced as the clients are told to concentrate on a specific time for oestrous detection; their attention is focused on the cows treated and aids to oestrous detection such as tail paint are often used.

True anoestrus: no functional luteal tissue

Two points should be remembered when dealing with these cases:

- All healthy, suitably fed cows will start cycling in the first two months after calving.
- There must be an underlying reason for the occurrence of this type of true anoestrus and an attempt should always be made to find the cause and deal with it. Where the cause appears to be nutritional, improved feeding should be part of the treatment of the affected individual and should also be considered for other recently calved cows. Consideration should also be given to the body condition changes and feeding regimen of the dry cows as well as the management and nutrition of the transition cow. Particular care should be taken to ensure that high-genetic-merit dairy cows do not become too fat during the dry period (Rukkwamsuk *et al.*, 1999).

At present there are two main hormonal treatments for inactive ovaries: (i) administration of gonadotrophin-releasing hormone (GnRH) or analogues with GnRH activity and (ii) insertion of a progesterone-releasing device (see p. 681).

Administration of an adequate dose of GnRH results, in the majority of cases, in luteinization or ovulation of healthy dominant follicles present at the time followed by a transient period of progesterone production that can first be identified about five days after treatment. The duration of this progesterone phase is very variable, ranging from one or two days to the life-span of a normal cyclic corpus luteum, and therefore the interval from treatment to oestrus is very variable, about 8–22 days. It is desirable to follow up these cases to ensure that luteinization or ovulation has taken place; this is best done by ultrasound scanning or by progesterone assay.

If there is luteal tissue present at the follow-up examination 7 days later, it is useful to treat the animal with PGF_{2α} or an analogue, as this will make the resulting oestrus more predictable. Regular fertility control visits at weekly intervals are ideal for this regimen; however, visits are often at fortnightly intervals and this may be a less suitable period between the initial and follow-up treatment when using the GnRH–PGF_{2α} regimen.

If, on the follow-up examination, there is no luteal tissue the cow should be dealt with as a new case.

The use of a progesterone or synthetic progestagen slow release device also mimics the progesterone rise before first ovulation. This device is left in the vagina or implanted subcutaneously at the base of the ear for 8–12 days and the animal should be served at the oestrus that occurs in many cases about two or three days after withdrawal. Fixed-time insemination 48 and 72 hours (or a single insemination at 56 hours) after withdrawal may be carried out (follow data sheet recommendations for whichever product is selected). If oestrus is observed later another insemination should be carried out. Avoid stress and drastic change of diet during and after treatment (see p. 683).

In those animals in which increased negative energy balance, poor body condition or very strong behavioural effects inhibit LH pulse frequency and thus dominant follicle maturation, final differentiation of the preovulatory dominant follicle or the preovulatory oestradiol rise may have to be enhanced. The addition of equine chorionic gonadotrophin (eCG) given at the end of the progesterone or synthetic progestagen treatment will induce oestrus 48 hours later. Similarly, treatment with a very low dose of oestradiol benzoate 24 hours after device withdrawal will induce oestrus 12–20 hours later, but consideration will have to be given to the national legislation relating to the use of these drugs in dairy or beef cattle.

The treatment of follicular cysts involves either using intravaginal progesterone releasing devices (PRID or CIDR) or establishment of endogenous luteal tissue with chorionic gonadotrophin or GnRH (Dobson *et al.*, 2001a). There is evidence to suggest that the success of

treatment of follicular cysts depends on whether the cyst is producing oestradiol or not, as reflected by the presence or absence of other follicles >5 mm in diameter. Treated with either an intravaginal progesterone releasing device or GnRH, cystic follicles in the presence of other follicles had a pregnancy rate to all inseminations of 91 per cent compared with 69 per cent if no other follicles were present at the time of treatment (Tebble *et al.*, 2001).

True anoestrus: functional luteal tissue

The therapeutic approach is to cause luteolysis by parenteral administration of PGF_{2α}, or an analogue, followed by intensive oestrous detection up to one week after injection and insemination at observed oestrus. In the case of pyometra (Fig. 35.9), the client should be advised to delay service until it appears that the infection has cleared up, as indicated by an oestrus at which the mucus from the vulva is free of pus. It is advisable that the veterinary surgeon should examine these cases at a follow-up visit to ensure the uterus has returned to normal (Figs 35.7 and 35.8).

The treatment of cystic ovarian disease depends largely on whether the structure is progesterone producing or not. If considered a luteal cyst with functional luteal tissue, as judged by ultrasound examination or milk progesterone assay, the logical treatment is to administer PGF_{2α}, although alternative therapies such as the use of intravaginal progesterone releasing devices may also be successful (Douthwaite & Dobson, 2000).

Silent oestrus/unobserved oestrus: corpus luteum present

There are two standard approaches in these cases, the choice being between (i) the induction of luteolysis using PGF_{2α} or an analogue and (ii) leaving the animal untreated to be observed when she comes in heat. The method chosen will depend on many variable factors, such as the season, the time since calving, the herd calving pattern and the inclination of the client, and therefore the decision has to be made individually for each case.

Treatment with PGF_{2α} or an analogue should, in the majority of adult cows, result in oestrus in 2 to 7 days, with the peak period being days 3 and 4 after treatment. Service should be at observed oestrus and aids to oestrous detection should be used. Enhanced oestrous expression may be observed when combining a progesterone or synthetic progestagen device with PGF_{2α}.

Cows that are not seen in oestrus after treatment should be re-examined after 14 days (Young, 1989)

with a view to treating with PGF_{2α} or an analogue, if appropriate.

Conservative treatment is preferred in the first instance by some clients who would rather leave the animal untreated, are content to know that she is cycling and hope to observe the next oestrus. In these cases aids to heat detection should be used and the animal re-examined if she is not seen in season within the next two weeks.

Silent oestrus/unobserved oestrus: no corpus luteum present

These cases do not benefit from immediate drug therapy as animals are showing ovarian cycles but have either just regressed their CL or are in the early luteal stage following ovulation. Improvements in husbandry, i.e. oestrous detection, and, possibly, feeding may be required to enhance detection and oestrous expression, and it may be useful to enhance oestrous expression hormonally by using eCG or oestradiol benzoate following treatment with a progestagen device (see above).

Because diagnosis is uncertain until the second examination (7 or 14 days later), it is questionable whether these cows should be treated at the first visit. If there is no corpus luteum on the second examination, the condition is to be regarded as true anoestrus and dealt with accordingly.

Prognosis

In considering prognosis, primary attention has to be paid to the return to cyclicity, which can be measured either by observation of oestrus or, more reliably, by one or more progesterone assays at planned times after treatment. The outcome of treatment is influenced by both the veterinarian and the client (and perhaps also by the cow), as presented in Box 35.10.

Factors influenced by the veterinarian, which affect the outcome of treatment for anoestrus, are as follows:

Box 35.10 Contribution of farmer and veterinary surgeon to influencing prognosis.

Prognosis influenced by veterinarian

- Accuracy of diagnosis
- Selection of cases
- Choice of therapeutic intervention
- Follow-up examination

Prognosis influenced by farmer

- Oestrous detection
- Herd pregnancy rate
- Culling rate

- The accuracy of diagnosis is the basis for correct treatment. There is good evidence that identification of a corpus luteum by palpation by experienced veterinarians is over 80 per cent accurate (see p. 537) and that differentiation between follicular and luteal cysts is much less accurate (see p. 539); however, such a diagnosis can now be more specific due to the routine use of ultrasound scanning, and can be enhanced via using milk progesterone assays.
- Selection of cases for treatment has an important influence on the outcome. For example, the corpus luteum early in the cycle is less responsive to PGF_{2α} or an analogue than is the mid-cycle corpus luteum. Accurate assessment of the stage of the cycle will aid in the correct selection of animals for treatment. Similarly, if treatment is confined to cases in which corpora lutea are positively diagnosed, better results may be obtained than if less critical selection of cases is undertaken. However, when PGF_{2α} treatments based on the presence of a corpus luteum were compared with 14-day fixed treatments, the fixed treatments were still superior resulting in better reproductive performance (Heuwieser *et al.*, 1997).

Other factors that influence the success of luteolysis and whether the cow comes in season after successful luteolysis are not well documented. However, it is possible that nutritional factors are involved in the subsequent expression of oestrus.

- None of the luteolytic products commercially available achieve 100 per cent luteolysis (Ball & Jackson, 1984; Martinez & Thibier, 1984).
- Re-examination and retreatment in good time of all cases that do not respond to the initial treatment will affect the time from initial treatment to oestrus, service and conception.

The farmer also affects the outcome of the treatment in important ways.

- The efficiency of detection of oestrus in the herd is crucial to the effectiveness of treatment when measured by the number of cases that come into season within a certain number of days.
- The first-service pregnancy rate in the herd which is to some extent under the control of the farmer, not least because correctly timed insemination is essential for conception, will have a great effect on the success rate as measured in time to conception.
- High culling rate and willingness to cull may result in apparently good results because the failures are culled, but depending on the economic factors pertaining at the time this may be a false economy (Esslemont & Kossaibati, 1997; Whitaker *et al.*, 2000).

Heifers

Freemartins and cases of bilateral ovarian hypoplasia are sterile and will never cycle or become pregnant.

Groups of heifers with delayed puberty due to low energy intake will return to cyclicity after restoration of a suitable energy intake level and other correction of the feeding. How long this will take depends on many things. Under the best possible circumstances, i.e. where the animals are in not excessively poor condition and where there is no complicating disease factor, it will take approximately two months of good feeding before most of the group start cycling (Imakawa *et al.*, 1986). Hormonal treatments to induce and thus advance first ovulation can be used if the management system is seasonally restricted; introduction of a bull may also aid in the induction and synchronization of first ovulation.

True anoestrus after calving in cows

In cases of pyometra with a corpus luteum, the failure to cycle is very effectively dealt with by using PGF_{2α}. Ott and Gustafsson (1981) reported that more than 80 per cent of treated cows emptied the uterus and came in season a few days after treatment. If one treatment fails to produce luteolysis, then a second injection almost certainly will be successful. There is evidence to suggest that treatment of pyometra is improved by the administration of two doses of PGF_{2α}, 8 hours apart (Archbald *et al.*, 1993) (see p. 524).

Inactive ovaries are treated with either GnRH to cause ovulation and thus a progesterone rise, which then primes the animal to express heat at the next ovulation, or a progesterone or progestagen releasing device. Some indications of the results that can be obtained were shown in a field study involving 62 acyclic cows (Ball & Lamming, 1983). There were two main differences between the two methods. Firstly, ovarian response to the progesterone intravaginal releasing device (PRID) was better, as 89.7 per cent of cows ovulated compared to 73.9 per cent of those treated with GnRH. Secondly, after the PRID, fixed-time insemination resulted in 59 per cent conceptions (measured by milk progesterone) whereas after GnRH, a number of cows that responded successfully were not seen in heat so that only 26 per cent of the cows treated became pregnant at the ovulation after treatment. One problem with GnRH treatment is that the luteal tissue produced has a very variable lifespan with the result that the timing of heat and the next ovulation cannot be predicted and may occur from 8 to about 20 days after treatment. In order to cause more predictable onset of oestrus and next ovulation following GnRH treatment, a luteolytic dose of PGF_{2α} can be given 6–7

days after GnRH. Such a protocol can be further combined with a second injection of GnRH or an injection of human chorionic gonadotrophin (hCG) 48 hours after PGF_{2α} to time the next ovulation in all animals and use fixed-time insemination (De Rensis & Peters, 1999). Occasionally, cows will come into oestrus quickly after GnRH treatment and this may be due to treating an animal that was just about to start cycling spontaneously.

In all reports on treatment of inactive ovaries there are some animals that do not respond to conventional treatment. It is obvious that cows that are still under the influence of the original aetiological factors (such as poor condition) are unlikely to respond well. Similarly, cows in deep anoestrus may not respond satisfactorily to hormonal treatment. It appears that those cows with inactive ovaries, lacking any detectable structures, respond poorly to treatment and may revert to an anoestrous state.

In considering the outcome of treatment of cows with cystic ovarian disease associated with anoestrus there are a number of relevant points to note:

- With the important exception of cases seen within six weeks of calving, spontaneous resolution of these cases is not to be relied upon (Garcia & Larsson, 1982).
- The condition tends to recur unless treatment results in ovulation of a healthy new dominant follicle and conception occurs.
- To the extent that there is a familial predisposition to cystic ovarian disease, the use of offspring from affected dams for breeding purposes is not advisable.
- Results have to be looked at in two stages. The first stage is the resolution of the cystic condition and the induction of normal oestrus and ovulation. The second is getting the affected cow pregnant.

Where diagnosis is correct and appropriate treatment is given the return to ovarian normality is good. The majority of luteal cysts respond to PGF_{2α} or an analogue; in one study (Booth, 1988) 79 per cent of cows had low levels of circulating progesterone within 7 days. In the same field trial, 73 per cent of cases with follicular cysts that were treated with GnRH or hCG plus progesterone had functional luteal tissue by 14 days after treatment.

The pregnancy rate achieved again depends very much on the ability of the farm staff to detect oestrus and have the cow served at the correct time. This, plus the difficulty in accurate diagnosis of the type of cyst present, means that on many farms an unacceptably high percentage of cows with cystic ovarian disease are eventually culled.

Silent and unobserved oestrus after calving in cows

Prognosis for unobserved oestrus is good and pregnancy rate is not greatly different from that for cycling cows in the same herd that have been observed in oestrus. Seguin (1981) compiled results from six trials in which 886 cows were treated; 67 per cent were in oestrus after treatment and pregnancy rate to service at that oestrus was 54 per cent. Seguin (1981) also cited trials in which controls and treated cows had the same pregnancy rate, whereas O'Farrell and Hartigan (1984) obtained a statistically significantly poorer pregnancy rate in the suboestrus cows treated with an analogue of PGF_{2α} than in controls. This latter finding is supported by an analysis of more than 10 000 cases of unobserved oestrus in Israel and 30 000 normal controls (Mayer *et al.*, 1987). First-service pregnancy rate for unobserved oestrus cows was 35.2 per cent compared with 60.3 per cent for the controls.

In an interesting study (Ball & Jackson, 1984) in which non-detected oestrus cows were treated with an analogue of PGF_{2α}, and monitored by observation and progesterone assays, 84 per cent of the cows had complete luteolysis after a correctly timed injection. Of all the cows treated 42 per cent were seen in oestrus within 4 days of treatment and 60 per cent within 14 days.

One factor that makes prognosis difficult is the effect of the age of the corpus luteum on the response to PGF_{2α} or an analogue. Luteolysis is unlikely to occur in cows treated before day 5 of the cycle and it may be day 7 before maximum effect results. Even when luteolysis occurs, the time from treatment to ovulation varies greatly depending, in a complex manner, on the stage of dominant follicle development when the cow is treated (MacMillan, 1983; Kastelic *et al.*, 1990). If there is a healthy dominant follicle present, oestrus will usually occur on the third day after treatment; should there be no dominant follicle present at the time of PGF_{2α} injection, 5–7 days will pass until induction of oestrus occurs.

Prognosis is improved if the veterinarian actively follows up all cases, both those treated and those left untreated, within two weeks.

Long interservice interval

Prognosis in these cases is similar to preservice cases, but because of the longer time since calving the urgency to get the cow mated is greater.

Prevention

The economic importance of prevention of anoestrus in all its forms can hardly be overstated. The cost-effective

application of preventive measures, however, calls for careful consideration, and a balance has to be achieved between undue intervention in cows that would resume normal cycles spontaneously and unnecessary loss of time due to leaving intervention too late. For example, the majority of cows that are not cycling by six weeks after calving will be coming in season by eight weeks, i.e. in time for service within the target period. On the other hand, cows that are left without examination and treatment until the end of the target period for first service, say 11 weeks after calving, will lose a great deal of production time. However, with the increase in milk yield and genetic merit of dairy cows, more prolonged voluntary waiting periods may be economically viable and of benefit to the individual animal.

Heifers

Prevention of delay in the onset of puberty depends on good nutrition and the avoidance of diseases that interfere with growth rate (see also Chapter 5).

The first step is establishment of clear targets. The farmer should decide at what age, or at what time of the year, the heifers should have their first calves. It is a simple calculation from that target to decide when the service period should start, so that the majority of the heifers calve within the planned period. The exact timing for the start of the service period will depend on how critical both the beginning and the end of the calving period are held to be. If conditions are good, such as a healthy, fertile young bull running with well-grown, healthy, cycling heifers, more than 80 per cent of heifers should be in calf after six weeks of the service period and practically all by nine weeks.

To ensure that the majority of the heifers are cycling at the beginning of the service period it is necessary to aim for a growth rate that achieves the appropriate body weight, taking account of the breed involved. Puberty occurs around 280kg in large Holsteins and Holstein/Friesians, around 260kg for Friesians and around 230kg for Jersey heifers; these weights equate to approximately 40–45 per cent of the expected adult weight. A rough rule-of-thumb for the rearing of heifers to calve at 2 years of age is to aim for prepubertal growth rates in g/day that equal the adult body weight in kg. For example, if the expected adult weight is 650kg, rear at a rate of 650g/day. Target growth rates and the key target weights for dairy heifers in the UK are given in Chapter 5.

The veterinarian has a number of roles to play. Initially, it is necessary to make the farmer aware of the need to plan for a specific calving season or age and what this implies in terms of growth rates. Thereafter, the job is mainly to give advice and to make sure that the client monitors the growth rate of the heifers

and onset of puberty. The farmer should consult the veterinarian at an early stage if it looks as though not enough animals are starting to cycle at the expected time, and hormonal treatments to induce first ovulation and synchronize oestrus and ovulation in a group of heifers may be considered.

Avoidance of disease conditions that will interfere with growth is also the veterinarian's responsibility and is described elsewhere in this book. This should not only assist the attainment of the target for age at puberty but should also help to reduce the high mortality rate that occurs between birth and puberty.

Most farmers are aware that female calves born twin to a bull calf are very likely to be sterile freemartins. Few realize that measurement of the vagina in the very young calf and comparison with a normal calf can be used to decide if a suspect calf is a freemartin. Alternatively, in valuable animals blood sampling both twins for karyotyping will usually clarify the issue and allow early culling if desired. However, this procedure is too expensive for use in most commercial cattle.

Prevention of anoestrus in adult cows after calving

The foundations for early return to normal cyclicity and getting cows served are listed in Box 35.11. All these factors are very much under the farmer's control, although the veterinarian has an important part to play in ensuring that the husbandry is up to standard, that intervention, if required, at and after calving is timely and appropriate and that cyclicity is monitored and aberrations are treated.

- *Prevention of dystokia and postpartum abnormalities* is a basic requirement for optimal cyclicity and fertility and has been discussed on p. 526.
- *Routine veterinary postpartum examination and treatment* can effectively limit the adverse effect of abnormalities around calving and delayed involution. It is essential to examine all cows that experienced dystokia or postpartum problems by not later than 28 days after calving. Many veterinary practitioners incorporate routine examination of all cows two to four weeks after calving, as this allows them to deal with problems early (see also Chapter 34).

Box 35.11 Factors likely to prevent postpartum anoestrus.

- Appropriate body condition and nutrition in the dry period
- Normal calving
- Disease-free puerperium, or adequate rapid treatment of diseases in the puerperium
- Suitable transition period feeding and regular checking of body condition score postpartum
- Efficient oestrous detection

Table 35.4 Effect of various treatments on interval from calving to first service.

| Calving – service interval (days) | | | | Reference |
|-----------------------------------|-------|------|-------|----------------------------------|
| PGF _{2α} | GnRH | Both | None | |
| – | 81 | – | 77 | Langley & O'Farrell (1979) |
| – | 88/89 | – | 83 | Nash <i>et al.</i> (1980) |
| – | 72/74 | – | 73 | Nash <i>et al.</i> (1980) |
| – | – | 61 | 63 | Richardson <i>et al.</i> (1983) |
| 92 | 108 | 85 | 84 | Etherington <i>et al.</i> (1984) |
| 61 | 67 | 64 | 58 | Benmrad & Stevenson (1986) |
| 73 | – | – | 69 | Young & Anderson (1986) |
| 81/51 | – | – | 91/58 | Schofield <i>et al.</i> (1999) |

There is an attractive concept that by routinely administering PGF_{2α} or an analogue, GnRH or both in the early postpartum period it is possible to improve return to cyclicity and pregnancy rate. It is clear that GnRH given before day 20 after calving will initiate early cycles and PGF_{2α} or an analogue given a little later increases the number of cycles in the first six weeks after calving (Benmrad & Stevenson, 1986). The effect of these treatments on overall fertility is less well defined; Table 35.4 shows results obtained in several field trials.

Meta-analysis of data from 4052 cows in 24 trials published in 10 papers looking at the effect of injecting PGF_{2α} in dairy cattle within 40 days of calving on the rate of pregnancy at first service and the number of days open came to the following conclusions. Treatment with PGF_{2α} during this early postpartum period had no effect on the first service pregnancy rate of cows with a normal or abnormal puerperium. An analysis of those data for the number of days open showed that a significant percentage (54 per cent) of the treated cows had fewer days open than the untreated cows, and that this difference tended to be greater for cows with an abnormal puerperium. The weighted average reduction in days open between treated and control cows was 2.6 days for trials with abnormal cows and 3.3 days for trials including normal and abnormal cows (Burton & Lean, 1995). This effect is probably largely due to improvements in the submission rate; it is questionable whether any improvement in calving-to-first-service and calving-to-conception interval justifies the treatment costs and the cost of the extra semen that would be used if PGF_{2α} were administered routinely to postpartum cows. Thus the routine administration of PGF_{2α} (or other hormone preparations) to cattle without a specific therapeutic indication probably cannot be justified.

In addition to the routine application of these treatments to normal cows not conferring any benefit in

terms of reproductive efficiency, there is the danger that induction of a corpus luteum with GnRH in a cow that still has an infected uterus after calving can lead to pyometra. Selected treatment of cows with uterine or ovarian pathology is on the other hand entirely justified.

- *Nutrition.* For normal reproductive function it is vitally important that nutritional levels before and after calving are correct. It has been suggested that condition score at calving should not exceed 3.0 and 2.5–3.0 should be the target at service.

Oestrous detection

Once the foundation for good fertility has been established it is essential to ensure that oestrous detection is as good as humanly possible.

Before discussing how oestrous detection can be improved it is worth asking the question: why is oestrous detection inefficient? After all, many stock-workers who carry out this task have worked with cows for years and know the signs of oestrus well. However, in a recent study of stockworker's attitudes, oestrous detection was recognized as being an important task, but was generally a task that was disliked (Seabrook & Wilkinson, 2000). This may be because it is time consuming and often requires the stockman to spend time watching cows at antisocial hours. The decreasing availability of labour on farms is resulting in reduced labour hours per cow per year and overworked staff often do not have the necessary time to dedicate to oestrous detection.

Good oestrous detection requires regrouping and possibly moving animals as well as accurate observation and recording of behavioural events several times a day over months on end and is therefore a very demanding task. It is made more difficult because of the short dura-

tion of oestrus exhibited by many cows, the time of the night or day when oestrus occurs, the weak and indefinite nature of signs shown by some cows when in season and the fact that some animals not in season exhibit some of the signs of oestrus. Veterinarians who wish to educate dairy workers on heat detection would be well advised to attempt to carry out heat detection themselves, so that they may understand the practical difficulties.

If oestrous detection is not a priority for staff and is impossible to organize even with the assistance of oestrous detection aids, then the use of hormonal treatments to synchronize oestrus and ovulation should be contemplated and discussed (see p. 678). This will reduce oestrous detection periods to very specific times, or allow the use of fixed-time artificial insemination with no heat detection. However, pregnancy rates to single fixed-time insemination may be low, and this will also have to be discussed with the client. The details of the various oestrous synchronization regimens for cattle are discussed elsewhere in this book (see p. 684).

The stockworker's dilemma occurs when a cow exhibits signs of oestrus just short of actually standing to be ridden and the decision is taken to have the cow inseminated. If the cow is not in season this decision is criticised. However, if the cow is not inseminated, a cow in season may have been missed. In a large herd these critical decisions have to be made many times a year.

Good heat detection is based on the following facts.

- The definitive sign of oestrus is standing freely to be ridden. It has been proposed that a cow that mounts onto another cow's head is in pro-oestrus. Cows in oestrus, of course, also mount other cows.
- There may be an interval of as much as 30 minutes between bouts of riding.
- Oestrus rarely lasts for more than 18 hours and in many cases lasts for less than 6 hours.
- Oestrus often starts during the night.
- Oestrous expression is greatest during quiet times of the cow's day and night. This means oestrus is seen less often around milking times and when cows are fed.
- As well as a willingness to stand on the part of the cow in oestrus, it is necessary to have a cow that wants to and can mount as discussed above (see aetiology, p. 532). This can cause particular problems when most cows in the herd are pregnant.
- When cows are loose housed there is often a particular area that cows prefer to use for oestrous expression.
- Stalled cows may have reduced physical expression of oestrus (Claus *et al.*, 1983).

A rational system of oestrous detection should be based on these facts and the following points are required for a good heat detection system:

- (1) The cows should be observed three times per day for 30 minutes each time. The periods of observation should be when the herd is peaceful after milking and feeding. Often these times are:
 - (a) briefly before collecting the cows for morning milking;
 - (b) in mid-morning;
 - (c) before the evening milking; and
 - (d) late in the evening, a very good time for detection of oestrus.
- (2) The housing conditions must be suitable for cows and observer. Good non-slippery floors on which the cows feel secure are essential. The observer must be able to see all the cows clearly, should be comfortable and should have a paper and pen to write down details of the cows' behaviour. Good lighting is required.
- (3) The cows must be clearly identifiable from a distance.

There are many aids to oestrous detection; however, there is at present no one substitute for close observation of the cows' behaviour (review by Boyd, 1984; Stevenson, 2001). Aids to heat detection either detect unobserved standing to be ridden or depend on the fact that cows in oestrus are likely to behave in ways that, although not unique to oestrus, occur with greater frequency during oestrus. Increased frequency of bellowing, increased restlessness, reduced milk yield, change in routine behaviour such as order of coming into the milking parlour for milking, and increased body temperature are non-specific, oestrus-related events. There are also a number of physical changes in the genitalia related to oestrus that can be measured, such as change in electrical resistance and viscosity of the vaginal mucus.

Marking systems fixed on the cow's pelvic region to detect standing to be ridden when the cows are not being observed can be valuable in suitable circumstances. Examples are tail paint, tail flags and detectors that contain dye that is squeezed out under sustained pressure from another cow. All of these suffer from the defect that rubbing or pressure that is not caused by the cow standing freely to be ridden may trigger them.

Television cameras with video recording have also been used to observe cows continuously and can be viewed later, at increased speed. There are problems of identity (very big numbers on shoulders and rumps are needed) and replaying the recordings is a tedious chore.

Milk progesterone assays, which can be used either as an aid to or as a replacement for oestrous detection, are discussed later (see p. 548).

Pedometers that automatically monitor and record the cow's level of activity can also be used to detect behavioural changes that are consistent with oestrus in some management systems.

It is probable that in future sophisticated decision support software integrated into computerized milking parlour systems will be developed to detect cows likely to be in oestrus and automatically shed them from the main herd for the attention of the stockman. These decision support tools will use various data automatically generated from a number of sources such as pedometers, milk yield, milk temperature, order of milking and milking frequency (fully automated milking systems only), and data detected by integrated biosensors such as in-line milk progesterone assays and assays of other milk constituents. Cows will be identified by implanted microchips. These may also advance beyond the current static data-specific microchip that simply holds the data it was implanted containing, to a new generation of smart chips that record the animal's health and disease history along with other information such as its movement history. It may even be possible in future to develop integrated implanted biosensors that analyse and record the animal's physiological state, including data related to reproduction.

Anoestrus after service

In the majority of cases, delayed return to service is due to unobserved oestrus, as has been shown in the reduction in the number of long return-to-service intervals when oestrous detection is improved. One problem, in a case where the return-to-service heat signs are not clear, is that the result of inseminating by AI a cow that has been served, and could be pregnant, may be loss of the conceptus.

Improved efficiency by the use of aids for heat detection is particularly useful in these cases because the service date can be taken as the start of the oestrous cycle. Clearly, in those cases where insemination takes place in the luteal phase this starting point is erroneous, a fact that will become clear to the stockworker as heat detection aids and substitutes are used.

Use of a three-week calendar and the application of a marker such as tail paint shortly before expected return to service can help efficiency of observation.

Systematic use of milk progesterone assays at about the expected time of return to service can help in overcoming problems of long interservice intervals. High progesterone followed by two successive days of low progesterone is an indication that service should be carried out on the next day. Eddy and Clark (1987) demonstrated, in four large dairy herds, that the efficiency of heat detection after service could be improved greatly by the use of milk progesterone assays. The pre-

ferred sampling regimen was every second day from days 18 to 24 after service. The financial benefit to cost ratio was 7.5:1. Some veterinarians report improvements based on a single progesterone assay on day 19 after service. For good results it is necessary for the stock personnel to understand the test and to be willing to carry out the extra work carefully and conscientiously. Very poor pregnancy rates have been reported to result if progesterone assays are used as the only basis for insemination without the active incorporation of oestrus detection (Foulkes & Goodey, 1988). However, the use of milk progesterone assays to confirm that cows are in oestrus before inseminating them can improve pregnancy rates and reduce the number of mis-timed inseminations (McLeod *et al.*, 1991; Watson, 1996). Strategic milk progesterone monitoring as a diagnostic and management tool in dairy cattle is discussed by Darwash and Lamming (1997). Under experimental conditions milk progesterone monitoring has also been used in suckler cow fertility investigation and management (Mann *et al.*, 1998); however, logistical problems will almost certainly prevent widespread use of this technology in the field.

Resynchronization of repeats following an initial synchronizing treatment using a progesterone device is used successfully in New Zealand and other locations where the breeding period needs to be kept short; used progesterone devices are re-inserted on day 16 to days 21 or 22 following first service, and return oestrus detected on days 23 or 24 (Van Cleeff *et al.*, 1996; McDougall, 2001). This increases submission rates in the first three weeks of the breeding season and focuses heat detection periods to a specific time following first service. A similar regimen has been successfully used in the UK in beef suckler herds (Penny *et al.*, 2000).

Chapter 36

Failure to Conceive and Embryonic Loss

D.C. Barrett, H. Boyd and M. Mihm

| | |
|--|-----|
| Manifestation | 552 |
| Aetiology | 554 |
| Stage 1 Failure of ovulation after oestrus | 554 |
| Stage 2 Fertilization failure | 557 |
| Stage 3 Embryonic death | 559 |
| Stage of failure not known | 562 |
| Diagnosis | 563 |
| Treatment | 566 |
| Prognosis | 569 |
| Prevention | 572 |

Manifestation

Return to service or detection of non-pregnancy up to six weeks after insemination/natural service are the ways in which poor pregnancy rate due to failure to conceive and embryonic losses are presented. This can have a major economic impact in any herd, but is particularly noticeable where a tight seasonal calving pattern is sought.

Interservice intervals

The interval in days that has elapsed between the unsuccessful service and the next oestrus is part of the manifestation of the condition of return to service. The concept of normal and abnormal interservice intervals has been discussed in connection with postservice anoestrus (see p. 531). While the distribution of interservice intervals varies greatly between herds, reflecting in part the management efficiency in the herd, in many cattle populations fewer than 50 per cent have a normal interservice interval of 18–24 days.

Observable abnormality

Another manifestation of return to service is the normality or otherwise of the cow at the return oestrus. The farmer can observe certain deviations from normality in these cows, in particular the presence of a purulent discharge from the vulva. The farmer may also report aberrant sexual behaviour. In relevant cases, the observant client may notice some of the changes associated with chronic cystic ovarian disease, such as slackening

of the pelvic ligaments and voice change. In general, however, the cow that returns to service presents an apparently normal oestrus as regards both behaviour and visible signs.

The way in which the client presents return to service cases affects the clinician's response to the problem. It is presented either as an individual cow problem or as a herd (or group) problem, and it is presented with or without evidence of past or present pathology.

Individual cows

Individual cases are presented in two quite different ways, which influence how they are dealt with.

In the first way, some cows are presented to the veterinarian that have been served two or three times and are still not pregnant. To understand these cases properly they have to be considered within the context of the entire population of cows and heifers in the herd. In any group of apparently normal cows served correctly by a fertile bull or inseminated properly with good semen, either for the first time after calving or at a repeat service, a considerable number will return to service depending on first-, second- and third-service pregnancy rates in each particular herd. Most of these animals are only temporarily infertile and the majority will become pregnant within an acceptable time. Although there is some understanding of the stage at which these losses occur, i.e. whether there is fertilization failure or early embryonic death, the aetiology is known to only a limited extent. For this reason these returns appear to happen at random.

Field studies show that about 12 per cent of cows are still not pregnant after three services as is demonstrated in Table 36.1, which is taken from a population of 5744 cows with a first insemination pregnancy rate of 60.6 per cent (Boyd & Reed, 1961a). 'Actual results' are compared with the 'expected results' that would have occurred if all subsequent inseminations had had a pregnancy rate of 60.6 per cent. However, in recent years a drop in pregnancy rates of approximately one per cent per annum has occurred in high-genetic-merit dairy cattle populations (Royal *et al.*, 2000; Barrett, 2001). This has resulted in expected pregnancy rates of

Table 36.1 The percentage of cows that required various numbers of inseminations for pregnancy with a first insemination pregnancy rate of 60.6 per cent.

| Number of inseminations required for pregnancy | Actual results | | Expected results | |
|--|----------------|-----------------------|------------------|-----------------------|
| | Percentage | Cumulative percentage | Percentage | Cumulative percentage |
| 1 | 60.6 | 60.6 | 60.6 | 60.6 |
| 2 | 20.4 | 81.0 | 23.9 | 84.5 |
| 3 | 7.2 | 88.2 | 9.4 | 93.9 |
| >3 or culled | 11.8 | 100.0 | 6.1 | 100.0 |

50 per cent or less to a single service, thus increasing the proportion of animals within a herd not pregnant after three services.

Farmers often wait until a cow has had three unsuccessful services before presenting her to the veterinarian and Table 36.1 shows that (with certain reservations) about half of these cows, 6.1% versus 11.8%, are not pregnant because of the same (unknown) factors that establish the level of the first insemination pregnancy rate. It is therefore to be expected that half of these cows will not exhibit any diagnosable cause of return to service and that their expectation of pregnancy at the next service is about the same as that for first insemination. However, pregnancy rates to three or more services are usually reduced due to an accumulation of animals with reproductive problems. Warren (1984) cited published data from four different cattle populations in which pregnancy rates to first service ranged from 47–57%. Within these populations, however, the herd pregnancy rates would vary widely.

In the second instance, other cases, for which the term 'chronic repeat breeder' might be used, are presented because they have returned to service repeatedly over a long period of time. These cases have been differentiated into apparently normal repeat breeders and those with abnormalities on the basis of cycle length, sexual behaviour and detectable abnormality, a differentiation of limited clinical value. These chronic repeat breeders require a different approach from the cases discussed above because they are generally cows that the owners regard as particularly valuable and therefore the clinician can devote more time and money to their diagnosis and treatment. The prognosis in chronic repeat breeders is inevitably poor because they have been given so many opportunities to become pregnant without success. It is animals of this type that may be hospitalized in teaching and research institutions where they are given expensive diagnostic and therapeutic treatment, although this is becoming more and more uneconomic within the UK.

There is no realistic incidence figure for chronic repeat breeders because their retention in the breeding herd is dependent on extraneous factors but clearly is unlikely to be more than 6 per cent of the breeding population, although it may be higher in individual herds. The number in any given herd will be determined by various economic factors which dictate at what point it becomes more economic to cull a cow and replace her rather than persist in attempting to get her in calf. Overall culling rates in UK dairy herds are about 20–25 per cent per annum (Esslemont & Kossaibati, 1997; Whitaker *et al.*, 2000). Poor fertility is the single most important reason for involuntary culling. With 30–40 per cent of cull cows being culled for infertility, this represents almost 10 per cent of dairy cows calving each year (Kossaibati & Esslemont, 1995). The exact cost to the farmer of an involuntary cull will vary from farm to farm and from time to time, depending on the cost of a replacement, the value of a cull cow, the milk price and availability (and cost) of milk quota, loss of genetic merit and many other factors. For this reason it is impossible to give an exact cost here, but on a typical commercial dairy farm it is probably between £600 and £800 per cull cow at the present time (2003).

Herd or group problems

Return to service may affect many animals in the herd in which case the client is very worried about the extent of the problem and the serious effect it will have on production and profits. For an assessment of the condition it is necessary to analyse the breeding records to determine pregnancy rates to first, second and further inseminations (or other measure of the success rate of services) and interservice intervals (see also Chapter 41(b)).

The range of incidence of return to service is very wide. In a population of herds with any given mean herd pregnancy rate there is a tendency for the herd averages to be distributed at random round this mean, as demonstrated in Table 36.2. Just over 40 years ago,

Table 36.2 Distribution (%) of herd average first insemination pregnancy rates in 191 dairy herds (Boyd & Reed, 1961a).

| Herd first insemination pregnancy rate (herd average) | | | | | | | Total |
|---|-------|-------|-------|-------|-------|------|-------|
| <31 | 31–40 | 41–50 | 51–60 | 61–70 | 71–80 | >80 | |
| 3.1% | 3.7% | 16.2% | 25.1% | 27.2% | 19.4% | 5.2% | 99.9% |

the overall herd first insemination pregnancy rate in 191 herds was 59.9 per cent (Boyd & Reed, 1961a). Although not demonstrated here, it is usual for the distribution to be skewed towards the lower end of the scale. The skewed distribution of these data tends to be seen in all studies, however in more recent surveys the first insemination pregnancy rates are lower than those reported by Boyd and Reed (1961a). For example, the mean first service pregnancy rate in 90 herds in the UK was reported as 47.3 per cent in the 1992/1993 calving season (Kossaibati & Esslemont, 1995). National Milk Records (NMR) data from approximately one million dairy cattle in 9000 herds showed that the pregnancy rate to first service (based on available pregnancy diagnosis data and non-return rates at 48 days) was 52.5 per cent in September 2000 (Barrett, 2001). This will be an overestimate of the true pregnancy rate as a proportion of the data are based on non-return rates which will include some cows culled that were not rebred after failing to conceive. Royal *et al.* (2000) reported that 265 first services out of 667 resulted in pregnancy in their study of Holstein Friesian dairy cows between October 1995 and June 1998. This equates to a first service pregnancy rate of 39.7 per cent. Given these recent data it seems reasonable to accept a target first service pregnancy rate of 50 per cent in modern dairy herds, while accepting that in some high yielding herds this may be difficult to achieve.

It is helpful to think of the pregnancy rate for any individual herd as dependent on the combined effects of the following factors:

- The random variation around the mean of the population of herds.
- The background effect, which is dependent on management and environmental factors that are liable to be constant over a long period. Examples, any of which individually would tend to result in low herd pregnancy rates, are inaccurate oestrous detection, unsatisfactory feeding, a high incidence of endometritis (see p. 521) or poor semen handling and insemination techniques (see Chapter 39).
- Specific pathogenic causes, such as a subfertile bull or venereal diseases such as campylobacteriosis, or other infectious conditions known to affect fertility

Box 36.1 Reasons for unsuccessful services.

- Stage 1 Ovulation failure
- Stage 2 Fertilization failure
- Stage 3 Loss of the conceptus, due to early (3 week return intervals) or late embryonic death (3–6 week return intervals) or fetal death (>6 week return intervals)
- Stage of failure unknown

such as bovine virus diarrhoea virus infection (see p. 578) or leptospirosis (see pp. 580, 735).

- The incidence of chronic repeat breeders, which to some extent relates to the background effect.

Aetiology

There are three main stages at which failure to achieve or maintain a pregnancy can occur. Although it is often not possible to assign an individual case to one of these stages this knowledge is useful in understanding the aetiology of return to service. The stages are shown in Box 36.1.

Stage 1 Failure of ovulation after oestrus

The most important condition in which there is oestrus without ovulation is cystic ovarian disease. It is important to define 'cystic ovarian disease' because not all cases of ovarian cysts are pathological (see Box 36.2). This traditional definition implied that cysts were static structures; however, cysts should be considered dynamic both in structure and function (Cook *et al.*, 1990). When studying the aetiology of ovulation failure the conclusions reached are affected by which animals are included as clinical cases. For example, cows identified as having cystic ovarian disease at routine preservice veterinary examination will form a different population from cystic ovarian disease cases detected in repeat breeder cows.

Histological and biochemical examination of ovarian cysts demonstrates that cysts are complex structures. On clinical examination and gross anatomical inspec-

Box 36.2 Definition of cystic ovarian disease (see also Chapter 35).

- Persisting, steroid-secreting follicles >2.5 cm in diameter
- No functional corpus luteum present for more than 10 days
- Abnormal sexual cycle (anoestrus, nymphomania, virilism)
- More than six weeks after calving

Box 36.3 The possible pathogenesis of cystic ovarian disease.

- Insufficient luteinizing hormone (LH) release: hypothalamic–pituitary dysfunction causing lack of GnRH release (commonest cause)
- Insufficient production of LH by the pituitary (rare)
- Failure of the dominant follicle to respond to LH

tion, however, there appear to be two main types of cysts: follicular cysts, which are like large follicles, and luteal cysts, in which obvious luteal tissue produces a thicker cyst wall. These may be difficult to differentiate from a corpus luteum with a central lacuna, which frequently occurs during the normal oestrous cycle (Okuda *et al.*, 1988).

It is well known that follicular cysts can occur and spontaneously resolve during the first few weeks after calving in some cows that then return to normal cyclic ovarian function, albeit later than normal counterparts (Savio *et al.*, 1990). It is often suggested that cows with cystic follicles up to six weeks after calving should be regarded as normal and not be interfered with unless they are nymphomaniac or show other signs of abnormality.

Box 36.3 is to some extent hypothetical but should act as a reminder that there are several possible routes that can result in cystic ovarian disease, among them long-term exposure to oestradiol or subnormal concentrations of progesterone (Dobson *et al.*, 2001a) and cortisol release following stress (Dobson *et al.*, 2001b). There have also been suggestions that energy imbalance due to high milk yields may be contributory, although this has not been substantiated by correlation with either β -hydroxybutyrate concentrations or body condition score (Dobson & Nanda, 1992; Tebble *et al.*, 2001).

There have been many studies of the causes of cystic ovarian disease and factors that predispose to the condition are listed in Box 36.4. There is lack of unanimity about causes, which may reflect differences between the populations of cattle selected for investigation as well as variations in the definition of cystic ovarian disease.

Box 36.4 Factors that predispose to or cause cystic ovarian disease.

- Heredity
- High yield
- Age
- Exogenous oestrogens
- Nutrition and season of the year
- Dystokia and periparturient disease

Heredity: A familial predisposition to cystic ovarian disease through sire or dam has been recognized for many years (Bane, 1964). Other studies have produced less clearcut results or even failed to detect a hereditary effect at all (Dohoo & Martin, 1984a). It is possible that this difference is partly due to the stage at which diagnosis is carried out. If the incidence is assessed at routine preservice checks most of the detected cysts are likely to be attributed to environmental factors rather than heredity; on the other hand, one might expect considerably more evidence of hereditary predisposition if the assessment is made on a sample of repeat breeders.

While most veterinarians are generally aware that there is a hereditary component in cystic ovarian disease, their clients want to know to what extent breeding a replacement heifer from a cow with cystic ovarian disease will increase the risk of that daughter having the disease. It is not easy to answer this because cystic ovarian disease may not occur in a daughter until she has had several calves and so field studies take many years and involve complex statistical analysis.

Early studies carried out by Henricson (1957) helped to answer the question. He analysed data from two artificial insemination (AI) centres of cases presented at the time of insemination and classified cows as:

- Having cystic ovarian disease on more than one occasion in a service period;
- Having only one observation of cystic ovarian disease; and
- Without cystic ovarian disease.

The effect of age was taken into account and the results expressed as an average frequency of the condition, where 1.00 is equivalent to an incidence of 100 per cent (Table 36.3).

Henricson (1957) also studied the effect of the sire and noted that the average frequency of cystic ovarian disease in individual bulls' daughters ranged from 0.00 to 0.258. Whether the low incidence of cystic ovarian disease in beef breeds is directly due to hereditary factors, to the lower milk production or to some other factor is not known.

High milk yield: Cystic ovarian disease may be related to high milk yield. It occurs most frequently at the peak

Table 36.3 Dam effect on incidence of cystic ovarian disease (COD) in daughters (Henricson, 1957).

| Number of times COD diagnosed in dam in one service period | Average frequency of COD in daughters | |
|--|---------------------------------------|----------|
| | Centre 1 | Centre 2 |
| >1 | 0.255 | 0.228 |
| 1 | 0.170 | 0.158 |
| 0 | 0.143 | 0.116 |

of lactation approximately six weeks postpartum and at the age when the cow has reached her full milking potential, which is why it is more common in pluri-parous cows than in first calvers. There is a secondary peak of cases late in lactation; presumably these are cases that have been picked up on the examination of repeat breeders. Bartlett *et al.* (1986b) discussed, without coming to a conclusion, whether high milk yield causes cystic ovarian disease, cystic ovarian disease causes high yield or there is a common cause of both! Saloniemi *et al.* (1986) thought that the relationship between cystic ovarian disease and ketosis was due primarily to high milk yield, leading to greater energy demands that in turn resulted in both ketosis and interference with LH production or release.

Some workers have been unable to find an adverse effect of high milk yield on the occurrence of cystic ovarian disease (Dohoo & Martin, 1984a).

Age: It is widely accepted that cystic ovarian disease is rare in heifers before their first calving, not common in first-lactation cows and then increasingly observed in mature cows, with possibly some slight fall off in old animals.

Exogenous oestrogens: Administration of oestrogens in the follicular phase will cause a premature LH peak. This will not cause ovulation if no dominant follicle is present at the time. If oestrogens are administered shortly before dominant follicle selection, the cow may not be able to produce a second LH peak due to down regulation of the hypothalamic response to oestradiol and consequently the dominant follicle will continue to grow and not ovulate. This may be one explanation why a single large dose of an oestrogen for therapeutic purposes may be followed later by cystic ovaries. Recent transitions to organic farming may involve grazing periods on pastures with a high component of oestrogenic plant material; however, a much increased incidence of cystic ovarian disease in such herds has not been reported to date. An analogous situation may

arise when oestrogenic substances, such as those found in mouldy brewers' grains, are eaten.

Seasonal effect: A very definite seasonal effect has been reported by many authors, with most reports indicating that the incidence is highest in winter (Dohoo *et al.*, 1984a,b; Saloniemi *et al.*, 1986). The effect can be so great that Bane (1964) stated that it is meaningless to talk of an incidence figure for cystic ovarian disease if details of season (and age) are excluded. The range in his data was from 2.23 per cent for cows that calved in May to 9.68 per cent for October calvers. The relative frequency of severe cases was higher in autumn calvers. Some authors (Bartlett *et al.*, 1986b) reported high levels in summer and autumn. The causes of the seasonal effect are not clear but may be linked to nutritional effects, and could also include the hours of daylight, temperature extremes and stressors such as housing.

Dystokia and periparturient disease: Some information suggests that dystokia and periparturient diseases may predispose to cystic ovarian disease. It is possible that preparturient factors that cause the postpartum conditions also affect the incidence of cystic ovarian disease, for example overfeeding leading to fatty liver (Reid *et al.*, 1979). It has been demonstrated experimentally that damage to the endometrium can prolong the existence of cystic follicles and so inhibit spontaneous recovery (Fathalla *et al.*, 1978) (see also Chapter 34).

Other causes: It is possible that gross adhesions can bind the ovary so tightly that ovulation does not take place, but this must be a rare phenomenon. Of much greater importance is the concept that in cows which had other reproductive disorders there were possibly more than the expected cases of cystic ovarian disease (Jasko *et al.*, 1984).

Reviews of the literature show that incidence ranges from about 6 to nearly 20 per cent (Bartlett *et al.*, 1986b; Garverick, 1997). However, diagnostic methods affect the reported incidence figure, for example Coleman *et al.* (1985) found that the single most important factor that influenced the incidence was the veterinarian who made the diagnosis! Selection of cases is also important, as has been discussed already.

It is generally agreed that follicular cysts make up about two-thirds of recognized cases of cystic ovarian disease (Booth, 1988; Garverick, 1997) although again this figure depends a little on the diagnostic method and criterion used.

While the most important reason for failure to ovulate is considered to be cystic ovarian disease, there are also a proportion of cows who have a delayed ovulation after oestrus, resulting in an extended period

Box 36.5 Causes of fertilization failure.

- Rectal palpation just before ovulation (bursting pre-ovulatory follicles, interference with egg flow into the uterine tubes)
- Interference with egg transport
- Interference with sperm transport
- Delayed ovulation
- Insemination at wrong time in relation to ovulation
- Service too soon after calving
- Poor quality spermatozoa
- Poor quality oocyte (e.g. from persistent follicles)
- Failure to serve the cow
- Metritis and salpingitis
- Vaginitis and cervicitis

Box 36.6 Causes of ovarian and bursal adhesions.

- Trauma
- Rectal palpation
- (Enucleation of corpus luteum – no longer indicated as a therapeutic practice in cattle)
- Caesarean section – inducing (localized) peritonitis
- Ascending infection
 - Postpartum metritis
 - Therapeutic infusion of uterus
- Descending infection
 - from peritoneum
- Specific infections, e.g.
 - Ureaplasma* sp.
 - Mycoplasma* sp.

from insemination to ovulation. The incidence of delayed ovulation can be as high as 11 to 13 per cent, as shown in one study by Lamming and Darwash (1998).

Stage 2 Fertilization failure

To achieve fertilization a number of events in the cow (oestrus, ovulation, gamete transport) and in the bull (spermatozoa production, insemination) have to take place and must synchronize with each other. Failure of any one of these events to occur correctly or at the right time will almost certainly result in fertilization failure. The causes of fertilization failure will be discussed, mainly based on the headings shown in Box 36.5. The first two causes, interference with gamete transport, are relatively rare occurrences.

Interference with egg transport: After ovulation the egg has to be transported to the site of fertilization in the uterine tube. Adhesions affecting the ovary and bursa and blockage of the uterine tube will prevent this happening. Factors that cause adhesions, which are fairly rare, are listed in Box 36.6. The ease with which fluids and small objects can be transported spontaneously up or down the uterine tube is demonstrated in two techniques used to investigate uterine tube patency. In one of these tests, phenolsulphonphthalein (PSP) dye is introduced into the uterus and ascends spontaneously through the uterine tube into the peritoneal cavity and becomes absorbed and secreted in urine. In the other test, starch granules deposited in the bursa descend through the uterine tube into the uterus and vagina (Kessy & Noakes, 1979).

Transport in the uterine tube is under hormonal control and can be affected by abnormal variations in steroid hormone production and by oxytocin, but the role of these factors in field conditions is not known.

As transport of the egg depends on secretory and ciliary activity in the uterine tube, salpingitis will interfere with transport of both eggs and spermatozoa, even when the lumen remains patent.

Interference with transport of spermatozoa: Adhesions in the female tract that block egg transport, and have been discussed above, will generally interfere with transport of spermatozoa. There are rare anatomical abnormalities such as white heifer disease (segmental aplasia of the paramesonephric ducts), which results in blockage of the tubular genitalia at various levels.

Poor AI technique, such as insemination in the anterior vagina or caudal half of the cervix, will result in the majority of cases in the loss of much of the inseminate by reflux through the vulva. In contrast, in natural service the ejaculate is deposited in the anterior vagina and on the external os of the cervix, but the volume of the ejaculate and the enormous number of spermatozoa allow loss by reflux while sufficient spermatozoa are transported to the uterine tube. Returning to AI, a rough operator could damage the uterus with the insemination pipette. While it is unlikely that bad insemination technique is much of a problem with a technician inseminator service, it is very likely that the range of expertise among stockworkers who inseminate their own cows is so great that some gross technical errors may be made.

Hunter (1999) discusses possible modifications of the technique used for AI involving deep intrauterine insemination and the effects this may have on the transport and storage of spermatozoa within the female reproductive tract.

Delayed ovulation: Delayed ovulation is a condition in which the interval from the onset of oestrus to ovulation is so much longer than normal that service at the recommended time does not result in fertilization

because of the ageing of the spermatozoa. While many authors are of the opinion that the condition is rare, there are a number of papers that suggest that it occurs quite commonly (Hancock, 1948; Nakao *et al.*, 1984; Lamming & Darwash, 1998). Watson and MacDonald (1984) studied events around insemination using rectal palpation and assays for progesterone and oestradiol- 17β . They concluded that in cows with a follicle in the ovaries on the day after insemination (which may indicate delayed ovulation if onset of heat occurred more than 30 hours before) this was often due to erroneous timing of insemination in relation to the onset of oestrus and not to delayed ovulation.

As the condition is so difficult to study, ideas about its aetiology must be theoretical. It is possible that there is an abnormality of the LH surge or response of the preovulatory dominant follicle to the LH surge. It has been hypothesized that deficiency of energy intake may be involved in the aetiology.

The role of stress is also speculative, but it is interesting that corticosteroids can block LH release (Wagner & Li, 1982); also the fact that the adrenal cortex under the influence of adrenocorticotrophic hormone (ACTH) can produce some progesterone may be significant in suppressing the LH surge (Watson & Munro, 1984). The importance of stress in bovine reproduction is reviewed by Dobson *et al.* (2001b).

A little understood condition called prolonged low or suprabasal progesterone was described by Jackson *et al.* (1979) as affecting 18 per cent of cows treated with an analogue of prostaglandin F_{2 α} (PGF_{2 α}) and also about 18 per cent of control cows. After oestrus there was an excessively long period of low progesterone, followed by a rise which seemed to indicate that ovulation took place eventually. The herd incidence ranged from 7 to 33 per cent and appeared to be low in herds with adequate nutrition. Other surveys have not revealed such a high incidence. Some workers think prolonged low progesterone is most commonly associated with treatment with PGF_{2 α} or an analogue causing incomplete luteolysis and subsequent recovery of some luteal function. Independent of its cause, it will lead to persistence of a dominant follicle resulting in lowered fertility following its ovulation. This does not appear to be due to poor fertilization rates, but to more losses during early embryonic development (Mihm *et al.*, 1994).

Insemination at the wrong time in relation to ovulation: Service during the luteal phase is only a minor problem with natural service but a major one with AI (Sturman *et al.*, 2000). However, on farms using hand mated natural service, a cow restrained in a service crate may be mated when she is not in oestrus.

Artificial insemination at the wrong time is an important cause of fertilization failure. Progesterone assays

of milk or blood taken on the day of insemination will detect insemination during the luteal phase of the cycle but will fail to pick up inseminations that are one or two days too early or too late. The reported incidence of luteal phase progesterone levels on the day of insemination is variable. The incidence of 5.2 per cent in well-run herds reported by Claus *et al.* (1983), with over 20 per cent in problem herds, is typical of several other trials. Laitinen *et al.* (1985), in a large field study, reported that the lowest incidence of luteal phase inseminations occurred in the summer. Oltner and Edqvist (1981) observed that in herds with a high incidence of wrongly timed inseminations, even inseminations apparently at the correct time resulted in low pregnancy rates, presumably because of other aspects of poor management.

The reasons are misidentification of a cow that actually is in season or misinterpretation of sexual behaviour, such as jumping another cow, which is thought incorrectly to indicate oestrus. The stockworkers are often under considerable pressure to get all cows served by a target date and are criticised by veterinarians and others, that cows in oestrus are missed too frequently. This can result in error through an overenthusiastic determination to increase the oestrous detection rate. The importance of inseminating only cows in oestrus was demonstrated by Sturman *et al.* (2000), who reported that in a herd they studied 19 per cent of inseminations were performed when progesterone levels were high in the oestrous cycle or while cows were pregnant. Insemination of pregnant cows led to an estimated 17 per cent induced embryonic death or abortion!

Incorrect timing of insemination in relation to onset of oestrus also occurs. Watson *et al.* (1987) confirmed that insemination 24 hours or more after the cow is first seen in oestrus results in a marked reduction in pregnancy rate, possibly due to ageing of the oocyte before fertilization. It is likely that insemination very early in oestrus also causes reduced fertility, possibly due to reduced sperm survival rates before fertilization. There is a long-established, successful rule of thumb about the ideal time for insemination (Trimberger, 1948). Cows first seen in the morning should be inseminated late that afternoon. Cows first seen in the afternoon or evening should be inseminated next morning. Cows still in oestrus 24 hours after first being seen should receive a second insemination. This pragmatic recommendation takes account of the relatively short lifespan of both spermatozoa and ova within the female tubular tract (about 24 hours), the need for capacitation of bull spermatozoa (about 6 hours) and the interval from the onset of oestrus to ovulation (about 24–30 hours).

Incorrect timing within oestrus is of little significance with natural service in which the service is usually early

in oestrus. The large quantity of the ejaculate and the great numbers of spermatozoa deposited in the anterior vagina ensure that there is a long-lasting supply of fertile spermatozoa in the uterine tube at the site of fertilization.

Service too soon after calving: It has been known for many decades that service within six weeks of calving results in reduced pregnancy rates. The expected conception rate increases from approximately 20 per cent, at 20 days post partum, to reach normal rates (at the time the studies were carried out these were 50 per cent calving rates) from 50 days post partum. The reasons are likely to be both ovarian and uterine in origin so in some cases the cause is most probably fertilization failure and in others embryonic death. Elimination of infection and restoration of endometrial structure and function after a normal calving requires 5–6 weeks in most animals.

Poor-quality semen or poor insemination technique: Poor semen quality may result in either low pregnancy rate or no pregnancies at all, mainly through fertilization failure but also to some extent through embryonic death. Again there are marked differences between natural service and AI. Because of laboratory control of the semen and follow-up of the results of insemination it is very unlikely that semen supplied by a reputable AI organization will give poor pregnancy rates. The exception to this is semen that has been poorly stored or incorrectly handled on farm for use in DIY AI systems. Schermerhorn *et al.* (1986) found that a technician inseminator service gave rather better results than farmer DIY insemination, although this may depend on the level of training received by DIY inseminators before they begin inseminating their own cows. Howells *et al.* (1999) showed that the amount of training received with live cows significantly affected future pregnancy rates; for those who spent up to three days training in an abattoir using live cows there was an increase of 5.9 per cent in the calving rate they achieved in their first year for every day they spent training. If AI technique is satisfactory, poor results with DIY inseminations could possibly be related to mishandling of the semen. By contrast a bull used for natural service may be of reduced or low fertility or even sterile and serve a number of cows before the owner realizes that something is wrong. Farmers are often not aware that a bull that has been fertile may become infertile or lose libido (see Chapter 38).

Where fresh diluted semen is used, semen that is stored too long will give poor results.

Failure to serve the cow: In certain circumstances when a bull is used to serve the cows, a cow in oestrus is not

served. Bulls can develop abnormalities of the penis that prevent normal service, and lack of libido is not uncommon (see p. 610). When animals are running freely, such as heifers or beef cattle, it is essential to include an adequate number of bulls in the group. If there are too few bulls for the number of cows, some cows in oestrus may not be served. The required cow to bull ratio depends on the type of terrain, the age and libido of individual bulls (see p. 610).

Metritis, salpingitis, vaginitis and cervicitis: Infection of the tubular genitalia may interfere with the survival of the spermatozoa in transit and so reduce the chance of fertilization. Endometritis and metritis are fairly common (see p. 524) but in addition a number of species of organisms have been recovered from the uterine tubes and may cause salpingitis or directly affect fertilization, as for example reported by Grahn *et al.* (1984), in connection with fertilization failure with BVDV infection (see pp. 578, 853). Infectious agents in the uterine tube include *Leptospira hardjo* (see p. 735), *Ureaplasma* spp. and *Mycoplasma bovigenitalium*.

Stage 3 Embryonic death

The stage of the embryo lasts from fertilization of the egg until about day 42 after conception, by which time the organ systems have been laid down and placentation has been established. Failure of maternal recognition of pregnancy will cause early embryonic loss, and the animal returns to oestrus at normal intervals (<25 days). Late embryonic loss occurs after maternal recognition of pregnancy, and animals may show their next heat 25 to 40 days after the previous heat.

In any group of breeding cattle, however normal they appear, there will occur a considerable amount of embryonic death, most of it within the first three weeks after fertilization (Sreenan & Diskin, 1986). Ayalon (1978) produced data to show that in repeat breeders the majority of the losses occurred approximately 5–7 days after insemination, around the time the early embryo enters the uterus and begins to synthesize its own proteins (Table 36.4). However, the exact timing of early pregnancy losses in the modern high-yielding dairy cow is largely unknown. Knowledge of the aetiology of this important condition is still very limited but it is possible to produce a list of factors that have been shown to cause embryonic death or are at least very likely to be involved (Box 36.7). In the vast majority of cases the actual cause is never established.

Factors that may contribute to embryonic death

Extreme environmental temperatures: Controlled experiments have demonstrated that cattle that are mated

Table 36.4 Timing of embryonic death, determined by slaughter and dissection of the cow (number and percentage containing viable embryos) (from Ayalon, 1978).

| Time of slaughter (days) | Normal cows | | Repeat breeders | |
|--------------------------|-------------|------------|-----------------|------------|
| | Number | Percentage | Number | Percentage |
| 2–3 | 10/12 | 83 | 12/17 | 71 |
| 4–5 | 22/25 | 88 | 20/25 | 80 |
| 6–7 | 10/12 | 83 | 5/12 | 42 |
| 8–10 | 13/18 | 72 | 9/18 | 50 |
| 11–13 | 16/18 | 89 | 9/18 | 50 |
| 14–16 | 16/20 | 80 | 10/20 | 50 |
| 17–19 | 12/21 | 57 | 9/21 | 43 |
| 35–42 | 9/13 | 69 | 8/24 | 35 |

Box 36.7 Factors that may contribute to embryonic death.

- Extreme environmental temperatures, particularly heat stress
- Specific and non-specific endometritis or metritis
- Specific infections of follicles, gametes and/or embryo
- Maternal pre- and postovulatory endocrine environment
- Aged gametes
- Local trauma
- Genetic factors, resulting in non-viable genetic defects
- Nutrition
- Possible fetal/maternal incompatibility

in a high environmental temperature and kept there after service exhibit a high rate of embryonic death. The dominance of the large preovulatory follicle is suppressed by heat stress, and the steroidogenic capacity of theca and granulosa cells is compromised. Progesterone secretion by luteal cells is lowered during the summer in hot climates, and in cows subjected to chronic heat stress this is also reflected in a lower plasma progesterone concentration. Heat stress has also been shown to impair oocyte quality and embryo development, and increase embryo mortality. In addition to the immediate effects of heat stress, delayed effects have also been detected. These include altered follicular dynamics, suppressed production of follicular steroids and lower quality of oocytes and developing embryos. This may explain why poor fertility may persist for some time after periods of heat stress (Wolfenson *et al.*, 2000).

Poor pregnancy rate is a problem when European cattle are introduced into hot countries where they are exposed to ambient temperatures above 30°C; it is quite likely that increased embryonic death is part of the reason. There is little doubt that genetic factors are involved in this as in other aspects of heat tolerance.

Crosses between indigenous heat tolerant breeds and European breeds are more heat tolerant than the imported animals and they are more fertile (see Chapter 6). The improved fertility appears to be the result of the dam's enhanced ability to control body temperature rather than an inherited ability of the embryo itself to tolerate high intrauterine temperatures. The position is less clear with extreme cold, but there are indications that a corresponding adverse effect occurs. The problem could arise during unusually cold periods in temperate climates where housing tends to provide cover rather than warmth.

Metritis/endometritis: Metritis or endometritis in varying degrees of intensity is a common condition causing infertility in cattle (see Chapter 34). Where caused by infection it can be divided into non-specific, exemplified by *Arcanobacterium pyogenes* infection, and specific, typified by *Tritrichomonas fetus* (see p. 584) and *Campylobacter fetus* (see p. 582) infection. There are also a number of infections that are difficult to classify such as bovine herpes virus-1 (BHV-1), *Ureaplasma* spp. and *Haemophilus somnus*.

Non-specific metritis is the result of either massive infection or of the infective organisms taking advantage of a deficient uterine defence mechanism, usually caused by damage at and after calving. Non-specific infection can be facilitated by the synergistic action of different organisms, for example *A. pyogenes* and *Fusobacterium necrophorum*.

Specific infections colonize the undamaged uterus. Two important specific infective agents are *C. fetus* and *T. fetus*. Campylobacteriosis is spread venereally and causes a mild endometritis in infected females that have not had previous experience of the condition. It has been shown in slaughter experiments that in infected animals fertilization rate is normal and that the infertility is due in the main to embryonic death within three

weeks of conception. Loss of the embryo is likely to be due to interference with the uterine environment. Venereal campylobacter infection and its control in the UK has been reviewed by Taylor (2002). Trichomoniasis, a parasitic venereal disease that still occurs in some countries (Clark *et al.*, 1986), is clinically similar to campylobacteriosis with one major difference, the occurrence of pyometra in a number of cases (Bon-Durant, 1997).

Another infectious agent that is introduced from the vagina into the uterus at insemination, but not at natural service, is *Ureaplasma* (Doig *et al.*, 1979), which causes a purulent metritis and infertility. *Haemophilus/Histophilus* also causes vaginitis and reduced fertility. For detailed discussion of a wide range of infectious agents see Morrow (1986). For more details on both endometritis and metritis see also Chapter 34.

Infectious conditions can cause infertility in at least four ways:

- The febrile reaction raises the temperature of the uterus. Bluetongue (Chapter 43a) is an example of a disease that causes a high temperature resulting in loss of the embryo at about the time of hatching from the zona pellucida, about day 10–12 after service.
- The organism infects the uterus and causes metritis, which presumably interferes with embryo nutrition and may also infect the embryo. Examples are BHV-1 virus (see p. 289) and *Chlamydiales* infections. It is likely that, in general, mild endometritis causes embryonic death whereas in cases of purulent metritis there may be interference with spermatozoa survival and thus fertilization failure.
- Infection of the conceptus can cause its death. The thought that embryo transfer could transmit infectious diseases from the sire or the dam is worrying. In theory, bacterial and fungal infections are less likely than viral infections to be carried by embryos. From experimental studies with many different viruses it appears that if the zona pellucida is intact and the embryo is washed properly, there is little danger of the transmission of viral infections by embryo transfer (Singh, 1987; Wrathall, 1995). However, the advent of *in vitro* technology may increase the risk of disease transmission due to differences in the zona pellucida of *in vitro* derived embryos, enabling easier adsorption of pathogens, and due to the use of biological products for culture which may be contaminated with pathogens (Stringfellow & Wrathall, 1995; Guerin, *et al.*, 1997).
- Endotoxins produced by Gram-negative infections can increase PGF_{2α} production and cause premature luteolysis (Fredriksson, 1984).

Maternal endocrine environment: Mann and Lamming (1995) showed that low plasma concentrations of progesterone resulted in the development of a stronger luteolytic signal. This was taken as an explanation for the fact that cows with lower plasma concentrations of progesterone postinsemination are more prone to embryo loss than those with higher progesterone levels.

Interferon tau (IFN-τ) is a protein produced by the embryo that acts locally within the uterus to block luteolysis and maintain the corpus luteum; it prevents PGF_{2α} secretion by inhibiting the development of oxytocin receptors in the endometrium (Robinson *et al.*, 1999). More recently, further work has shown that successful maternal recognition of pregnancy in cows depends on the presence of a sufficiently well developed embryo producing sufficient quantities of IFN-τ, which is, in turn, dependent on an appropriate pattern of maternal progesterone secretion (Mann, 1997; Mann & Lamming, 2001). Thus the maternal endocrine environment, and particularly maternal progesterone levels within the first one to two weeks after insemination, is likely to be extremely important in determining whether an embryo signals its presence to the dam and survives or is lost as the cow returns to oestrus.

Aged gametes: Fresh chilled semen ages after several days and the inseminated cows have a lower pregnancy rate almost certainly due to both reduced fertilization rate and increased loss of embryos. There is no evidence of adverse effects from ageing of frozen semen stored in liquid nitrogen. Fertilization of ageing eggs following ovulation of persistent dominant follicles (Mihm *et al.*, 1994; Austin *et al.*, 1999) is also likely to result in an increased amount of early embryonic death.

Local trauma: This cause of loss affects the late embryo and early fetus. One source of local trauma to the pregnant uterus is the hand of a person carrying out manual pregnancy diagnosis, or some other palpation of the uterus. In one study the average loss was 2.82 per cent of cows diagnosed pregnant (Beghelli *et al.*, 1986). Franco *et al.* (1987) reported a fetal loss rate of 9.5 per cent in cows diagnosed pregnant on days 42–46. The technique, which was carried out on two days, involved palpation of fetal fluid, identification of the amniotic vesicle and slipping of the chorioallantoic membranes. However, with good transrectal ultrasound examination technique such losses should now be largely preventable.

In a very large field study in which they used milk progesterone assays, Laitinen *et al.* (1985) estimated that 1.8 per cent of cows that returned to service were pregnant at the time of re-insemination. When a pregnant cow is inseminated, the conceptus must be at risk either through direct trauma or by the introduction of

infection into a progesterone-dominated uterus. An experienced inseminator may be able to feel the difference in the cervix and uterine horns and avoid insemination into the body of the uterus, electing instead to deposit the semen in the anterior cervix or not to inseminate the cow at all.

Genetic factors: Mention has been made of the variable breed susceptibility to high environmental temperature that causes embryo death.

In some cattle, in the process of cell division, translocation of parts of certain chromosomes without loss of genetic material has taken place, a condition that is passed on to future generations. These individuals can be identified by cytogenetic examination of leukocytes. When semen from bulls with a translocation is used for insemination there is a slight increase in the incidence of return to service, which is believed to be the result of embryonic death, presumably because of lack or excess of some genetic material due to abnormal division at meiosis.

It is also probable that many genetically abnormal embryos are lost early in development, with the advantage that the dam can return to normal breeding at the earliest opportunity. Early embryo development and non-infectious causes of embryo loss are reviewed by Kastelic (1994) and Sreenan *et al.* (1999).

Stage of failure not known

It should be clear from the limited number of factors listed as known to cause embryonic death, that in the majority of cases the cause is unknown. Some factors that result in return to service can affect different stages, for example late insemination can result in fertilization failure in some cases and embryonic death in others. There is a very large grey area concerning the aetiology of return to service, particularly where groups of affected animals are concerned. The difficulty concerning the relationship between (possible) aetiological factors and return to service is twofold.

Some factors almost certainly cause an increased return to service via an unknown mechanism. An example is the aetiological relationship between loss in body condition from calving to service and associated poor pregnancy rate. The possible sites where inadequate nutrition may have detrimental effects on reproductive function include:

- The hypothalamus/pituitary gland to impair gonadotrophin release.
- The ovaries, possibly resulting in altered follicular growth patterns and reduced quality of oocytes and subsequent reduced embryo survival.
- Inadequate uterine environment resulting in impaired embryo survival (Webb *et al.*, 1997).

To complicate matters further, additive effects of two or more types will produce low pregnancy rates. Two or more independent minor adverse factors that occur at the same time will produce a poor result. For example, Boyd and Reed (1961b) observed that variations in three factors (calving-to-first-service interval, age of cow and age of fresh semen) caused a range of pregnancy rates from 22 to 70 per cent. As mentioned above, synergistic action of two or more adverse aetiological factors, for example *A. pyogenes* and *E. necrophorum*, can result in a more severe pathological condition than either alone.

Many of the putative causes of return to service are far from being proven but they cannot be simply dismissed for that reason. Amongst these possibly adverse factors are the following:

- Short-term change in feeding and environment, particularly at turnout in the spring and at housing in the autumn. This has been postulated to be due to an energy–protein imbalance changing the uterine tube and uterine environment (pH and urea concentrations) and thus affecting normal early embryonic development.
- High milk yield leading to excessive metabolic stress.
- Stressful effect of disputes about dominance among cows that are subject to frequent changes of groups in dairy herds.
- Non-reproductive systemic illness.
- Deficiencies and imbalances in minerals and vitamins (almost impossible to generalize because of very local effect of feeding practices, local soil deficiencies and many other variables).
- Other conditions that stress the animal or affect its dry matter intake such as lameness.

There are various reasons why there is so much uncertainty in a field where numerous workers have gathered observations and data for several decades. Because expected pregnancy rate is about 50 per cent, the random variation in fertility in groups is great and this necessitates large, properly controlled groups in trials in order to give reliable results. The possibility of erroneous conclusions from any single trial is so great that only results that are consistently repeated in different populations can be regarded as reliable.

In recent years there have been a number of epidemiological studies of a highly statistical nature on the relationships between various aspects of management and production, disease and reproduction. Because of the complexity of interrelationships very large numbers of observations are needed and these reports are based on data from populations that range from about 2000 to >70 000 lactation records. For the practitioner this means that evaluation of fertility in small herds is

difficult due to the large impact of small numbers of observations on overall herd results.

While there are considerable differences between the findings certain concepts have emerged:

- Reproductive diseases at and after calving tend to occur as an interrelated complex (see Chapter 34).
- Some diseases that are not specific infections of the reproductive tract have an adverse effect on reproduction, e.g. *Leptospira hardjo*, BVD virus (McGowan & Kirkland, 1995) and BHV-1.
- There is disagreement on the effect of high yield on fertility.
- There is disagreement on the effect of hereditary factors on fertility.

Although the relative importance of the factors listed above, along with other management factors, is still poorly understood, what does seem to be beyond doubt now is that fertility, at least in high producing dairy cows in the UK, is declining over time (Barrett, 2001).

The relationship between nutrition and fertility is a complex one that is still not fully understood. The reader may find the following reviews of interest: Britt (1995); Webb *et al.* (1997); Wathes *et al.* (1998); Webb *et al.* (1999); O'Callaghan and Boland (1999); Garnsworthy and Webb (2000) and O'Callaghan *et al.* (2000).

As an example of the complex interactions affecting fertility, data from the very large study by Saloniemi *et al.* (1986) showed the consequential effects of specific causes described in Table 36.5.

For details of other complex interactions, the reader is referred to some original texts: Andersson *et al.* (1991) and Gustafsson and Emanuelson (1996): hyperketonaemia and fertility; Bartlett *et al.* (1986b) and Garverick (1997): cystic ovarian disease; Bartlett *et al.* (1986a) and Sheldon (1999): metritis/endometritis; Curtis *et al.* (1985): metabolic disease, mastitis; Dohoo and Martin (1984a): age, season and sire; Dohoo & Martin (1984b): mastitis and ketosis; Britt (1995): nutri-

tion, weight loss and fertility; Loeffler *et al.* (1999): time of disease, milk yield and body condition; Dohoo *et al.* (1984): disease, production and culling; Rowlands *et al.* (1986) and Peeler *et al.* (1994): interrelationship of diseases; Saloniemi *et al.* (1986) and Fourichon *et al.* (2000): reproductive diseases.

Diagnosis

Although a herd consists of many individuals, diagnosis of a return-to-service problem that affects a large part of a herd requires a different approach from that taken to investigate the cause in an individual animal. For this reason the individual will be dealt with first, followed by the herd fertility problem.

Diagnosis of the individual repeat breeder cow

One problem with diagnosis is that by the time the cow is recognized as being a repeat breeder the situation that prevailed at the time of reproductive failure may well have changed.

The clinician should take a history and carry out a systematic clinical examination to find out whether any of the factors that are likely to cause return to service are present. The fullness and, therefore, costs of the investigation will need to be discussed with the farmer in advance and a diagnosis may only be pursued in valuable animals.

A systematic approach to diagnosis is essential and the following procedure is suggested (Box 36.8).

History: The history should cover various points as shown in Box 36.9.

General examination: The clinician should carry out a brief general examination looking at the following points:

Table 36.5 The consequential effects of management and disease on problems of fertility (reproduced from Saloniemi *et al.*, 1986 with permission of the publisher).

| Cause | Consequential effect | | | |
|--------------------------|--------------------------|----------|----------------------|---------------------|
| | Retained fetal membranes | Metritis | Anoestrus/suboestrus | Ovarian dysfunction |
| Winter calving | No | Yes | Yes | Yes |
| Highest herd milk yield | Yes | Yes | Yes | Yes |
| Parturient paresis | Yes | Yes | | |
| Mastitis | | Yes | Yes | |
| Ketosis | | Yes | Yes | Yes |
| Retained fetal membranes | | Yes | | |
| Metritis | | | Yes | Yes |

Box 36.8 The systematic diagnosis of return to service.

- History
- Analysis of records
- General clinical examination and body condition
- Examination of the reproductive tract (rectal, vaginal and suitable aids including ultrasound examination)
- Appropriate laboratory tests

Box 36.9 The main factors to be covered in history taking.

- Date of calving.
- Dystokia and puerperal diseases
- Postpartum reproductive disease
- Other diseases (e.g. lameness, metabolic diseases)
- Service details
 - Dates
 - Bull used
 - Natural or AI
- Inseminator service or DIY AI
- Major management or environmental changes
- Is this considered to be a herd or individual cow problem?

- Body condition and conformation;
- Signs of non-reproductive disease;
- Signs of vaginal discharge or dried pus or mucus on the tail or hindquarters; and
- Other signs, for example a raised tailhead.

Rectal examination: The technique of rectal palpation of the genital tract is fully described in various textbooks, as are the characteristics of the various normal and abnormal structures in the ovaries and tract. The purpose of carrying out a rectal examination is to assess:

- The state of the ovaries;
- The condition of the bursae and uterine tubes;
- Uterine abnormality or status (e.g. metritis, adhesions, pregnancy);
- Internal slackness of the pelvic ligaments;
- Absence of fat inside the pelvis (body condition);
- Vulval discharge (stimulated by palpation);
- Evidence of other conditions detectable on rectal examination (e.g. cystitis, pyelonephritis, fat necrosis).

Nowadays it is general practice to supplement, or even replace, the manual rectal examination with a transrectal ultrasound examination. This has the same aims as listed above, but will on the whole give more accurate results. The use of transrectal ultrasound examination as a diagnostic tool and the comparative levels of accuracy of rectal examination and ultrasound

are discussed more fully in Chapter 35 (see p. 536). The use of milk progesterone assays may also improve diagnostic accuracy (see p. 548).

Accuracy of diagnosis of cystic ovarian disease by rectal examination: When undertaking rectal palpation there are obvious difficulties in trying to assess the nature of a cyst without rupturing it. A large, soft corpus luteum with no palpable ovulation papillum can be mistaken for a cyst. Some authors are very sceptical about the accuracy of diagnosis of cystic structures by rectal palpation alone, for example Stolla *et al.* (1980) and Guenzler and Schallenberger (1981). However, accuracy is immensely improved with transrectal ultrasound examination (Douthwaite & Dobson, 2000), and once again milk progesterone assays have their place in confirming whether functional luteal tissue is or is not present (Chapter 35).

Accuracy of diagnosis of endometritis: Clinical diagnosis of endometritis is discussed in some detail in Chapter 34 (see p. 521).

Vaginal examination: There is a choice of two methods of vaginal examination on the farm: manual or visual using a vaginal speculum. In both cases the perineal region and vulva are thoroughly cleaned and the veterinarian uses fresh plastic gloves. With manual examination mucus in the anterior vagina is gathered and on withdrawal of the hand examined visually and olfactorily. Minimum lubrication is used to avoid confusion between clear mucus and the lubricant. The cervix and vaginal wall are palpated for lesions and abnormalities. The vaginal speculum should be introduced with care and, when fully inserted, will give a clear view of the cervix. With both techniques the clinician may have difficulty in passing the vulvo-vaginal junction, which is the narrowest part of the tract at this level. When using a speculum great care should be taken to ensure that the speculum does not transfer infection between cows. This is best achieved by using disposable, single-use specula or autoclaving equipment between cows. If a single speculum is to be used on a number of cows at a single visit, it must be thoroughly disinfected between cows. Box 36.10 shows the factors that should be checked in a vaginal examination.

Selection of samples for laboratory examination: Selection of the appropriate laboratory examinations and the frequency of sampling depend very much on circumstances, including the value of the cow. The items listed in Box 36.11 may be considered.

To extend the physical examination beyond what is possible by palpation and transrectal ultrasound, the patency of the uterine tubes can be investigated using the phenosulphonphthalein (PSP) dye test and/or starch grain test as described by Kessy and Noakes (1979).

Box 36.10 Factors to be checked by vaginal examination.

- Anatomical abnormalities.
 - Heifers
- Damage
 - Caused by dystokia:
 - Rectovaginal fistula
 - Pneumovagina/urovagina (see p. 519)
 - Damage to the cervix
 - Serving injuries caused by the bull
 - Sadistic human interference
 - Other acquired conditions
 - Vaginitis (see p. 519)
- Type and quantity of mucus
 - Purulent
 - Bloody
 - Smelly
 - Clear oestrous mucus

Box 36.11 Types of samples required for various laboratory tests.

- Single milk progesterone assay: an adjunct to rectal palpation and ultrasound examination
- Serial milk progesterone assays: monitor events around service, confirm diagnosis, monitor treatment
- Oestrone sulphate from milk, blood (specifically from the placenta: indicates live calf)
- Heparinized blood for cytogenetic analysis
- Clotted blood for serology (e.g. BHV-1, BVDV, *Leptospira hardjo*, *Neospora caninum*)
- Purulent material from the uterus: aerobic and anaerobic culture, antibiotic sensitivity
- Uterine biopsy for histology
- Samples from the cervix and uterus for serology and cytology
- Vaginal mucus for campylobacter diagnosis using the vaginal mucus agglutination test (VMAT)

New technological aids to diagnosis: In recent years advances in biochemistry, electronics and fibre optics, along with skills and materials developed for embryo transfer, have opened up new diagnostic possibilities. There is every reason to believe that new equipment and concepts will continue to be produced, which presents problems as well as opportunities for the veterinarian. Most of the new techniques do not require specifically veterinary skills and so may be used by a wide range of operators, although for best effect knowledgeable interpretation is needed. Choices have to be made about the lasting value of each new step forward as investing capital and training in inappropriate technology is unproductive.

The relatively new aids to diagnosis can be classified as:

Box 36.12. Steps required to diagnose a herd fertility problem.

- History
- Analysis of records
 - Breeding
 - Health
 - Production
- Selected clinical examinations and sampling
- Conclusion

- Quick, cheap and, in some cases, automated hormone analysis;
- Non-invasive (or acceptably invasive) examination of internal organs: hysteroscopy, endoscopy (transrectal ultrasound is already routinely used during farm fertility examinations);
- Automatic or semiautomatic recording of physical, behavioural and biochemical changes that are related to the animal's reproductive status, such as body temperature, restlessness, changes in milk composition and hormone content;
- Computer analysis of data: compilation over time of various measurements in the individual and analysis of herd records (see Chapter 41b).

Diagnosis of a herd problem

It is necessary to approach the diagnosis of a herd fertility problem systematically. It is not practical to lay out in any detail a series of steps to be followed because as the investigation develops the information obtained guides the continued course of the investigation.

The four main causes of herd problems are poor fertility management, an infertile 'male', nutritional errors and deficiencies and infectious conditions. In general terms the steps required are shown in Box 36.12.

History: The object of history taking is to acquire information on the factors shown in Box 36.13.

Analysis of the records: It is useful, if possible, to examine the breeding records before visiting the herd. If there are no records then establish a recording system. The objectives of record analysis in connection with a herd fertility problem are the following:

- (1) To assess the current level of fertility in the herd and to establish whether a problem exists, and if so to determine the seriousness of the situation.
- (2) To look for clues to aetiology, by looking at the fertility of subgroups within the herd:
 - Bull, semen or inseminator;
 - Age (lactation) group;
 - Yield group;

Box 36.13 History taking in determining herd fertility problems.

- General aspects of the herd and farm
 - Number of breeding stock (male and female)
 - Stocking density
 - Type of housing
 - Details of grazing
 - Targets for reproduction and production
 - Other enterprises
 - Information about the stockworkers
- Definition of the perceived problem
 - Anoestrus
 - Return to service
 - Vaginal discharges
 - Other manifestations
- Duration of problem
- Proportion of herd affected
- Reproductive management
 - Calving management
 - Service management: cows and heifers (heat detection, timing of AI, technician or DIY AI)
 - Bulls
- Nutrition
 - Ration formulation
 - Feeding system
 - Assessment of adequacy of nutrition e.g. yield, milk composition, condition score, metabolic profiles
- Details of 'herd health plan'
 - Disease monitoring
 - Intervention levels
 - Preventive medicine initiatives
 - Vaccination protocols
 - Biosecurity
- Disease status of herd
 - Details of herd status for infectious diseases known to affect fertility, e.g. BVDV, BHV-1, leptospirosis
 - Incidence of conditions that have a direct effect on fertility, e.g. retained fetal membranes, endometritis
 - Other diseases and conditions in the herd, e.g. lameness

- Seasonal effect;
- Familial effect;
- Relevant infectious disease: e.g. non-specific endometritis after calving, *Campylobacter fetus*, *Leptospira hardjo*, *Neospora caninum*, BHV-1, BVDV, etc.

Analysis and interpretation of herd fertility records are discussed in much more detail in Chapter 41a,b.

Once a cause of the infertility is suspected, a valuable technique is to group the records of all animals that are influenced by the suspect factor and compare these with the records from all other cows. It can be difficult to identify the cause of a problem where farmer insemination is associated with poor pregnancy rate. In these

cases there may be no comparative data on the bull's fertility; the problem could be due to poor insemination technique or to improper semen handling.

Examination of the animals: It is very useful to examine as many cows as possible to obtain a current picture of the herd, to observe the condition of the cows and to detect or confirm the incidence of obvious reproductive abnormalities. It also reveals the (in)accuracy of the information supplied by the farmer or farm staff. Advice should be given about culling of individuals that have a very poor prognosis.

By this stage the clinician should have a good idea of the type of problem; how the investigation then develops is a matter of clinical judgement which cannot be detailed further.

Treatment (see Chapter 42)

The veterinarian is faced with some difficulties when having to decide on appropriate and effective treatments for cows that are presented as infertile. This is partly because of the complex aetiology of return to service, but also because of the time that has passed since the factors that initiated the problem were present. When using pharmaceutical products the reader is advised to consult the manufacturers' data sheets for details of treatment, withdrawal periods, dangers and contraindications. Wherever possible the treatment should be followed up to see whether it has been successful or not and, if need be, repeated or changed.

Ovulation failure

The most important cause of ovulation failure is cystic ovarian disease. Treatment is based on whether the cyst has been diagnosed as follicular or luteal. In most cases the condition is probably caused by hypothalamic-pituitary dysfunction and it is, therefore, logical to treat the condition systemically. There is little or no benefit in rupturing the cyst manually, which also involves a risk of causing haemorrhage and ovarian adhesions. Nor does there appear to be any benefit from administration of drugs directly into the cyst.

Many cystic structures found less than 42 days after calving are transient and benign, and in general these do not require to be treated. Only if abnormal behaviour indicates that they are pathological or if there is some pressing management need should they be treated.

For follicular cysts the three therapeutics of choice are human chorionic gonadotrophin (hCG),

gonadotrophin-releasing hormone (GnRH) or GnRH analogues, such as buserelin, and progesterone-releasing intravaginal devices (PRIDs) and controlled internal drug release (CIDR) (Dobson *et al.*, 2001a). They all work in different ways to achieve the same end, i.e. to put the animal under the influence of progesterone. One effect of this is to allow a build-up of LH in the pituitary so that enough endogenous LH is available after removal of the progesterone devices or regression of the (induced) corpus luteum. This leads to normal preovulatory follicle development and ovulation, and in all cases the cow should be served at the first heat after treatment. The duration of exposure to exogenous or endogenous progesterone is thought to be important in the non-recurrence of the cystic condition, with 14 days being preferable to seven (Nanda *et al.*, 1989). There is also evidence to suggest that the success of treatment of follicular cysts depends on whether the cyst is producing oestradiol or not, as reflected by the presence or absence of other follicles >5 mm in diameter. Following treatment with an intravaginal progesterone releasing device or GnRH, animals had a pregnancy rate to all inseminations of 91 per cent when other large follicles were present in addition to the cyst, compared with 69 per cent if no other follicles were present at the time of treatment (Tebble *et al.*, 2001).

Human chorionic gonadotrophin has an LH-like direct action on the ovary to induce luteinization of the cyst or follicles. GnRH stimulates the release of LH from the pituitary to achieve the same result. In both cases the lifespan of the luteal tissue produced is variable, ranging from about six days to about 18 days, and oestrus can be expected about 8–22 days after treatment. It is desirable to examine the treated cows about seven days after treatment for the presence of luteal tissue. If luteal tissue is found, treatment with PGF_{2α} or an analogue is a suitable way of increasing the predictability of the following oestrus. Service should be at that oestrus and aids to oestrous detection should be used. If there is no satisfactory response to the first treatment, the cow should be re-examined and treated again.

For cysts containing functional luteal tissue as judged by ultrasound examination or milk progesterone assay, injection of PGF_{2α} or an analogue followed by insemination at observed oestrus is the most suitable treatment.

An alternative treatment, suitable for both types of cystic ovarian disease, is the insertion of a PRID/CIDR, which can be left in position for 12 days, and after withdrawal the cow should be served, either at a fixed time or preferably at observed oestrus (Douthwaite & Dobson, 2000). If the type of cyst cannot be diagnosed accurately, then administration of PGF_{2α} or an analogue, either on the day of PRID/CIDR withdrawal or

up to three days before, can improve predictability of the oestrous response. If fixed time insemination is used and oestrus is observed later the animal should be inseminated again.

Fertilization failure

Delayed ovulation: For many years one of the standard ways of treating apparently normal repeat breeders on the farm has been to administer hCG or GnRH on the day of service. The theory behind this was that many of these cases were thought to be due to lack of an adequate gonadotrophin surge delaying ovulation, although controlled trials of this type of treatment are lacking and a better approach may be to inseminate the cow again 24 hours after the first insemination.

Interference with transport of egg or spermatozoa: When this is due to bilateral blockage of the uterine tubes (or other parts of the female tract), there is no simple treatment. In some cases the diagnostic dye test may remove a minor blockage and attempts have been made to achieve this by adding antibiotics and corticosteroids to the dye, which is introduced into the uterine tube end of the uterus under gentle pressure using a cuffed catheter.

In valuable animals the use of ovum pick-up techniques using transvaginal ultrasound-guided oocyte aspiration can be used to harvest oocytes for *in vitro* production of embryos. One or more of these embryos could then be implanted back into the uterus of the donor, although it is probably more advisable to implant valuable embryos derived in this way into other healthy heifers. In those animals that are not considered of high enough genetic merit to be used as oocyte donors, but which the farmer simply wishes to get back in calf so as to induce another lactation, the implanting of a low cost embryo may be used as a treatment. This has now become commercially feasible and technically achievable for repeat breeders with no uterine or endocrine abnormalities; single step (in straw) embryo thawing, using embryos frozen in ethylene glycol, is used, which allows embryo transfer with little more equipment and skill than that required for AI (May, 1996).

Other factors that can cause failure of fertilization are:

- Service at the wrong time;
- Poor-quality semen;
- Infertile bull;
- Problems with artificial insemination.

These are dealt with elsewhere under Prevention, in Chapter 38 on the bull, or by common sense.

Embryonic death

Although the aetiology of early embryonic death is listed under nine headings (Box 36.7) only non-specific endometritis (already dealt with in Chapter 34), specific metritis caused by *C. fetus* (see p. 582) and a variety of other infections and possibly maternal endocrine environment are suitable for conventional treatment. All the other conditions should be corrected by management improvements or are dealt with in different chapters of this book.

A number of different *Campylobacter* spp. are associated with infertility and abortion in cattle, the speciation and subspeciation of which is complex and currently under review using modern molecular techniques. However, it is clear that the most common isolates associated with fertility problems in the UK are *C. fetus* subsp. *venerealis* and *C. fetus* subsp. *fetus* (Newell *et al.*, 2000). Infection with either of these subspecies should be thought of as a herd problem. In the case of *C. fetus* subsp. *venerealis* the natural habitat of the organism is the bovine reproductive tract and it does not multiply in the intestinal tract; it is thus transmitted only as a venereal disease (Taylor, 2002; see also p. 582).

In the bull, in which infection with *C. fetus* subsp. *venerealis* is limited to the surface of the prepuce and penis, spontaneous cure does occur but is erratic and unreliable. Moreover, if the bull continues natural service of infected cows he will be re-infected as the superficial nature of the infection does not stimulate an immune response in the bull. The organism colonizes the crypts of the preputial epithelium which increase in both size and number as the bull ages. This means that the prepuce of the older bull provides favourable conditions for the persistence of the organism, giving a higher incidence of carrier bulls among those over 5 years of age. Diagnosis and treatment are also more difficult in the older bull (Taylor, 2002).

The usual treatment of the bull involves preputial lavage with streptomycin in a viscous oily medium and parenteral treatment with the same antibiotic. Taylor (2002) recommends daily systemic (e.g. intramuscular) treatment with a combination of streptomycin and dihydrostreptomycin, each at 150mg per ml as sulphates at a dose rate of 10mg per kg body weight. Taylor (2002) gives a detailed description of the technique of preputial lavage. It is important that both systemic and local treatments are carried out thoroughly and are repeated daily for three consecutive days. This needs to be combined with further sampling for the organism not less than 30 days after treatment has finished to confirm success of treatment. In a confirmed outbreak of campylobacteriosis, the bulls should be sampled twice, not less than three days and not more than seven days apart, and this should be repeated a

further 30 days later. Taylor (2002) describes in some detail the technique for collecting samples by preputial washing.

Although there is no natural immune response in the bull, one successful form of treatment depends on vaccination (Clark & Dufty, 1982). The vaccine is licensed for use in a number of countries but not in the UK, although one can be made under licence in the UK for specific herds.

Treatment of cows with local or systemic antibiotics is unreliable and because cows develop resistance to the infection it is usually best to wait for this to develop. Whatever course is followed an infected cow should be regarded as potentially infective for at least two gestations after initial infection. Even after this time a few cows may remain infected. As it takes only one cow to infect a bull when natural service is practised, it is clear that it is hazardous to allow natural service of any cows that have ever been infected. Vaccination of cows (where permitted) is widely and fairly effectively practised in range conditions.

On a herd basis, when campylobacteriosis is diagnosed the best advice is that natural service should stop and all services should be by AI using semen from non-infected bulls. Recently infected cows will continue to return to service for some time. In suckler herds where the use of AI to observed natural oestrus may be problematic this approach can be facilitated by the use of repeated oestrous synchronization and fixed-time artificial insemination as described by Penny *et al.* (2000).

There is a management alternative, which is extremely difficult to carry out successfully over a long period and should be advocated only under special circumstances. This is to segregate the herd and use the infected bull(s) on infected cows and AI or non-infected bulls on non-infected cows and heifers. However, this depends on the accurate identification of the infection status of all animals.

Manipulation of the maternal endocrine environment post insemination by the exogenous administration of progesterone or progestagens has been tried as a treatment of repeat breeder cows or where herd conception rates are particularly poor. However, the results of such studies are variable and seem to be affected by the time of progesterone administration and the initial fertility levels. A meta-analysis of 17 progesterone supplementation studies showed that treatment during the first week of pregnancy resulted in an increase in pregnancy rate, especially on farms with poor fertility, while treatment during the second and third weeks of pregnancy gave no overall significant increase (Mann & Lamming, 1999). At the present time treatments of this type cannot be recommended as a means of improving conception rates, and more research is needed to identify suitable hormonal treatment strategies.

An alternative post-insemination treatment involving the administration of GnRH (or GnRH analogues such as buserelin) to the cow around 11 days after insemination has become popular in recent years. In some studies this has been shown to give very good results. For example Sheldon and Dobson (1993) achieved an improved pregnancy rate to first service of approximately 10 per cent. A recent meta-analysis of studies of the effect of GnRH 11–14 days after insemination concluded that while results were not consistent across all studies, there was a significant improvement in pregnancy rate amongst 2541 cows across six studies (Peters *et al.*, 2000). However, post insemination hormonal treatments remain an unpredictable means of improving pregnancy rate on any one given farm, and in most instances resources would probably be better targeted at improving the management of the herd rather than instigating such treatment regimens.

Stage of failure unknown: non-specific endometritis

The two most common therapeutic approaches are (i) promotion of the cow's normal resistance to infection by inducing oestrus and (ii) the use of antibiotics. There is a tendency for spontaneous elimination of the infectious agents from the uterus, most likely due to the cow going through successive periods of oestrus. The current practical approach to treatment is discussed in detail in Chapter 34 (see p. 521).

Prognosis

From the client's point of view successful treatment means that the cow becomes pregnant; this is a two-stage process. Firstly, the cow has to return to normal reproductive function and secondly she has to conceive and remain pregnant. While the first stage is mainly the responsibility of the veterinarian, the second stage often depends on the farmer and farm staff. Where poor husbandry (i.e. feeding, housing or breeding management) is thought to be causing return to service, prognosis must be guarded because it is often a difficult and slow task for the veterinarian to effect a marked improvement.

Results of treatment reported by different workers are rarely comparable because different criteria for selection of cases and assessment of success may have been applied. In many cases self-cure is a phenomenon and because controlled studies are rare, interpretation of results is problematic. Accordingly it is suggested that, as well as reading published reports, clinicians should analyse their own practice records of diagnosis, treatment and outcome.

The most common situation is the cow presented after a few unsuccessful inseminations (or services), which on examination appears to be normal. These *apparently normal repeat breeders* have an expected pregnancy rate at the first service after examination that is about the same as the first service pregnancy rate in the herd, as indicated in Table 36.6.

This is not to say that the factors influencing fertility in first service and repeat breeder cows are the same. In the first service cows, fertility may be affected by closeness to calving and the stress of peak yield. The population returning to service will have overcome these problems, but will include a higher proportion of cows that will never become pregnant. Unfortunately before their ultimate disposal, cows in the last group will have had two or three different treatments and several examinations at regular visits. In most cases there is no reliable way of identifying these problem cows.

Where economics allow the hospitalization and intensive investigation and therapy of repeat breeder cows in referral centres (now very uncommon in the UK), the owner should be given a definite prognosis as soon as possible to minimize the cost involved in keeping and treating cows over several weeks. Much of this cost is due to the fact that once an animal has been served there is little positive that can be done except to monitor changes until pregnancy or non-pregnancy is confirmed. With modern diagnostic methods such as ultrasound scanning it is now possible to reduce the waiting time from service to diagnosis of non-pregnancy to a minimum of 25–30 days, and milk progesterone analysis can be used to give an indication of pregnancy status as early as 19–20 days post service. Other methods of early pregnancy diagnosis such as assays for bovine pregnancy-associated glycoprotein

Table 36.6 Response of apparently normal repeat breeders served without treatment.

| Number of cows | Treatment | Percentage pregnant at first AI after examination | Reference |
|----------------|-----------|---|-----------------|
| 191 | None | 59.7 | de Kruif (1975) |
| 141 | None | 60.0 | Refsdal (1979) |

(bPAG) may also be used to speed up pregnancy diagnosis (Skinner *et al.*, 1996). If the prognosis is favourable, costs are reduced if the cow is returned to the owner's farm where the local veterinarian can treat her.

Accurate prognosis with long-term repeat breeder cows is also difficult. The prognosis for natural conception must always be regarded as poor, but particularly so in cases with blocked uterine tubes, persisting endometritis and anomalous steroid hormone production from the ovaries. For example, of 33 chronic repeat breeders treated by Boyd *et al.* (1984) only eight became pregnant. However, the use of embryo transfer techniques to maintain animals for subsequent lactations may offer some hope and has been shown in some studies to give reasonable results. May (1996) reports pregnancy rates in the region of 50 per cent using single step (in straw) embryo thawing, with embryos frozen in ethylene glycol. Furthermore, nowadays it is also possible to harvest oocytes from valuable animals for *in vitro* production of embryos, and thus offspring, using transvaginal ultrasound-guided oocyte aspiration of ovarian follicles.

The two most commonly diagnosed specific pathological causes of return to service are cystic ovarian disease and purulent endometritis.

Cystic ovarian disease (see p. 526)

In data collected from a number of veterinary practices Bartlett *et al.* (1986b) recorded that culling rate for cows that had cystic ovarian disease was 26.6 per cent, compared with 21.6 per cent for other cows. Cows with cystic ovarian disease that conceived had an interval from calving to conception 33.5 days longer than cows without cystic ovarian disease. More recently cystic ovaries were associated with 6 to 11 more days to first service and with 20 to 30 more days to conception in a meta-analysis of papers published between January 1987 and January 1999 (Fourichon *et al.*, 2000).

In general, three factors affect the outcome:

- The time that has elapsed since calving. Cases of cystic ovaries that occur up to six weeks after calving have a good chance of spontaneous recovery. Cases that are first seen six months after calving have a very poor prognosis.
- The accuracy of diagnosis. If the type of cyst is misdiagnosed, selection of inappropriate treatment may give poor results.
- The aetiology of the condition affects the outcome. If the cyst is caused by a temporary environmental influence such as poor nutrition, then the prognosis is good even without treatment, once this environmental influence is corrected. At the other extreme, if it is one of the minority of cases caused by deficiency of LH receptors in preovulatory dominant follicles, the prognosis may be poor in the short term as this may be the consequence of events occurring up to months previously.

The results presented in Table 36.7, in most of which diagnosis and outcome were checked by progesterone assays, are typical of earlier published field trials. However, these data do not illustrate the ultimate benefit of treatment, which should be measured in terms of calving or treatment to conception intervals and culling rates (see Table 36.8).

Guenzler and Schallenberger (1981) treated 66 cows in which luteal cysts had been diagnosed by rectal palpation. After treatment with an analogue of PGF_{2α}, complete luteolysis occurred in the 35 cows with mid-cycle levels of progesterone and all but three of these started normal cycles. The first service pregnancy rate for these cows was 40 per cent. The two groups of cows with lower levels of progesterone cycled erratically after treatment and had first service pregnancy rates of 20 and 24 per cent. Nanda *et al.* (1988) treated 77 luteal cyst cases with an analogue of PGF_{2α} and 65 per cent of these exhibited initial recovery, i.e. the cyst regressed and a corpus luteum formed;

Table 36.7 The treatment of follicular cystic ovarian disease with GnRH.

| Number of cows | Type of cyst | Confirmed by progesterone assay | Treatment | Successful result: progesterone rose within 14 days | Reference |
|----------------|--------------|---------------------------------|--------------------|---|----------------------------|
| 104 | Follicular | Yes | GnRH | 73 (70%) | Nakao <i>et al.</i> (1983) |
| 30 | Follicular | Yes | GnRH | 25 (83%) | Ax <i>et al.</i> (1986) |

^a From Douthwaite and Dobson (2000).^b From Tebble *et al.* (2001).

not all became pregnant and in 18 per cent the cyst recurred.

More recent results from Douthwaite and Dobson (2000) and Tebble *et al.* (2001) are summarized in Table 36.8. In these studies the overall interval from calving to conception was significantly greater than that of matched controls irrespective of cyst type or treatment. Cows treated for luteal cysts took significantly longer to get in calf than those treated for follicular cysts, again irrespective of treatment. Cows treated for follicular cysts had a higher culling rate than those with luteal cysts. It would seem that at least in the herds used in these studies, farmers and veterinarians were prepared to persevere with cows diagnosed with luteal cysts, even at the expense of an extended calving to conception interval, whereas cows with follicular cysts tended to be culled earlier.

Purulent endometritis/metritis (see pp. 519, 521)

Ott and Gustafsson (1981) reviewed reports on over 600 cases and showed that in 85 per cent the uterus was emptied within a few days of treatment with PGF_{2α} or an analogue. In most reports the authors stated that pregnancy rate after successful treatment was lower

than in normal cows. Time from treatment to conception was about 75 days.

Factors that affect prognosis have been quantified by Anderson (1985) who modified a system proposed by Studer and Morrow (1978), which was based on a careful analysis of clinical and laboratory observations. Anderson took into account (i) the time since calving, (ii) whether oestrus had occurred since calving, (iii) the amount of pus, (iv) the size of the cervix and (v) the diameter of the larger affected horn. By giving points for these factors a cumulative score was calculated that gave a useful prediction about the eventual outcome of the case. Cows that had been in oestrus had a poor prognosis, presumably because they had not responded to the normal defence mechanism.

Pepper and Dobson (1987) found that the relative amount of pus in the discharge gave a (non-significant) indication of the pregnancy rate after treatment and that time from calving to treatment was significantly related to pregnancy rate after treatment. Cows treated with PGF_{2α} or oestrogen within 40 days of calving had a pregnancy rate of about 55 per cent compared with a significantly poorer result for cows treated later. From Anderson's (1985) data it appeared that in successfully treated cows there was a high incidence of

periparturient problems at the resultant calving and a very high culling rate in this group of animals in the year after treatment, observations that warrant further study. The treatment and control of endometritis and metritis are discussed in more detail in Chapter 34.

As regards the outlook for herds with a return-to-service problem prognosis varies and obviously is related to the diagnosis. Some episodes of herd infertility are of short duration and normal fertility returns spontaneously.

In cases where a definite infectious cause is identified, such as campylobacteriosis, the outcome can be completely satisfactory with the elimination of the infection and the return to a normal herd pregnancy rate. This depends on treatment being carried out carefully and the subsequent control of breeding management being optimized.

Where the problem is related to poor husbandry caution should be expressed until clear signs of improved management are noted.

Prevention

Improvement in pregnancy rates is achieved by encouraging good husbandry and avoiding factors that have an adverse effect on fertility. While it is possible to achieve a very high fertilization rate (up to 100 per cent), some embryonic death is inevitable, which is why it is rare for a herd to achieve a pregnancy rate of greater than 70 per cent.

There are a number of items, listed below, which contribute to good fertility, but deficiency in any one of these is likely to produce poor pregnancy rates.

- (1) Accurate heat detection.
- (2) Proper nutrition and maintenance of suitable body condition before and after calving.
- (3) Avoidance of dystokia and post partum abnormalities and timely veterinary intervention where indicated. This should reduce the incidence of delayed involution, non-specific endometritis (Chapter 34), blocked uterine tubes, cystic ovarian disease, etc. (see Chapter 34).
- (4) The proper use of records can help to achieve a good pregnancy rate and to avoid long interservice intervals. This is done by:
 - (a) not serving cows too soon after calving (not before 42 days);
 - (b) being aware of the expected return-to-service date (for example, by using a three-week calendar);
 - (c) ensuring early pregnancy diagnosis via transrectal ultrasound and milk progesterone assays;

- (d) checking the fertility of the bulls;
- (e) checking the efficiency of the inseminators, and the quality of the semen used;
- (f) understanding the causes of fertility variations in a specific herd.
- (5) Avoidance of service contact outside the herd and ensuring veterinary examination, isolation and testing of bought-in breeding stock, especially bulls will reduce the risk of introducing venereal diseases and other diseases affecting fertility. (See also Chapter 57 for a more in-depth discussion of biosecurity.)
- (6) Good housing environment and cattle handling will help to avoid stress, lameness, discomfort and fear in the herd.
- (7) Consideration should be given to reproductive dysfunction with a hereditary component, e.g. cystic ovarian disease.
- (8) Interventions that may cause embryonic death should be avoided, such as drastic changes in feeding and environment, herd medication and the administration of vaccines in the weeks after service. In the case of vaccines the manufacturer's recommendations should always be followed.
- (9) Drug therapy, using either antibiotics or hormones, in the post partum phase has been advocated as a way of improving pregnancy rates. The doubtful value of this is discussed below.

Where specific drug therapy is applied selectively in cows identified as likely to have poor fertility this is obviously a suitable approach. However, it has been proposed that routine treatments should be applied to all cows, normal and abnormal, and this is much more questionable. For example in one study post partum administration of PGF_{2α} 21 days after calving reduced the interval to first oestrus and first service by about 10 days. Pregnancy rates to first service were increased and the number of services to conceptions was reduced from 2.0 to 1.3 (Schofield *et al.*, 1999). However, a number of trials have given conflicting results. Meta-analysis of 24 trials where PGF_{2α} was administered to cattle within 40 days of calving reported no beneficial effect on first service pregnancy rate, although there was a small reduction in days open for treated cows (Burton & Lean, 1995). It is now becoming socially unacceptable to administer hormonal products to cattle as 'routine' treatments, and some sectors of the industry such as organic milk producers and many consumers would rather that hormone preparations were not used at all, or that their use were restricted to individual cows with particular problems that cannot be treated by any other means.

The routine use of antibiotics in both normal and abnormal cows after calving or at the time of

insemination should be strongly discouraged; results have shown no benefit to normal cows. Antibiotic usage should be restricted to those animals where there is a specific therapeutic indication, and where failure to treat may compromise the animal's welfare.

In order to overcome problems with oestrous detection, oestrous synchronization and fixed time AI may be employed; Lane *et al.* (2001) have reviewed methods of synchronization. The technique is best suited for dairy heifers and beef suckler cows. For best results the farmer, the veterinary surgeon and a member of the insemination organization should discuss the whole operation well beforehand. The best results are obtained when only reproductively normal cows at least six weeks after calving (preferably longer) or maiden heifers are included, although it is possible to synchronize cows that have had a shortened post partum period (Penny *et al.*, 2000; Penny & Lowman, 2002). First calvers and animals in poor body condition tend to give poor results and may need additional hormones such as equine chorionic gonadotrophin and nutritional treatments. Results following synchronization of dairy cows can be satisfactory (Biggadike & Mawhinney, 1996; Jobst *et al.*, 2000) and cost-effective (Esslemont & Mawhinney, 1996), but currently still need inseminations at observed oestrus for optimal results. Stress and any change in management and diet should be avoided during preparation and for three to four weeks after insemination. As far as possible other interventions such as vaccination should be avoided during the same period. Some of the oestrous synchronization regimens may be used for the repeat synchronization of cows not in calf to the first service (Penny *et al.*, 2000; McDougall, 2001; Penny & Lowman, 2002); this allows repeated fixed time insemination. However, if repeat synchronization is not to be used it is essential that preparation is made to deal with the cows that return to oestrus, such as an intensive period of heat detection approximately 19–24 days after the initial service. If natural service is to be used on these returns it is essential that the 'sweeper bull' is not presented with an excessive number of cows in oestrus over a very short period of time (see Chapter 38).

Introduction

The failure of the cow to carry a calf to full term or to produce a live calf causes financial loss through disruption of the normal pattern of milk production, the loss of genetic material or an absolute loss in output for the beef cow. These losses can have a profound effect at the herd level. For example, neosporosis has been reported to cause abortion rates of 26 per cent (Wouda *et al.*, 1999). Losses on this scale may be relatively unusual, but annual losses of 10 per cent are not uncommon. Assessing the scale of these losses is made difficult by the definitions used and the differing clinical manifestations. In Britain abortion is described as the birth of a live or dead calf before 271 days' gestation and stillbirth as the production of a dead calf after 272 days of gestation (Noakes, 1986). However, agents that infect the conceptus, such as bovine viral diarrhoea virus (McGowan & Kirkland, 1995) or leptospira organisms

(Bolin & Alt, 1998) can cause embryonic death or death that occurs shortly after birth. Such embryonic loss or early abortion is difficult to detect and increased neonatal mortality may not be immediately associated with disease processes that affect the fetus.

It is also important to define what is normal or unavoidable loss. Spontaneous chromosomal abnormalities are commonly held to account for the bulk of unavoidable wastage and a loss of 20 per cent of embryos by day 45 of gestation has been estimated (Roche *et al.*, 1981). After this period losses are far lower: an abortion rate of 6.5 per cent was calculated by Forar *et al.* (1995) who reviewed 26 published studies. Stillbirth losses of 4 to 6 per cent have been quoted (Miller, 1988) and a study of more than 2000 beef cow calvings found a mortality rate of 4.5 per cent within 24 hours of birth (Nix *et al.*, 1998). In contrast, the target used in beef production in Britain for live calves born is 94 per cent (MLC, 1998) and the estimate of 1.9 to 2.0 per cent losses after day 42 of gestation (Sreenan & Diskin, 1986) may be a more realistic target for unavoidable fetal loss. This is further supported by a survey of Irish dairy cows that found an abortion rate of 1.7 per cent (Mee, 1992). From this it would seem justifiable to use an interference level of 3 per cent for abortions or losses after confirmation of pregnancy at around 6 weeks and one of 2 per cent for deaths at parturition and in the neonatal period.

Pathophysiology

The clinical manifestation of disease of the conceptus is largely the consequence of the stage of development when exposure to the agent occurs (McGowan & Kirkland, 1995), the difference in virulence between strains of recognized fetal pathogens (Dubovi, 1992) and the degree and duration of exposure in the case of non-infectious causes. The corpus luteum is necessary for maintenance in the first half of gestation (Wendorf *et al.*, 1983) and destruction of the corpus luteum during that time will usually result in the termination of pregnancy and the expulsion of a fresh fetus and membranes. However, fetal death may either cause lysis of

the corpus luteum and the expulsion of an autolysed fetus some days later or the corpus luteum may persist and the fetus and membranes then undergo mummification. If bacterial infection is present maceration of the fetus is the result. As a consequence, early abortions are rarely observed and when they are the advanced autolysis limits the examinations that can be carried out.

The fetus and placenta maintain the pregnancy in the later stages. Fetal death removes this support and abortion follows after a period of a few days. Autolytic change is a feature in these cases too, characterized by the presence of bloody fluid in the body cavities (Dillman & Dennis, 1976) and a loss of microscopic cell detail. However, fetal death is not the only consequence of disease processes affecting the fetus and placenta. Fetal stress primarily due to anoxia will trigger the steroid response necessary for normal parturition (Knickerbocker *et al.*, 1986) and a relatively fresh fetus can be expelled in these circumstances; indeed, calves may be born alive and survive from day 260. Signs of prolonged fetal stress include staining of the perineum by meconium and inhalation or ingestion of meconium.

Placentitis

Placentitis is the principal lesion in several infectious disease processes associated with fetal loss, and in cattle the placenta is often retained after abortion in the second half of gestation. The precise reasons for placental retention are not known, but this is a further factor limiting the investigation of many cases.

Causes of abortion

A wide range of infectious and non-infectious causes of abortion have been reported, many of which are associated with only occasional or sporadic fetal loss. The following discussion concentrates on the more prevalent conditions in British herds, with only occasional reference to exotic causes.

Viral causes of abortion

Bovine viral diarrhoea (BVDV) (see p. 853)

Laboratory diagnostic rates of 5.4 per cent (Kirkbride, 1992a) and 6.5 per cent (Caldow *et al.*, 1996) have been reported, but the widespread evidence of infection in English dairy herds (Paton *et al.*, 1998) and the ability

of the virus to cause abortion in the early stages of gestation, at a time when both finding the fetus and achieving a diagnosis are more difficult, suggest that the true rate of fetal loss due to BVDV may be higher.

Infection is most often introduced into the herd by the purchase of a persistently infected (PI) breeding replacement and can be maintained in the herd by the birth and survival to breeding age of further PI animals. In the beef herd infection can be maintained within successive calf crops as the calves are kept with the cows during the breeding period and beyond the first trimester of pregnancy. Persistently infected animals produce the largest amount of virus, particularly in their nasal secretions, while acutely infected animals are also infectious to others for at least 15 days (Duffell & Harkness, 1985). Both persistently infected bulls (Meyling & Mikel-Jensen, 1988) and bulls undergoing acute infection (Paton *et al.*, 1989) can pass the virus in semen.

Acute infection during the breeding season and in the first trimester of pregnancy can result in a range of outcomes from reduced conception rates or fetal death to the persistence of infection in the fetus (Kirkland *et al.*, 1997). Infection in both the first and the second trimester can cause abortion or developmental abnormalities, particularly of the nervous system (Baker, 1987). The virus appears to be less pathogenic to the fetus in the third trimester and from 100 to 120 days of gestation the fetus can mount an immune response to the virus, a response that becomes more effective as the pregnancy progresses.

Following acute infection, the virus multiplies in the placentome, but does not cause placentitis, before moving into the fetus. In the first trimester lesions in the fetus include meningitis with cerebellar cortical destruction and necrotizing bronchiolitis (Casaro *et al.*, 1971), but these are rarely observed due to autolysis. Sublethal damage in the first trimester and beyond can result in the birth of calves with lesions such as retinal dysplasia and cerebellar hypoplasia. The difference in virulence between strains described for both type 1 and type 2 viruses (Dubovi, 1992), along with stage of gestation at which individual cows are exposed to infection and the variation in the level of herd immunity, explain the wide differences seen in the outcome of BVDV infection in breeding herds.

The virus can be isolated from an aborted fetus although the success of this is limited by autolysis. It can also be demonstrated in fixed tissues using immunohistochemistry. This allows the agent to be associated with lesions observed on histological examination (Ellis *et al.*, 1995). Nested reverse chain transcriptase polymerase chain reaction (PCR) techniques have been used to detect viral RNA in tissues and may, in future,

become the diagnostic technique of choice (Nettleton & Entrican, 1995). As maternal antibody cannot cross the bovine placenta, antibody detected in fetal fluids indicates fetal infection. However, when antibody is detected in late abortions without the presence of specific pathology BVDV may not have been responsible for fetal death (Brown *et al.*, 1979).

Maternal immunity to infection is not life-long. Infection with heterologous strains of the virus can also overcome natural immunity. Control should therefore be based on a programme that includes best practice biosecurity, identifying and removing persistently infected breeding animals from the herd and screening purchased replacements for the presence of PI animals. Vaccines (p. 1011) now available in Britain have been shown to prevent fetal infection (Brownlie *et al.*, 1995), but vaccination should not be relied upon as the sole preventive strategy. The success of eradication and biosecurity as a means to control BVD can be measured by the progress made by the countries that have embarked on national or regional control programmes (Hult & Lindberg, 1998)

Bovine herpes virus 1 (BHV1) (see also p. 289)

In Western Europe there is little to suggest that BHV1 is a significant cause of abortion. In contrast, in North America BHV1 has been shown to be the most frequently diagnosed viral cause of abortion (Kirkbride, 1992a; Anderson *et al.*, 1997) and experimental challenge models to test vaccine efficacy have resulted in a high rate of fetal loss (Miller *et al.*, 1995). This difference may be the consequence of a variation in virulence between the strains of the virus found on the two continents.

BHV1 exists as two distinct subgroups and causes two clinical syndromes: infectious bovine rhinotracheitis (IBR) and infectious pustular vaginitis (IPV). Neither clinical syndrome is exclusively associated with a particular genotype of the virus and abortions have been observed with both subgroups (Barr & BonDurant, 1997). As with all herpes viruses the agent is maintained in a latent form in infected animals, but can be re-activated at times of stress (Kaashoek *et al.*, 1996). In young animals epidemic IBR often follows the introduction of market purchased animals to the herd. Similar outbreaks of clinical disease may be seen in adults, but subclinical disease is more common in this age group. Infection in breeding herds tends to become endemic, with young cows infected as they enter the breeding herd (Pritchard, 1992).

Experimental infection with the virus at 25 to 28 weeks of pregnancy resulted in abortions between 17 and 85 days later (Miller *et al.*, 1991). In abortions

attributed to natural infection with BHV1, fetuses show no typical gross lesion, but histological examination consistently reveals multifocal coagulative necrosis in the liver and less frequently in the lung, lymph nodes, kidney and placenta (Kirkbride, 1992b). These changes and the absence of fetal antibody suggest an acute infection and appear to conflict with the prolonged period between experimental infection and abortion.

Virus can be isolated from up to 50 per cent of fetuses that show histological lesions typical of BHV1 infection with the placenta being the most useful tissue for culture (Kirkbride, 1992b). Other diagnostic techniques that have been described include fluorescent antibody staining on cryostat sections of fetal tissues, immunostaining of lesions observed in fixed tissues and PCR techniques (Rocha *et al.*, 1999).

It seems likely that active immunity ensures that re-infection does not result in significant clinical disease and the use of a live modified vaccine has been shown to prevent abortion following experimental challenge (Cravens *et al.*, 1996). However, it remains unclear how long after infection cows are protected from the abortifacient effects of the virus.

As BHV1 is an insignificant cause of fetal loss in Britain there is little financial incentive to control the disease in breeding herds for this reason alone. However, the virus may be found in the semen of infected bulls and it is illegal to sell semen from antibody-positive bulls to third countries within the European Union (EU). Several continental European countries have successfully eradicated the disease or have national control programmes in place and individual herds within these countries are unable to import seropositive animals. There is therefore a sound argument for pedigree and high genetic merit herds to eradicate the disease by a test and cull programme supplemented by biosecurity measures. Gene deleted vaccines offer an alternative to a test and cull programme and have been used in the Netherlands (Kaashoek *et al.*, 1995). Even where breeding herds do not sell semen or pedigree animals, the apparent difference in virulence between European and North American strains of the virus makes it prudent to exclude exotic strains of BHV1 by implementing biosecurity measures.

Other viruses

While a range of other viruses have been isolated from aborted fetuses there is little to support their role as important causes of fetal death. The exceptions are bovine herpes virus 4 (BHV4) and Akabane virus. There is epidemiological evidence of an association between BHV4 seropositivity and abortion in cows in

Belgium (Czaplicki & Thiry, 1998) and in the USA the virus was the third most frequently isolated from fetal submissions to a diagnostic laboratory over a 10-year period (Kirkbride, 1992b). There is no published record of the agent's involvement in British cattle and relevant diagnostic tests are rarely used. It may be of value to consider BHV4 when the usual investigative procedures in problem herds have been unsuccessful. Akabane virus is an arthropod borne virus that has been shown to cause a range of congenital abnormalities that include arthrogryposis and hydranencephaly as well as abortion. The virus occurs in Australia, Japan, South East Asia, Africa, Israel and Turkey and it would appear to be maintained in a range of mosquito and culicoides species (Charles, 1994). The significance of Akabane virus to British herds is limited, but the trade in live animals that would follow inclusion of countries such as Turkey to the European Union could render this virus something other than an exotic curiosity.

Bacterial causes of abortion

Brucellosis (see also p. 461)

According to EU criteria Britain is officially free of *Brucella abortus* infection, but animals from areas with a lower status for this disease are imported and as a consequence the government continues to carry out post import checks and routine serological monitoring of the herds in Britain.

The organism is an intracellular pathogen that is spread in infected uterine discharges. After infection has occurred, usually by ingestion, an animal remains infected for life and the principal sign of this infection is abortion due to placentitis. This is characterized as a purulent intercotyledonary placentitis with necrosis of the cotyledons. Live calves are produced from subsequent pregnancies although the uterine discharges remain a source of infection. Apart from the severe effects on cattle production the disease is also an important zoonosis.

In Britain there is a legal obligation for farmers to notify the government's animal health service of any bovine abortion and it is then at their discretion to require the collection of diagnostic material by the farmer's veterinary surgeon. Microscopic examination of smears made from vaginal swabs, bacteriological culture of milk and vaginal swab and a range of serological techniques can then be employed to screen for evidence of the disease. It is important for both farmers and their veterinary surgeons to recognize that these procedures are not used to test for other abortion agents.

Control of the disease is the preserve of the State Veterinary Service in Britain and test and cull policies

are pursued. Vaccination has been used in many national or regional eradication programmes, often in the early stages of control (see p. 1013).

Leptospirosis (see also p. 735)

The disease in cattle is caused by the organisms collectively referred to as *Leptospira hardjo* (*L. borgpetersenii* serovar *hardjo* and *L. interrogans* serovar *hardjo*, previously named *Leptospira interrogans* serovars *hardjobovis* and *hardjoprajitno*, respectively). These are host-adapted serovars responsible for disease in cattle. In New Zealand there is little evidence that these are significant pathogens of cattle and their importance lies in their zoonotic impact (Bolin & Alt, 1998). Conversely, disease surveillance figures from New Zealand have found *Leptospira pomona*, a serovar that is not adapted to cattle, in 1.3 per cent of abortion cases examined (Thornton, 1991). In Victoria, Australia, experimental infection of pregnant heifers with a locally isolated strain of *L. interrogans* serovar *hardjo* failed to cause abortion or to establish fetal infection (Chappel *et al.*, 1989). In Britain and Ireland leptospirosis is associated with infertility, abortion and milk drop. As it is difficult to detect evidence of infection in the fetus it is also difficult to determine the true significance of leptospirosis as cause of fetal death, however diagnostic rates of 1.7 per cent have been observed in Scotland (Caldow *et al.*, 1996) while in Northern Ireland 42 per cent of aborted fetuses showed evidence of infection (Ellis *et al.*, 1982). The disease is widespread in the national herd and bulk milk antibody testing showed 75 per cent of samples from dairy herds in England and Wales to have antibody present (Pritchard, 1999).

Infection is through exposure to contaminated urine and leptospires penetrate intact mucosal surfaces to establish a bacteraemia. The agent localizes in the urinary and reproductive tracts and is passed in large numbers in the urine in the early stages of the disease and may be passed intermittently for prolonged periods thereafter. Spread of infection within a herd is most rapid during the grazing season, an observation that has been explained by the longer survival times for the organism that occur in the moist neutral pH conditions found at pasture in contrast to the more acid environment that prevails when animals are housed, particularly where ensiled forage is fed.

Infection is generally considered to be introduced to a herd through the addition of infected cattle, but both sheep and horses can maintain the infection and one study has suggested that sheep, the use of natural service and the presence of water courses that have run through other farms may all be risk factors for leptospirosis infection (Pritchard *et al.*, 1989).

As with several other infections, abortion occurs as a chronic sequel, following up to 12 weeks after what is often a subclinical acute infection of the dam. Aborted fetuses and placentas do not show any characteristic pathology that is of diagnostic value, but the time course of infection is such that the fetus may have been able to mount an immune response and produce antibody. This antibody can be detected in fetal fluid by the microscopic agglutination test (MAT). Isolation of leptospires from fetal tissues is a preserve of the specialist laboratory and is not routinely used as a diagnostic test. The fluorescent antibody test performed on cryostat sections or impression smears of fetal tissues found favour for some time but inherent difficulties of such techniques in autolytic tissues mean that these tests too are now less frequently used. Once again the detection of specific DNA may well become the technique of choice and several PCR methods have been described (Smith *et al.*, 1994).

The literature on maternal serological response is extensive and serves to underline the diagnostic limitations of serological techniques. The MAT has long been the standard test and principally detects antibody of the IgM class. These antibodies are produced as an early response to infection and may have fallen to undetectable levels by the time the animal aborts. The enzyme linked immunosorbant assay (ELISA) can be designed to detect a specific subclass of antibody or a mixture, but the commercially available ELISAs usually detect predominantly IgG. After infection an animal produces detectable levels of IgG by 21 to 28 days and these persist for prolonged periods. Serology does not allow the differentiation between vaccinal titres and those that follow natural infection. For these reasons maternal serology is of little value in the individual animal that aborts and is best used as a herd diagnostic technique on the understanding that it may have limited applications in vaccinated herds.

In dairy herds a principal reason for controlling the infection by vaccination is to reduce the risk of zoonotic disease in those milking the cows, but one study has claimed an improvement in fertility indices after vaccination (Dhaliwal *et al.*, 1996). In beef herds the risk of zoonotic infection is low and there is no published study to demonstrate the value of vaccination, although this is a commonly used control strategy. Similarly the use of quarantine, serological screening and antibiotic treatment of animals that are seropositive are measures that have been recommended (BCVA, 1992). A successful national herd control programme based on the application of biosecurity and test and cull exists in the Netherlands. In Britain a programme of accreditation of freedom of disease has operated since 1989 (MAFF, 1989). Both approaches offer the benefit of allowing

the sale of breeding replacements accredited free of infection.

Bacillus licheniformis

Bacillus species are saprophytes that are widely distributed in the environment and with the exception of *Bacillus anthracis* are generally considered to have little pathogenic potential. Species differentiation is not easy, but the principal isolate from bovine abortions is *Bacillus licheniformis*. Bacillus organisms have been isolated from 9.8% of fetal specimens (Caldow *et al.*, 1996) and outbreaks of abortion associated with this agent are commonly observed (David, 1993). Just how an organism that is considered to have little pathogenic potential can appear to be such an important fetal pathogen is not clear. It has been suggested that the risk of abortion may be related to the weight of infection in the environment, either in silage or in other forage or in contaminated water. However, other factors may be important and in 45 per cent of fetuses where a diagnosis of *Bacillus licheniformis* abortion was made evidence of fetal infection with *Neospora caninum* was also found (Caldow *et al.*, 1996). Despite this the experimental infection by the intravenous route alone has resulted in placentitis and abortion with lesions similar to those observed in naturally occurring incidents (Agerholm *et al.*, 1999).

Usually abortion occurs relatively late in pregnancy and lesions of a necrotizing placentitis are observed with thickening of the intercotyledonary areas and adventitious placentation. Suppurative bronchopneumonia and occasionally pericarditis can be found in the fetus. The organism is readily isolated from the placenta, fetal lung and fetal stomach contents, but on occasion the organisms can no longer be cultured from the fetus despite isolation from the placenta and the presence of typical pathology.

There is no indication that the bacteraemia that precedes the abortion is associated with any clinical disease in the dam and no serological test has been developed.

In herds experiencing outbreaks group treatment with antibiotic is sometimes advocated, but there is no evidence of efficacy. It is prudent to screen cows for the presence of other agents that may be acting as cofactors as well as to carry out bacterial counts on silage. A threshold of 10^4 colony forming units/g has been suggested above which forage should not be fed to pregnant cows (David, 1993). Other potential sources of the organism should also be investigated, including drinking water.

***Listeria monocytogenes* (see also p. 904)**

There are similarities between listeria and bacillus as causes of abortion, although *Listeria monocytogenes* is

generally considered to be a more significant pathogen. It may be associated with clinical disease in the dam, but is usually only a sporadic cause of cattle abortion. *Listeria monocytogenes* is a small Gram-positive rod that grows rapidly in aerobic or microaerophilic conditions at temperatures of between 3 and 45°C. It can tolerate pH values as high as 9.6, but is inhibited by pH values lower than 5.6 and exists as a plant saprophyte or as an animal pathogen (Low & Donachie, 1997). It is these characteristics that are crucial to the epidemiology of the disease in ruminants, allowing growth of the organism in poorly fermented silage and infection by ingestion.

The clinical syndromes most commonly observed in cattle are iritis and meningoencephalitis, with abortion an uncommon sequel of either of these. Silage feeding is associated with a risk of listeriosis, however disease can occur when animals are grazing pasture. In addition to *L. monocytogenes*, the closely related *Listeria ivanovii* is also isolated occasionally from cattle fetuses (Alexander *et al.*, 1992).

In listeric abortion the aborted fetus is often autolytic, but non-specific lesions of placentitis and fetal septicaemia may be seen (Barr & Anderson, 1993) and the organism can be readily isolated from fetal viscera, stomach contents and the placenta. Serological tests for exposure to listeria exist, but are not used in the diagnosis of bovine abortion.

The same restraints on treatment and control of bacillus apply to listeria. High-risk forages, which in this case are poorly preserved silages with a pH greater than 5, should not be fed to pregnant cattle. In addition to ensuring conditions that promote good anaerobic fermentation during the ensilage process, measures should be taken to reduce soil and faecal contamination of the grass prior to and during harvesting.

Salmonellosis (see also Chapter 15; p. 850)

According to British diagnostic data, salmonella organisms were isolated from 159 to 300 cases of bovine abortion in each of the years of 1994 to 1998 (MAFF, 1998a). During this period *Salmonella dublin* made up 82 per cent of these diagnoses. In contrast, *S. dublin* accounted for 31 per cent of the non-abortion salmonella cases in adult cattle whereas the figure for *Salmonella typhimurium* was 54 per cent (MAFF, 1998b). These data suggest that *S. dublin* is more likely to manifest as a primary abortion problem than is *S. typhimurium*. There is a variation in the number of *S. dublin* cases diagnosed on a regional basis, indicating an endemic problem in some areas.

Salmonella organisms are members of the Enterobacteriaceae and as such can be found as part of the intestinal flora in many species of domestic animals and

wildlife. The carrier state is particularly important in the spread of the disease and *S. dublin* shows a greater tendency towards the carrier state than *S. typhimurium* in cattle. Studies on the epidemiology of *S. typhimurium* determinant type 104 have also demonstrated the important role of newly introduced animals in the spread of this disease (Evans & Davies, 1996). While it remains unclear how important wildlife are in initiating new outbreaks, infection was found to be maintained in rodent and wild bird populations after an outbreak.

Infection of the placenta follows bacteraemia and extension to the fetus can follow from this. However, neither infection of the fetus nor indeed placentitis is required to cause fetal death or abortion. Where fetal infection has occurred gross lesions are non-specific; histological lesions of fetal septicaemia may be found and the organism may be isolated from fetal tissues and the placenta. If the cow is showing signs of septicaemia at the time of abortion it is advisable to attempt to isolate the organism from faeces. Serological tests for salmonellosis are available, but are not used routinely for diagnostic purposes in the investigation of bovine abortion.

Once a diagnosis of salmonellosis has been made control rests on efforts to minimize further spread of infection within the herd through improved hygiene and thorough cleaning and disinfection. There are conflicting reports of the effectiveness of vaccination against *S. typhimurium* in the face of an outbreak (Davies & Renton, 1992; Mee & Malone, 1995), but a *S. dublin* vaccine is available and has been used successfully in endemically infected herds (Wray *et al.*, 1989). The removal of *S. dublin* carriers after an outbreak appears to be an attractive course of action, but this approach is impractical as excretion is periodic. Faeces must be cultured with negative results on three occasions at 14-day intervals before an animal is considered to be free of infection. In addition, animals must be individually housed or stall-tied with this method as there is the possibility of passive excretion if animals are loose housed or at pasture (Radostits *et al.*, 1994).

Farmers should be aware of the risks that purchased breeding replacements pose and added animals should be placed in quarantine and screened by culture as above.

Campylobacter (see also p. 568)

Venereal campylobacteriosis is considered to be an important cause of bovine infertility wherever natural service is used and abortions are a feature of this disease. Recent observations have suggested that the condition may be more prevalent in beef herds in Britain than has been widely presumed (Caldow & Taylor, 1997).

Campylobacter fetus is a microaerophilic, motile bacterium that has two recognized subspecies: *C. fetus* subsp. *venerealis* and *C. fetus* subsp. *fetus*. Differentiation has been based on the variation of antigenic and biochemical characteristics of the subspecies, notably that *C. fetus* subsp. *venerealis* will not grow in 1 per cent glycine whereas *C. fetus* subsp. *fetus* will. This differentiation is important, as *C. fetus* subsp. *venerealis* is considered to be adapted to the bovine reproductive tract and to be the cause of venereal campylobacteriosis, whereas *C. fetus* subsp. *fetus* is a gut commensal causing sporadic abortion in cattle. However, strains of the latter vary in their biochemical characteristics and strains identified as *C. fetus* subsp. *venerealis* have developed tolerance to glycine (Chang & Ogg, 1971). In addition, strains identified as *C. fetus* subsp. *fetus*, when used in experimental studies, have resulted in disease indistinguishable from that caused by *C. fetus* subsp. *venerealis* (Schurig *et al.*, 1973) and field outbreaks of venereal campylobacter infertility associated with *C. fetus* subsp. *fetus* have been identified (MacLaren & Agumbah, 1988). It would therefore appear that strains of both subspecies are capable of causing venereal infertility and whenever *C. fetus* is isolated from abortion material the possibility of herd venereal infertility should be investigated.

In the case of sporadic abortion not associated with venereal infertility, invasion from the intestinal tract is the probable route of infection.

The venereal form of the disease is usually introduced to the herd via an infected mature bull and while younger bulls or breeding females are less likely sources, any animal that has previously been mated constitutes a potential source of infection. The use of hired bulls is considered to be a particularly high-risk practice. Infection in the bull follows natural mating with an infected cow, but is not associated with clinical signs or pathological changes. In mature bulls infection becomes established in the lumen of the epithelial crypts of the prepuce, while bulls younger than 6 years of age are more resistant to infection (Clark, 1971). In natural service the spread of infection is from the penis to the anterior vagina, where the organism becomes established before entering the uterus to cause a mild endometritis and salpingitis. Pathological changes are most pronounced at 8 to 13 weeks after infection and have resolved by four to five months (Dekeyser, 1986). Where conception has occurred embryonic death and a delayed return to oestrus, abortion or the birth of a live full term calf can follow. Of the abortions that are detected the gestational length is usually around four to five months. A marked placentitis and pericarditis may be seen on gross examination of the tissues and histological findings are of fetal septicaemia and pneumonia.

Diagnosis of *C. fetus* as a cause of abortion rests on the isolation of the organism from the fetus. As faecal contamination of the placenta may occur after the abortion, isolation from the placenta should not be considered diagnostic unless reinforced by histopathology.

After venereal infection in the cow, antibody is secreted in the uterine and vaginal fluid. Of this IgG is the most important component and can be detected eight weeks post infection, but is largely undetectable by six months. IgA is produced by three to five weeks and is still detectable for up to a year after infection (Corbeil *et al.*, 1974). Despite recovery, the development of immunity and the establishment of normal pregnancies, *C. fetus* has been isolated from the vaginal mucus more than a year after infection (MacLaren & Agumbah, 1988), creating the potential for cows as well as bulls to maintain the infection in the herd from one year to the next.

The sampling technique most frequently used in bulls in Britain is the collection of sheath washings (BCVA, 1995) and phosphate buffered saline (PBS) is adequate for the lavage fluid provided samples are relatively free from gross contamination and transported to the laboratory within four to six hours. However, where immediate delivery to the laboratory cannot be achieved the use of transport enrichment medium (TEM) has proved to be effective in maintaining the viability of the organism (Hum *et al.*, 1994). A fluorescent antibody test is available, but does not allow differentiation between the two subspecies and it is of limited value in the diagnosis of the disease. Vaginal mucus should also be collected without gross faecal contamination and this can best be achieved by using pipettes with the end closed off and perforations made in the last few centimetres. Twenty ml of PBS are injected through a 60 ml syringe and then aspirated back, bringing with it vaginal mucus (Lander, 1983). As with sheath washings, TEM can be used if there is to be a delay of more than six hours between sample collection and the inoculation of media.

In the vaginal mucus agglutination test (VMAT) antigens prepared from *C. fetus* are used to detect agglutinins in the vaginal mucus. Immunoglobulin A is the antibody present in the mucus, but where serum or blood contaminates vaginal secretions false positives can arise as serum antibody to *C. fetus* is common in cattle (Wilkie & Winter, 1971). In addition, where cattle are in oestrus, large amounts of mucus is produced, IgA is diluted and false negatives can occur. Problems have been reported with the test and it has been suggested that only 50 per cent of infected animals will be positive by VMAT and of those 50 per cent will be negative six months after infection. An enzyme-linked immunoassay has been developed to overcome some of the problems experienced in using the VMAT (Hewson

et al., 1985; Hum *et al.*, 1991), but the test is not currently used in Britain.

As a consequence of the delay between infection and investigation in most herds and the cows' ability to clear the infection as well as the limitations of the vaginal mucus agglutination test it is necessary to sample a minimum of 12 cows. Where endemic infection is suspected animals in their first year in the breeding herd should be sampled to offer the best chance of achieving a diagnosis. Bulls should be sheath washed in the course of a herd investigation, but a negative result is of little value as the screening is a relatively insensitive test.

Artificial insemination using semen from campylobacter-free studs offers a simple and successful method of control, but for some herds, particularly where mating occurs at grass, this may not be practical. Vaccination is used in many countries where the disease occurs in range cattle and a vaccination programme to eradicate infection from within a herd has been described (Hum & MacInnes, 1987). Antibiotic treatment of the bulls is suggested as an additional measure (Hum *et al.*, 1993). However, there is no licensed vaccine in Britain and an emergency vaccine must be produced under the authority of the Veterinary Medicines Directorate (see Chapter 59).

Prevention can be achieved by maintaining a strict closed herd policy, but in practical terms the purchase of virgin heifers and virgin bulls does not constitute a risk. Difficulties arise where bulls have to be replaced at short notice. In these situations a synchronization and insemination programme would offer the safest course of action with a young unproven bull used to sweep up. If mature bulls are used these should be screened and treated with antibiotics (BCVA, 1995).

Miscellaneous bacteria

Species of bacteria associated only with sporadic abortions can be split into those that can be readily isolated from the posterior reproductive tract of the normal animal and those that cannot.

The former category includes organisms such as *Haemophilus somnus*, *Arcanobacterium pyogenes*, *Streptococcus dysgalactiae*, *Mycoplasma bovis* and *Ureaplasma diversum*. These may gain entry to the uterus through the cervix as a sequel to some other disease process affecting the fetus. It is possible that strain differences in virulence exist, but at the present time these agents should be considered to be of minor importance. Ureaplasmas have been suggested as important, but isolation methods for these organisms are rarely employed in diagnostic laboratories (Sanderson & Chenoweth, 1999).

The second category includes *Yersinia pseudotuberculosis*, *Mannheimia haemolytica*, *Erysipelothrix rhusiopathiae* and *Staphylococcus aureus* where infection of the fetus follows bacteraemia in the dam. *Arcanobacterium pyogenes* may also gain entry to the conceptus in this way and experimental infection via the intravenous route with this organism has resulted in abortion (Semambo *et al.*, 1991).

These infections are unlikely to represent a herd problem and as such do not merit further discussion.

Protozoal causes of abortion

Trichomoniasis

Bovine trichomoniasis is caused by the protozoan parasite *Tritrichomonas fetus* and is a venereal disease responsible for early embryonic death, infertility, pyometra and abortion. It is a particular problem in range cattle, where as many as 50 per cent of the herds may be infected (Dennet *et al.*, 1974). There is no recent report of the disease from within Britain, but there is no biological barrier that would prevent the disease from occurring here and diagnostic laboratories in Britain do not routinely use techniques that would identify the presence of this agent. Therefore trichomoniasis should be considered in the differential diagnosis in herds using natural service where infertility, abortions and pyometra are observed.

Although most pregnancies are lost at around 17 days after conception, one review reported that death can occur at any time up to the fifth month of gestation (Yule *et al.*, 1989), and fetal infection has also been demonstrated in late abortions and in full term calves (Rhyan *et al.*, 1988).

No specific gross changes are seen in the abortion material. Histological examination reveals lesions of placentitis and pyogranulomatous bronchopneumonia with evidence of tissue invasion with the parasite (Rhyan *et al.*, 1995). The organism can be cultured from vaginal discharges, preputial smegma and fetal tissues by using a specific medium in a pouch system (Kvasnicka *et al.*, 1996).

Trichomoniasis can be controlled through the use of artificial insemination and commercial vaccines are available in the countries where the disease is endemic.

Neosporosis (see also p. 283)

Protozoal abortion has been recognized as a problem in the dairy herds of California since the mid 1980s (Anderson *et al.*, 1991) and around the same time a protozoan parasite of dogs was identified in Norway

(Bjerkås *et al.*, 1984). This was subsequently named *Neospora caninum* (Dubey *et al.*, 1988) and the link was made to the infection of cattle (Thilsted & Dubey, 1989). Since then *N. caninum* has been identified as a cause of abortion in many parts of the world and a major volume of research publications has been generated (Dubey, 1999). Serological studies have found evidence of exposure to the organism in 16 per cent of aborted fetuses in Scotland (Buxton *et al.*, 1997) and in 13 per cent of cows that aborted in Northern Ireland (McNamee *et al.*, 1996). Outbreaks described range from 11 per cent of cows that aborted in one herd in England (Dannatt *et al.*, 1995), to as many as 57 per cent of a herd in The Netherlands (Wouda *et al.*, 1999). While neosporosis is a recently recognized disease there is nothing to suggest that the parasite or the disease is new.

Neospora caninum is an apicomplexan protozoan closely related to *Toxoplasma gondii* and although the complete life cycle of the parasite is still to be determined dogs have been shown to be a definitive host and to pass small numbers of oocysts in faeces from 8 to 23 days after experimental infection (McAllister *et al.*, 1998). Tissue cysts and tachyzoites have been found in cattle, sheep, goats and horses and it is possible that the intestinal stage of the life cycle is not limited to the dog. Vertical transmission occurs in addition to the point source outbreaks, where cows are presumed to be infected for the first time and abort. As post natal infection rates are probably as low as 1 per cent (Hietala & Thurmond, 1999) most cases are due to vertical transmission where an infection rate of 95 per cent has been found (Davison *et al.*, 1999). Infection of the fetus may often be a relatively benign event and care should be taken in attributing significance to evidence of infection in an aborted fetus (Thurmond *et al.*, 1997). Co-infection with other agents is often found and potentiation or the presence of factors that cause immune suppression in endemically infected herds may explain some of the cases that appear as epidemics (Bartels *et al.*, 1999).

Experimental infection of pregnant cattle has resulted in fetal death and lesions indistinguishable from those seen in naturally occurring outbreaks (Barr *et al.*, 1994). Abortion most frequently occurs in the second half of pregnancy and the commonly observed lesions are limited to placentitis, focal non-suppurative encephalitis, non-suppurative myocarditis and myositis and widespread non-suppurative infiltrates in other organs (Anderson *et al.*, 1991). The tissue cysts are well tolerated and the host response is limited to the tachyzoites. Histological examination of the fetus is important in order to determine the severity and therefore the significance of the lesions in terms of fetal death (Thurmond *et al.*, 1999). The histological appearance of

the lesions is considered significantly characteristic to warrant a diagnosis and immunohistochemistry gives further specificity to this. Autolysis often hampers examination although tissue cysts do survive and may be recognized. The fetus is capable of mounting an immunological response to neospora infection and detection of specific antibody in fetal or precolostral sera is a reliable indicator of fetal infection, but not of infection causing fetal death (Otter *et al.*, 1997). At present, despite the availability of molecular biological techniques for the detection of neospora DNA they are not routinely used for diagnostic purposes.

Maternal infection is followed by the production of antibodies within 14 days that peak by 46 days and in most cases the time lag between maternal infection and abortion is such that antibody production will have peaked before the abortion and may occasionally have fallen to undetectable levels by two months after the abortion (Wouda *et al.*, 1999). In the congenitally infected individual there is fluctuation in antibody level and at times antibody is undetectable. The observations that congenitally infected animals have been found to have a higher risk of abortion at their first gestation compared to the second gestation and that abortions occurred at an earlier stage in the first gestation than subsequently suggest the possibility of a protective immunity developing in infected animals (Thurmond & Hietala, 1997). Given the close relationships between neospora, toxoplasma and sarcocystis species there were concerns that serological cross-reaction could occur, however it has been shown that such cross-reactivity is negligible and of no importance diagnostically (Dubey *et al.*, 1996).

The lack of a complete understanding of the life cycle and knowledge of the range of definitive hosts has led to a cautious approach to control, but there seems a clear argument emerging in favour of culling seropositive animals from the herd. These have been shown to have lower levels of production and suffer a higher risk of abortion than seronegative cows within the herd. By using information from the literature in a mathematical model it has been shown that annual culling of seropositive animals was the most effective and rapid method of control. Effective control at a slower rate could be achieved if the action was limited to excluding the offspring from seropositive cows from the breeding herd (French *et al.*, 1999). At the present time the question of the cost-benefits of these strategies has not been addressed, but given the large outbreaks that can occur, action to prevent a sudden catastrophic, albeit low-risk, occurrence might be justifiable. Irrespective of culling practices, all fetuses, placentas and cattle carcases should be disposed of in a way that prevents recycling of *N. caninum* infection through definitive hosts.

Other infectious agents causing abortion

Chlamydia and rickettsia

Q fever, *Chlamydophila abortus* and *Cytoctetes phagocytophilia* have all been identified as occasional causes of bovine abortion. There is serological evidence of exposure to the agent of Q fever in Britain (Paiba *et al.*, 1999), but no recent report of abortion in cattle due to this agent. Occasionally a purulent placentitis and the presence of elementary bodies in modified Ziehl Neelsen stained smears of placenta and stomach contents are observed. Establishing the precise aetiology in these cases can be difficult, but *Chlamydophila abortus* has been isolated from such material and in one report the strain was found to be identical to that responsible for chlamydial abortion in sheep (Griffiths *et al.*, 1995). The outbreak may have been the result of close contact between cattle and an infected sheep flock on the same premises.

Cytoctetes phagocytophilia, the cause of tick borne fever (TBF), will cause abortion in cattle when first exposure to ticks occurs during pregnancy. Diagnosis can be difficult to confirm, as there is no longer parasitaemia by the time the abortion occurs. A presumptive diagnosis may be based on the herd history and the presence of ticks and antibody to the TBF agent.

Mycotic abortion

Mycotic abortion with placentitis and fetal infection is reported throughout the world. In one detailed study 7 per cent were mycotic abortions and *Aspergillus fumigatus* infection accounted for 62 per cent of these (Knudtson & Kirkbride, 1992). Other species of fungi have been reported and it would appear that most are opportunist pathogens. The source of these infections is often poorly preserved hay or ensiled feed that has undergone aerobic fermentation.

Placentitis follows a septicaemia that has resulted from either ingestion or inhalation of spores from the environment. The placenta is frequently thickened and may be of a leathery appearance. White plaques on the skin of the fetus are an occasional feature of this disease, but apart from this gross lesions are seldom observed. At the microscopic level hepatitis, pneumonia and placentitis are evident and Grocott's stain can be used to reveal fungal hyphae in fixed sections. Fungal elements can be seen on direct microscopy of the placenta and the stomach contents, the latter being diagnostic. These organisms are readily cultured from the fetus and the placenta, but environmental contamination after the abortion has occurred may explain isolation from the placenta alone.

There is little information on the development of

immunity after infection or whether the cow is likely to return to normal fertility.

Prevention of mycotic placentitis is by reducing the degree of fungal contamination pregnant cows are exposed to, particularly in preserved forage. Fungal growth occurs in other feedstuffs and bedding materials and after a diagnosis of mycotic abortion the management system should be reviewed in order to identify possible sources of these organisms. A visual examination of suspect materials may be sufficient, but where doubt over the source remains it is also possible to use quantitative culture methods to assess the degree of fungal contamination and to identify the organisms present.

Non-infectious causes of abortion

The failure to identify an infectious cause in many cases has led to the suggestion that non-infectious causes are of importance (Norton & Campbell, 1990). Nutritional factors that may be involved include excess dietary protein or non-protein nitrogen and selenium or iodine deficiency. Twin pregnancies are associated with shorter gestation lengths and an increased rate of abortion (Echternkamp & Gregory, 1999). Various poisonous plants have been implicated, but none is indigenous to Britain. Ponderosa pine (*Pinus ponderosa*) and locoweeds (*Astragalus* sp.) cause significant problems in some areas of North America. Deaths due to aflatoxicosis and to nitrate toxicity may be preceded by abortion, suggesting that either the fetus is marginally more sensitive to any toxic effect than the dam or that fetal death is the consequence of the clinical disease in the dam.

However, the literature fails to support non-infectious causes as a numerically significant cause of abortion in cattle (Norton & Campbell, 1990) and in the UK only iodine deficiency, manifest as hyperplastic goitre in full-term stillborn calves, is of importance. The condition is mainly reported in beef herds or in dairy heifers and is thought unlikely to affect dairy cows due to adequate dietary iodine intake. A threshold of 15 g for the weight of the intact gland, above which goitre is suspected, has been in common use. A better indicator is the ratio of thyroid weight to fetal body weight where the threshold value is 1:3000. However, oedema of the head and neck in stillborn calves can render this unreliable (Gee *et al.*, 1989) and histological examination of the gland to confirm the presence of a colloid goitre is recommended (Capen, 1993). There does not appear to be any suggestion that goitrogenic factors should be considered and the inclusion of iodine in an oral mineral supplement should prevent the condition (see pp. 257, 301).

Investigation

In abortion outbreaks in cattle herds abortions are frequently irregular and the single abortion may mark the start of an outbreak that does not become apparent for several weeks. An observed abortion may also represent a more extensive underlying herd problem and therefore there is justification for investigating every abortion. However, there are concerns over unnecessary costs and the diagnostic rate has been found to be higher in cases where there has been more than one abortion in the herd previously (Caldow *et al.*, 1996). Since there is a statutory requirement to report all abortions in Britain there is the opportunity to discuss the problem with the client and to carry out the investigations considered necessary in each individual case.

Investigations should follow a standard pattern:

- (1) History
- (2) Clinical examination of the cow
- (3) Necropsy of fetus
- (4) Collection of samples for the laboratory
- (5) Interpretation of results

History

The use of a standard form allows the systematic collection of the important details of the individual cow as well as production system, cow numbers, age structure, biosecurity measures, replacement policy and source of replacements (Fig. 37.1). Details on the feeding system and how feeds are stored are also of relevance. This can usefully be expanded to include details on herd fertility, retained membranes and any background clinical problem that may be of relevance. Careful evaluation of the information is essential to guide the investigation and to indicate the diagnostic tests to be employed.

Clinical examination

In most cases examination does not yield useful information, but it is important to exclude conditions such as acute salmonellosis, summer mastitis or tick borne fever and to allow treatment if the cow is ill. At this time a blood sample for serology should be collected and if salmonellosis is suspected a faeces sample as well. Where stillbirth is the problem the body condition of the cow should be assessed and other cows in late gestation can also be examined in this way. Where the majority of animals in the group have scores of 3.5 and above there is cause for concern over excessive body condition.

Even when it has been decided to limit diagnostic tests to those required for brucellosis, a serum sample can be stored frozen for possible retrospective examination.

Examination of the fetus and placenta

In the ideal situation, the entire aborted calf and fetal membranes with the appropriate samples from the dam should be delivered directly to a veterinary diagnostic laboratory. Where transport difficulties or other delays preclude this, the field veterinarian should collect appropriate samples while carrying out a necropsy of the fetus.

A standard approach to the examination should be adopted and the appropriate information recorded. The measurement of the crown–rump length can give an approximation of gestational age. A formula to estimate the fetal developmental age from the crown–rump measurement is $x = 2.5(y + 21)$, where y is the crown–rump length in centimetres and x is the gestational age in days. Measurement of the weight of the carcase is particularly important in stillbirths to explore the possibility of dystokia due to fetal maternal disproportion and for comparison with thyroid weight, for the diagnosis of hyperthyroidism.

Other important features to be aware of include the presence of white plaques of fungal hyphae on the skin of fetuses where there is fungal involvement. Meconium staining of the perineum or the presence of meconium in the airways or fetal stomach indicate fetal anoxia consistent with placentitis or the prolonged parturition of dystokia. Haemarthrosis of the shoulder or hip joints may be seen in dystokia cases. Traumatic lesions in fetuses where dystokia has not been the problem are occasionally observed and while trauma may be the cause of the abortion other causes should not be excluded too early in the investigation. Lesions of pericarditis, pleurisy, pneumonia or hepatitis can all be found on the gross examination, but none of these changes is specific. In calves that have lived for a short time after birth it is important to record whether the calf has fed as this prevents useful bacteriological examination of the stomach contents, but also means that maternal antibody may have been absorbed, interfering with fetal serological tests.

When the placenta is available as much of the surface area of the allantochorion as possible should be examined. Lesions can be focal and may be overlooked if insufficient care is taken. Commonly observed lesions are intercotyledonary thickening, necrosis of cotyledons and adventitious placentation. The last lesion is considered to be a chronic response to insufficient placental area and is seen following placentitis.

Collection of samples for laboratory investigation

If samples are collected in the course of a necropsy on the farm, the collection and transport of samples to the laboratory should have been discussed with the laboratory personnel. The samples required and the means of

Fig. 37.1 A standard form to collect systematically important information when investigating fetal losses.

preservation are determined by the causes of abortion that occur in an area and on the diagnostic facilities available to the laboratory. Nevertheless, basic rules do apply.

The minimum sample required for bacteriology is fetal stomach contents. These can be collected using a sterile vacutainer and needle through the unopened abomasal wall. Where the placenta is available a cotyledon representative of the lesions observed should also be submitted fresh. Samples may also include fetal liver and lung, allowing slightly higher diagnostic success for some bacterial causes of abortion. It has been suggested that in cases where the fetal membranes have been retained a placentome is removed manually *per vaginum* (Johnson *et al.*, 1994) for bacteriological and histological examination. However, this is not required when the fetus is available for examination.

Fetal blood or fluid can be collected from any body cavity, again by using a vacutainer. This sample is used for serological tests for BVD, neospora and leptospira. Fetal thyroid, spleen, kidney and brain are all tissues that can be used for virus isolation for BVD, while the placenta is the sample of choice for BHV1.

Histopathological examination is particularly useful to determine the significance of fetal infection with *N. caninum* or BVD, to confirm the significance of apparent thyroid enlargement and for further investigations where the standard screen for infectious disease is negative. The tissues of most value to collect are brain, lung, liver, thyroid (in stillbirths) and a cotyledon. It is important to be guided by the pathologist as to how these samples should be fixed. Tissues for histology must never be frozen.

The minimum samples are fetal stomach contents for bacteriology and fetal blood or serum for serological tests. These may be the samples of choice when investigating what appears to be a single abortion. If subsequent abortions occur then the range of tests can be extended.

Interpretation of results

When evaluating results it is important to consider them in relation to the diagnostic criteria for each disease. Hence, while the presence of antibody to BVD or to *N. caninum* is considered to indicate fetal infection, it must be remembered that infection of the fetus need not necessarily be lethal, especially as gestational age increases. Similarly, the isolation of foetopathic bacteria or fungal organisms from the placenta in the absence of histopathology is of no value as they may arise from environmental contamination after the placenta has been passed.

In the majority of infections maternal infection

precedes abortion so that paired serology is valueless. As many of the infections of importance tend to be endemic and circulating antibody may persist for long periods the presence of maternal antibody at the time of the abortion can only be taken to show that the cow has been exposed to the agent. The converse applies when the MAT is used for leptospirosis as the IgM antibody response can be so transient that the dam may be seronegative at the time of abortion.

In essence, serology tests in the dam are of more value when used to exclude infection with negative results than to attempt to confirm a diagnosis with positive results. This should not discourage the use of these techniques to establish whether or not there is evidence of these diseases in the herd, as control strategies may still be required.

Evidence of the involvement of several infectious agents is often found in the course of an outbreak, underlining the importance of proper evaluation of the results, but also raising the question of a potentiation effect amongst agents.

Prognosis

For the individual cow the prognosis is usually favourable as long as any systemic disease or uterine infection is detected and treated. After abortion, oestrous cycles start quickly and, in general, subsequent pregnancy rates are satisfactory. Prognosis for the rest of the pregnant animals in the herd is a more serious consideration and varies with the diagnosed cause of abortion.

Conclusion

Abortions are often the most obvious manifestation of an underlying herd problem that may be of significant financial importance to the owner of the cattle herd. Failure on the part of the veterinary surgeon to pursue or advise correctly could have a severe penalty for the producer.

Introduction

Since the domestication of cattle the bull has been a talisman and the desire to own a special bull a particular urge in all stock rearing countries. The bull is a symbol of power in the East, where Indra the sky deity is represented in myth as a mighty bull, while in the West as an example there is the Celtic legend of the Brown Bull of Quelgny stolen by Queen Mae of Connacht from Dara in Ulster only to be retrieved by the hero Cuchulain. Time has not diverted man a great deal from this interest in bull lineage and the performance of his offspring! The development of methodologies to assess the transmission of superior economic traits from bulls to their progeny over the last 50 years has been one of the success stories of the cattle industry. However, like the Brown Bull the truly outstanding sire is still very rare and the purchase of a young unproven bull is a gamble. Despite this the repeated need for young bulls (no bull is immortal) means that many are bought with this vision in mind, despite the difficulties in achieving it.

When all breeding was by natural service the potential for genetic improvement by a good bull was very limited. Furthermore, selling, sharing and hiring animals resulted in the spread of venereal disease with some disastrous results for those affected farms. Artifi-

cial insemination (AI) has proved to be one of the most successful reproductive technologies and it became a commercial reality in the UK just before the end of the Second World War. AI has fulfilled two objectives: firstly, it set in motion more focused genetic improvement coupled with the widespread use of good bulls and secondly, it has limited the spread of venereal diseases. Unfortunately, the expression of oestrus in the cow varies in time of occurrence, duration and intensity and many farmers find accurate and, more particularly, efficient oestrous detection difficult and time consuming. Furthermore, particularly in large beef suckler herds under essentially range conditions, oestrous detection and the handling of cattle for AI are less practical. These factors ensure that many farmers continue to use natural service entirely or partially even though, due to the genetic improvement from AI, dairy farmers in particular could afford to have a longer calving interval and yet still expect to have the same financial returns (Hillers *et al.*, 1982; Stott *et al.*, 1999).

The problem is illustrated by a study of UK national cattle population statistics where only approximately half the cows are bred by AI (Logue & Isbister, 1992), this figure being considerably higher for the dairy herd. Although confidentiality has stopped many of these statistics being easily available in the UK we have no reason to believe the proportion has changed. However, this figure may increase following the 2001 foot and mouth disease outbreak. In the USA the proportion bred by AI is probably a little higher (70 per cent). In addition, there have been a number of factors that have counteracted the undoubtedly improvements in the efficiency of AI.

- (1) The economics of dairy and beef production have resulted in a general trend to larger herds with fewer staff and so less time available for oestrous detection. Furthermore, the continuing financial pressure to cut costs has also made many dairy farmers economize by changing from paying for a technician AI service to inseminating their own cows (DIY AI). Many of these people keep a bull as a precaution against poor fertility arising from a doubtful insemination technique. Unfortunately, no figures are produced for the number

Table 38.1 Number of cows in DIY AI herds (Anon. 1988).

| | England and Wales | Northern Ireland | Scotland | Total |
|---|-------------------|------------------|----------|--------|
| DIY licences | 3300 | 1000 | 700 | 5000 |
| Average herd size | 69 | 37 | 89 | — |
| Number of cows | 227700 | 37000 | 54300 | 319000 |
| Cows inseminated (assuming 75%) by DIY AI | 170775 | 27750 | 40725 | 239250 |

Table 38.2 UK dairy cattle statistics (Anon. 1979, 1988, 1998).

| Year | Cow numbers × 10 ⁶ | Herd size |
|------|-------------------------------|-----------|
| 1960 | 4.01 | 20 |
| 1970 | 4.55 | 31 |
| 1980 | 4.69 | 55 |
| 1990 | 4.43 | 67 |
| 1997 | 4.41 | 72 |

of cows inseminated in the DIY AI sector in the UK. However, census data, the number of DIY AI licences issued by area and the assumption that 75 per cent of the cows in each herd are inseminated does allow an estimate (Table 38.1). It can be seen that DIY AI probably accounts for less than one in five of all dairy cow inseminations in the UK.

(2) The gradual increase in herd size has meant that the added costs of keeping one or even several bulls are relatively lower per unit of production. For example, in the UK, dairy herd size has increased dramatically over the last 30 years (see Table 38.2), and this has been mirrored in Europe and in virtually all countries with an advanced dairy industry.

(3) A further effect of the larger number of cows per herd has led to a more predictable production of heifer replacements because the male:female ratio remains nearer to the expected 50:50 as the numbers increase. This has meant that a definite block of heifers of similar age can be released for natural service.

(4) In many beef and dairy herds, calving, and thus breeding periods, are concentrated into relatively short periods of time for production and management reasons. This leads to a requirement for high oestrous detection rates and high fertility, both of which are best achieved by using a combination of AI and natural service.

(5) Finally, in the past an important reason for using AI was to reduce the introduction of disease. With the

increasing improvement in the health status of the national herd in many countries there is less pressure for AI use for this reason alone. However, this confidence is likely to be misplaced unless the farm takes adequate precautions when acquiring bulls.

Bull use in the UK

It is worthwhile defining the various types of herd breeding policy since this will influence the management of the bull and may give a guide to the needs of the unit with regard to disease control.

Four basic types of policy can be recognized:

(1) *Beef suckler herd.* The principal demand is to produce calves for finishing. The cows are mated while suckling. For many years and in most geographical locations it has been axiomatic that this system operates at highest efficiency when there is a short (but efficient) breeding period (Kilkenny, 1978). Ideally this should be less than 10 weeks and demands very high levels of fertility in both bull and cow.

(2) *Dairy heifers.* A considerable proportion of dairy herds use natural service when breeding heifers. This is mainly to avoid oestrous detection and the need to gather the individual heifer for AI when often these are run on a more remote area of the farm.

(3) *Sweeper bull.* This term usually refers to the running of a bull after a fixed period of 'AI-only' breeding. Generally, in dairy cattle, the bull used is a beef breed and thus any calves born are easily distinguished from purebred dairy calves. The use of synchronization and fixed-time AI with batches of maiden heifers using an easy-calving sire has to some degree replaced natural service in both dairy and beef heifers, but in many herds those heifers that return are served by a sweeper bull. The timing of the introduction of the sweeper is paramount since mating pressure will obviously depend on the number of non-pregnant cows or heifers left after the AI breeding period. Clearly a

drop in the pregnancy rates achieved with AI can result in an increase of mating pressure.

(4) *Modified sweeper*. The sweeper bull is utilized for mating selected cows throughout the breeding season, for example cows of low genetic potential, repeat breeders, cows not exhibiting firm signs of oestrus and cows with a history of being difficult to get in calf. Subsequently, the bull is used as a 'true' sweeper.

Finally, a minority of dairy herds still primarily use natural service.

The role of the veterinarian in bull use

The role of the veterinarian in the control and monitoring of bull fertility is three-fold (see Box 38.1). Veterinarians should be authoritative in these roles for their clients or be able and willing to refer matters to another veterinarian with the appropriate resources if the occasion demands.

Preventing infectious infertility and other diseases

Before considering the reproductive performance of the bull on the farm the first priority must be to keep disease out! No veterinarian or farmer should be without some appreciation of the risks that are being taken by the purchase of a bull (or even semen or embryos). In addition to the notifiable diseases (such as foot-and-mouth disease) there are a whole plethora of others that can cause economic loss. Unfortunately in the past, farmers in the UK, and for that matter elsewhere, have been pretty cavalier in their attitude to introducing disease. Veterinarians, by discussing these issues with their clients, can do much to reduce the risks of introducing disease and so protect the viability of their clients' farms. The loss of output arising from the

Box 38.1 Role of the veterinarian in bull fertility.

- (1) Preventing the introduction of infectious infertility and other diseases to the farm
- (2) Assessing fertility and the level of investigation that is needed:
 - (a) before purchase
 - (b) after purchase
 - (c) before use each breeding season
 - (d) after poor fertility results
- (3) Monitoring herd fertility (including the bull) by the assessment of breeding records

damaging effects of infectious disease impacts significantly on efficiency.

The most important source of infectious disease for cattle is other livestock, particularly cattle. Uncontrolled movement of a bull into a herd carries a significant risk of introducing disease. This can be minimized by the following measures but presupposes that other biosecurity precautions are in place:

(1) Bulls (and any other cattle) should be purchased only from herds certified free from specific diseases of concern by reputable cattle health schemes such as those registered with the Cattle Health Certification Standards (CheCS) body in the UK. While individual farm programmes can be undertaken or declarations made by the farmer and his veterinarian to the effect that a particular disease has not been seen, clearly these will have less certainty. The latter point is illustrated by Kallis *et al.* (1999) who revealed by faecal culture that 40 per cent of 100 Dutch dairy herds considered to be free of Johne's disease on the basis of owner and veterinary declaration were actually infected.

(2) Quarantine incoming cattle before entry into the main herd to allow testing for diseases that may be carried and development of any incubating diseases. In most cases four weeks should suffice, but this depends on circumstances and the diseases under consideration. Quarantine could also be applied to other species of livestock entering the farm that potentially carry diseases infectious to cattle.

(3) During the quarantine period an adequate testing programme and/or prophylactic treatment against diseases of concern should be employed. The latter may be necessary where testing is unreliable or gives an equivocal answer (e.g. for venereal campylobacteriosis and *Leptospira hardjo*).

The diseases of importance vary with country and area and are determined by the economic or practical importance of the disease, an assessment of the risk of introducing the disease, the availability of low cost and reliable tests and whether or not the disease is already present in the herd. In the UK the following non-statutory diseases are suggested as being worthy of consideration based on their prevalence and the economic impact that they may have on the herd.

Bovine virus diarrhoea virus (BVDV)

Infectious bovine rhinotracheitis virus (IBRV) (bovine herpes virus 1 [BHV-1])

Leptospira hardjo

Johne's disease (paratuberculosis)

Venereal campylobacteriosis

Salmonellosis (especially *S. dublin*)

Whilst neosporosis is a significant cause of bovine reproductive failure any epidemiological role of the bull is undetermined and the reliability of current laboratory tests for detecting carriers remains questionable. However, the precautionary principle suggests it is unwise to acquire bulls bred in herds infected with *Neospora caninum* at least until more is known about this infection. Outside and unfortunately even within the UK, diseases considered notifiable in the UK such as brucellosis and tuberculosis also need to be considered.

The two most important true venereal diseases are trichomoniasis and campylobacteriosis, although there is evidence for the venereal transmission of some *Ureaplasma* sp., *Mycoplasma bovigenetalium*, BHV-1, brucellosis and even *Haemophilus somnus*. Bovine trichomoniasis is a venereal disease characterized by early to mid-gestation pregnancy losses, reduced calving rates and pyometra; it is caused by the flagellated protozoan *Tritrichomonas fetus*. As far as is known, it is transmitted by venereal contact only. Campylobacteriosis, which also presents as a large increase in returns to service with early to mid-gestation pregnancy losses, is classically caused by *C. fetus venerealis*. However, there is evidence that this organism does not always follow the classic laboratory identification procedures and this has led to the proposition of *C. fetus intermediatus*, which also appears to cause the same clinical problems in cattle. This organism has many of the properties of *C. fetus fetus*. In these two venereal infections the bull is the long-term carrier of the organism, apparently without ill effects (i.e. no visible lesions are evident in recently or chronically infected bulls) and a distinct correlation exists between age and infection, with older bulls being far more likely to sustain an infection than younger bulls. Infection of the female occurs at the time of coitus. Diagnosis of campylobacteriosis in the female is by examination of vaginal mucus, collected by the method of Lander (1983), for antibody by the vaginal mucus agglutination test (VMAT) and for the bacterium by culture. Since antibody takes some time to appear after an infected service and false negative VMAT results are common, at least 12 cows should be sampled at least 50 days after a potentially infected service. Cows with blood in the mucus can give false positive results and cows in oestrus are more likely to give false negative results and such animals should not be sampled. In the bull, demonstration of the *Campylobacter fetus* bacterium in preputial washings by fluorescent antibody test and culture is used in the UK for diagnosis. Where samples of vaginal mucus or preputial washings are collected with a view to culture they should reach the laboratory within six hours of collection due to the fragility of the bacterium. Alternatively, samples can be submitted in transport

enrichment medium. Negative laboratory results in the face of a strong history of infertility and natural service and no other obvious causes should be viewed with suspicion.

Preputial washing

The method of preputial washing used routinely by the Scottish Agricultural College is summarized below.

Protocol for sampling bulls for Campylobacter fetus sp. screen

Materials required:

- Recovery fluid: 60ml phosphate buffered saline (PBS) (sterile).
- Sampling catheter: 10cm length of 3.5 × 6.5mm portex tubing (sterile).
- 60ml syringe: attached to catheter (sterile).
- 3 × 20ml sterile sample bottles.
- Individual set of sampling materials for each animal sampled.

Procedure:

- Clip preputial hairs.
- Wash preputial orifice with warm water. Do not disinfect.
- Load syringe with 60ml warmed PBS.
- Insert catheter as far into prepuce as possible. Clamp one hand over preputial orifice to seal around catheter and hold it in place (use hand nearest bull's head to facilitate massage with the other hand).
- Pass 60ml warmed PBS through catheter. Leave syringe in place.
- Retain fluid and catheter in prepuce by continuing to clamp one hand over preputial orifice and massage thoroughly along full length of prepuce to scrotum for one minute.
- Collect fluid into the original syringe by withdrawal using the plunger as the catheter is slowly withdrawn.
- Dispense sample into sterile containers and label.
- If the bull urinates during collection the sample should be discarded and the process repeated.
- All samples should be submitted to the laboratory within 6 hours of collection.

With preputial washings false negative results are again to be expected on a single screening, indeed four screenings have been recommended (Dufty, 1967) before a bull can be confidently declared free of infection. A more practical approach to reducing the risk of introducing this infection may therefore be prophylactic treatment of purchased, previously bred bulls by

preputial lavage with penicillin and streptomycin antibiotic (Melrose *et al.*, 1957) during the quarantine period. This could be refined by employing prophylactic treatment after a single negative preputial wash screening. Nevertheless, the most reliable way to prevent introduction of this infection is to acquire only unbred males and females. Control in infected herds is by disposal of infected bulls, suspension of natural service and use of AI with uninfected semen for 2 years (Clark, 1971) for all exposed cows, thus allowing the cows to develop immunity and eradicate the organism. Where this is not practicable, use of autogenous vaccine (there is no licensed vaccine in the UK), only using young bulls (<4 years) or operation of 'clean' and 'dirty' herds should be considered. The problems of diagnosis and control of venereal campylobacteriosis should not be underestimated and the reader is referred to Caldow and Taylor (1997) for a more detailed discussion of the subject in suckler herds.

Infectious disease control

Control of infectious disease is very dependent on an assessment of the risk of introducing the disease and on the quality of diagnosis, either of the disease or the carrier state, using laboratory tests. For example, in the UK bulls are not usually tested for trichomoniasis as it has not been diagnosed in home bred animals for many years. However, other diseases such as BVDV are very common and campylobacteriosis is not usual. In the first instance the background of the bull must be considered with regard to whether it could have been exposed and, as a consequence, be a potential carrier of any disease. Furthermore, when subsequent testing is contemplated the limitations of laboratory testing regimes specific for each disease must be appreciated before exclusion is considered. For example, testing individual healthy animals for antibody and/or by faecal culture for the presence of infection with the bacterium of Johne's disease leads to a high proportion of false negative results. Therefore, exclusion of this disease is best achieved by purchase of bulls from herds monitored free of Johne's disease under a reputable cattle health scheme rather than by individual animal testing and quarantine. Knowledge of the effects of disease, methods of control and the laboratory technology to detect disease is continually advancing. Understanding and awareness of BVDV in particular have improved greatly over the last decade. The infection is widespread in the UK and recent estimates of associated losses, which primarily arise from reduced fertility and abortion, suggest that these can be over £45 per cow annually in an infected suckler herd (Gunn *et al.*, 1998). Relatively recently, truly cost-effective control schemes have become a realistic option for certain diseases

(BVDV, IBRV and Johne's disease in the UK). However, as some may remember, lack of appreciation of the organism and its epidemiology meant that a pilot attempt to control *L. hardjo* by MAFF was not successful. Some hard lessons were learnt which have been applied to these new schemes.

Another consideration is whether the bull might itself be at risk of being infected by cattle in the herd it is being introduced to and so having a period of infertility as a result of illness. Completion of a vaccination programme during the quarantine period for the bull might be considered in light of knowledge of the disease status of the herd.

Investigation of bull infertility

Bull infertility is presented as one, or a combination of the four manifestations, namely:

- (1) Failure to mount
- (2) Failure to achieve intromission
- (3) Failure to thrust and ejaculate
- (4) Poor pregnancy rate with normal service behaviour

A wide range of conditions can cause each of these. Not only are the aetiological factors varied and numerous but also the management of the bull can contribute to the infertility. Consequently only by obtaining a good history of the bull (including previous fertility) and his present circumstances can one gain an informed appraisal of the most appropriate way in which to conduct the assessment of fertility.

Diagnosis is based upon a combination of bull and herd history, examination of the bull and the results of the various tests that are undertaken including an examination of a representative ejaculate of semen. Even if the diagnosis is tentative and the aetiology uncertain the findings will probably allow a prognosis and may give a rationale for treatment.

History

All investigations of bull fertility are built upon the usual prerequisite of obtaining a good history of the problem. This clearly involves both records of any bull in question but should also entail assessment of the herd as a whole. Usually the client will have given some information about the bull by telephone and, ideally, will have presented some farm records for perusal prior to the examination. At the outset, ask and record the answers to the questions in Box 38.2. One is looking for an estimate of the extent of the infertility by comparison to other bulls, when it was first manifest, if it has been continuous or varied and so on.

Box 38.2 Information required to define the problem.

Type and breed of bull?
 Age?
 Demeanour?
 Ringed?
 Type of herd?
 Role of bull in herd?
 When and where acquired and time with herd?
 Calves previously born to the bull?
 Extent and duration of problem?
 More than one bull with a problem?
 Can the problem be related to introduction of a new male or female?
 Are AI figures available for the same period?
 Is there an insurance/sale agreement status?

In cases where points (1) to (3) above apply it may be possible to give a firm diagnosis and an accurate prognosis based on the history and visual examination of the bull when presented with a cow in season, i.e. without even collecting and examining a semen sample. However, depending on circumstances it may still be advisable at least to attempt to collect a semen sample, even if only to confirm the history.

Examination of the bull for breeding soundness

The objectives of the visit to the farm are:

- To see the conditions under which the bull is expected to work.
- To confirm that the history is reliable and, if possible, to examine records.
- To examine the bull. In order to study semen for abnormal characteristics the operator must use a technique to obtain and prepare semen for examination that will be representative of the ejaculate of the bull in natural service.
- To ascertain the status of the bull as a possible vector of reproductive disease and possibly other diseases of a less specific nature but just as important from an economic point of view.

Where an infertile bull is suspected the following simple preliminary breeding soundness examination steps are worth considering before conducting a full breeding soundness examination which includes semen collection.

- (1) Ascertain by personal observation or a reliable report from the farmer whether or not the bull is serving normally.
- (2) Physically examine the bull for any obvious genital or other abnormalities. Bulls aged 2 years or more with a scrotal circumference of 30cm or

less are more likely to be infertile or have a lower than 'normal' fertility.

- (3) If the cause of the problem is not clear from (1) and (2) above and/or the bull is under a sale agreement or insured for infertility then it is necessary to consider a full breeding soundness examination. However this is not to be undertaken lightly and firstly we recommend consideration of:
 - (a) Sale agreement: if the time period for a claim has not elapsed ensure the farmer has contacted the market or vendor, informed them of the complaint and checked that a full breeding soundness examination will support the claim.
 - (b) Insurance case: ensure that the farmer has contacted the insurance company, informed them of the complaint and checked that the policy covers infertility and that a full breeding soundness examination will support the claim.

The goal is to obtain a cost-effective resolution to the problem. It may be very attractive to examine the semen of the bull but is it really necessary? For example, if there is a clear history of infertility and severe testicular abnormalities are found on physical examination of a commercial beef bull, then clearly one is not going to recommend that the bull is used as a reliable sire. Collecting and examining semen will be of little additional value to the client unless demanded by the insurance company. Once it is clear that a full breeding soundness examination is required a decision as to who will carry this out should be made. Referral within the practice or elsewhere may be needed to access the necessary expertise and equipment.

The order of events for the full breeding soundness examination should be:

- (1) Define the problem.
- (2) Prepare for the visit.
- (3) Set up the on-farm laboratory.
- (4) Assess the collection area and ability and reliability of the farmer and other animal handlers.
- (5) Introductory examination of the bull.
- (6) Semen collection and assessment.
- (7) Observation of natural service.
- (8) Full physical examination of the bull.
- (9) Collection of other diagnostic samples.
- (10) Preliminary diagnosis, prognosis and advice (e.g. treatment or sexual rest).
- (11) Final diagnosis, prognosis and advice after all test results are known.
- (12) Further action for the herd and its future breeding management.

Define the problem

This is often less easy than might be assumed and is based on the answers to the questions in Box 38.2 and on the information derived from the preliminary breeding soundness examination steps described above. On occasion the history is vague and the farmer is uneasy about this and the fact that his records may be inadequate. Careful and sensitive questioning may be needed to avoid missing some obvious point. In most cases where a full breeding soundness examination is being carried out the manifestation will be poor pregnancy rate with normal service behaviour. However, some remain undefined beyond infertility seen as 'too many returns' until semen collection is attempted.

Prepare for the visit

A full breeding soundness examination can go smoothly and efficiently and be completed in a couple of hours or alternatively take most of the day and not achieve a collection. Furthermore, it is potentially dangerous. Success, efficiency and safety all depend on good organization and attention to detail. Generally speaking a convenient date will be set for the examination and all parties involved (man and beast) need to be organized accordingly. The following factors, if they can be arranged, should help to make the visit go more smoothly and efficiently:

- (1) For a full clinical examination and for semen collection it is desirable that the bull be restrained, that he can be led on a halter and, ideally, that he should be used to serving while being restrained by a halter or ring-rope. The reasons for this are obvious but in our experience with fewer staff on farms, bulls are much less used to being handled and therefore restraint is often counterproductive. This leads to difficulties in reconciling the safety of the collector and handlers with the desire to obtain a good semen sample.
- (2) The bull should be sexually rested for at least one but preferably three weeks prior to the visit. This will enhance his libido and avoid depletion of semen reserves, ensuring the best chance of obtaining a representative sample of semen.
- (3) A quiet cow in oestrus, preferably halter-trained and that has not been served at that oestrus, should be available as a teaser. Synchronization with a progesterone releasing intravaginal device of at least six females, in our experience, maximizes the chances of one or preferably more being available on the allotted date. While keen young dairy bulls will usually mount a quiet non-oestrus cow, our experience is that collection can still prove difficult, particularly with inadequate

restraint and facilities. For experienced beef bulls it is definitely a case of no cow in oestrus, no collection!

- (4) There should be suitable facilities for restraint and examination of the bull, e.g. crush with removable sides to allow access to the penis and prepuce.
- (5) A suitable roomy fenced area with a non-slip surface and with an escape route for the collector should be available to allow collection of semen. This can be inside or outside.
- (6) Instruct the bull handler or those helping in the sequence of events, especially in relation to the bull mounting for collection.
- (7) Any cows that have been running solely with this bull should be nearby for pregnancy diagnosis or sampling (vaginal mucus or blood) should the occasion demand it. Unfortunately, often another bull will have remated these. However, even then examination may allow confirmation that the cows have conceived to the second bull.
- (8) If possible, another bull should be available nearby. This can be useful to confirm the teaser

Box 38.3 Check list for breeding soundness kit.

- Artificial vaginas, liners, cones, cord and adhesive tape
- Semen collection tubes (preferably graduated)
- Lubricant for artificial vaginas (e.g. KY jelly)
- Kettle and jug to fill artificial vaginas with warm water
- Thermometers to measure artificial vagina temperature
- Electro-ejaculator(s)
- Two funnels and wire funnel holder for collection of electro-ejaculated semen
- Electric plug adapters and circuit breakers
- Electric extension cable
- Microscope and light source
- Warm microscope stage
- Heated cabinet
- Transformer packs
- Stains: nigrosin–eosin, Giemsa and methylene blue
- Small test tubes and holder for use in staining and diluting semen for examination
- 2.9% sodium citrate, 0.9% NaCl and phosphate buffered saline
- Glass pipettes and rubber bulbs
- Slides, coverslips and slide holder box plus slide labels
- Small sterile bottles for fresh semen samples
- Immersion oil
- Paper wipes, cotton wool and swabs
- 50 ml syringe with tubing, phosphate buffered saline and sterile containers for preputial wash
- Tape measure (for scrotal circumference)
- Vacutainers, needle holder, needles and spirit
- Virus and *Mycoplasma* transport media
- Record sheets, slide markers and pens
- Spare light bulb for microscope

Fig. 38.1 The on-farm laboratory.

- cow is in oestrus when the bull under test has failed to mount.
- (9) Use a checklist of equipment and materials (see Box 38.3).

Set up the on-farm laboratory

This should be set up on arrival so that there is time for the heated cabinet, solutions, glassware and warm stage to reach the required temperature. Select a small area of bench space, which is covered, has an electricity supply and is not exposed to adverse weather (Fig. 38.1). It should be as near the area of semen collection as possible. Given the standard of some farm electrics a circuit breaker is a wise investment.

The on-farm laboratory should contain the following:

- Microscope with facilities to examine semen by $\times 50$ to $\times 100$ (for initial motility) by $\times 200$ to $\times 400$ (for progressive motility) and $\times 1000$ (for morphology).
- Warm stage (or equivalent). This is a prerequisite for the reliable estimation of motility. Ideally, it should be kept within 1°C of 37°C because either a high or low temperature can have considerable artefactual effects upon sperm motility. Unfortunately, this equipment is quite expensive and therefore many veterinarians use a small prewarmed flat bottle or brass plate as an alternative. If this approach is used then it is best to have two so that they can be alternated and so kept at as steady a temperature as possible.
- Heated cabinet. While it is possible to use the farm kitchen oven to keep slides, coverslips, pipettes and stains, regulation of a reasonable temperature range (35–40°C) is often difficult. For this reason it is

preferable to have a small portable cabinet specifically designed for this type of activity.

- Stains. It is well worthwhile using more than one stain routinely. The most commonly used are nigrosin–eosin and Indian ink for sperm morphology, methylene blue for examining the semen for extraneous cells and Giemsa for a combination of the two. Nigrosin–eosin and Indian ink are used directly, i.e. after preheating to 37°C they are mixed with the semen immediately after its collection and a smear is then made. The second stains are used on a direct smear of the semen, which is air-dried and then fixed before staining.
- Solutions to dilute semen for examination of progressive motility. A normal saline solution may suffice, although solutions commonly used for diluting semen are phosphate-buffered saline or 2.9 per cent trisodium citrate. These solutions should also be preheated to as near 37°C as possible.
- Artificial vagina (AV). In general, inexperienced bulls prefer rough liners and younger bulls a shorter artificial vagina, i.e. about 25 cm long. At least two should be assembled (Fig. 38.2) and be filled with warm water (prepared in an electric kettle for example) to a lumen temperature of about 60°C (they will often have cooled to around 45–48°C by the time they will be used). The lumen temperature should be between 42 and 50°C immediately prior to semen collection and this must be checked with a thermometer. In practice it is best to enter the collection area with the AV at 50°C since there will inevitably be some cooling before a collection is made. A sterile lubricant should be applied to the opening of the AV immediately before going to the collection area.

Fig. 38.2 Assembly of the AV. A 30 cm long rubber AV cylinder with latex liner and cone favoured by the authors for collection from adult bulls. A valve on the filling aperture conveniently permits air to be blown in to finely adjust the internal pressure. The graduated collecting tube is anchored to the cone by string and is protected thermally and physically by enclosure in a clear plastic container secured with adhesive tape. A small (1–2 cm) slit can be made in the cone near the AV to act as a safety valve. This reduces the risk of disconnection of the cone or collecting tube that may occur during the thrust if there is too high a pressure in the AV. The AV cylinder is disinfected between bulls and the latex can be sterilized by boiling.

Assess the collection area and ability and reliability of the farmer and other animal handlers

It is worth looking at where the farmer thinks it best for the collection to take place. Remember that while he or she may not understand the needs of collection well they do know the bull much better than you do! Some bulls can be totally inhibited in the wrong surroundings. Ideally, one should work in the place where the bull normally serves the cows. A good surface will encourage a bull to mount, for example a bull with laminitis or an old bull will often work better on a relatively soft

Fig. 38.3 On-farm semen collection in a straw yard using an artificial vagina (AV). The bull is searching for the vulva of the teaser cow. The collector is diverting the penis towards the AV.

surface such as grass or a firm straw bed rather than on concrete (Fig. 38.3). However, in most circumstances the latter is the preferred surface since it generally gives a sound secure footing. The bull falling causes most injuries to collectors. It is for this reason that most AI centres use service stocks and obviously if these are available they should be used. However, whatever adaptation or compromise is used, the collector must remember that his safety and that of the others involved is paramount. The main prerequisites are common sense, plenty of room and a safe footing. Listen carefully to all remarks about the demeanour of the bull. Be aware that sometimes farmers may be carried away by the novelty of this examination. Try to discourage bystanders!

Introductory examination of the bull

If practical it is worthwhile giving the bull an initial cursory examination prior to collection, gently running one's hands over the bull, touching the prepuce and genitalia. This allows the bull to get used to the personnel involved, particularly the collector of semen, and also allows the collector to judge what size and pressure of artificial vagina might be best and how the bull is likely to react to collection. Remember frightened bulls are dangerous.

Semen collection and assessment of ejaculate

The libido of the bull and the likelihood of a successful semen collection can be enhanced by allowing him to have sight and sound of one or more oestrous cows

without physical contact for a short while before collection is attempted. It is important to interfere as little as possible with the normal service behaviour of the bull to obtain a representative ejaculate. The best technique for the collection of semen is therefore the use of an artificial vagina. The teaser cow should be restrained in the collection area. The bull is held separately, but nearby, from where he can be introduced for the collection and returned immediately afterwards to avoid repeated service of the teaser between collections. The teaser cow is an important factor in obtaining a representative semen sample. A teaser cow in oestrus will stand to be mounted. This is very important, particularly with an experienced beef bull, which will generally refuse to mount if the cow does not stand steadily when the bull 'tests' her. Furthermore, since many bulls are not used to being handled and therefore have to be allowed to mount free of control it is wise to have something that they are more interested in than the collector! The cow must be physically capable of bearing the weight of the bull and ideally she should be restrained in the collection area by at least a halter. Unfortunately, many cows have never been haltered so they tend to object to this and thus, by struggling, put the bull off working. Furthermore, in other cases their stubborn lack of initial movement is itself off-putting to the bull and if nothing is happening it is worthwhile trying to lead the cow in front of the bull. In some cases, where it is deemed safe, collection can only be achieved with both the cow and bull running loose and a roomy collection area is essential for this to avoid the collector being knocked over or crushed.

Introduction of the bull to the teaser cow: When the bull is brought into the collection area for service the collector should watch only the bull and make the following mental notes:

- Demeanour – is he interested in the cow?
- Gait – is he lame, if so where?
- Libido – is he keen to work? Watch for the pumping of the ischiocavernosus muscle (this will be apparent by a rippling tail-head movement) and the dripping of clear pre-ejaculatory fluid from the prepuce. The penis may also be seen protruding a little from the prepuce: does this appear normal? Usually before mounting an experienced bull will grunt and make a quick movement at the rear of the cow just to test if she will stand. If the cow is not in season she will move, even if restrained, and this may be quite sufficient to stop the bull mounting.

Penile erection and ejaculation: As soon as the bull mounts the cow the collector should move forward quickly, but without panic, and with one hand on the

prepuce guide the erect penis towards the opening of the artificial vagina held in the other hand. Touching the penis directly will generally cause the bull to dismount. The bull will vigorously seek the vulva by rapid backward and forward movement of the penis. The temptation to force the AV over the penis at this point should be avoided as this can reduce the quality of the service. The bull should mount, clasp the cow, erect fully and search for the vulva with the penis, and, on finding the artificial vagina in its place, thrust and ejaculate in one movement. The search should not take more than a few seconds and a good thrust takes both hind legs off the ground in a forward direction. The sound of an explosive exhalation indicates ejaculation. It is important that the bull makes a firm thrust as this reflects stimulation of the full complement of ejaculatory fluids and so ensures that the sample is as representative of the natural ejaculate as possible. A poor quality ejaculate associated with a poor thrust may not be representative, often showing relatively poor motility, and semen collection should be repeated. The ejaculation should take place at the end of the AV, ideally within the cone itself, and thus the semen should be unaffected by the temperature of the AV. However, in some cases this is not what occurs and the sample may have to be allowed to run down from the AV, which is held vertically after collection. In such a case it may not only be affected by the AV temperature but also more contaminated than usual with preputial detritus.

Because of the rapidity of service in experienced bulls and the necessity of examining the semen sample as soon as possible after collection it is often difficult to examine the penis fully and collect semen at the same time. However, an appreciation of its firmness is possible, as is a quick visual assessment of both the penis and the prepuce. Should a more thorough examination be indicated, mounting can be repeated later without a collection being made, the penis (that part within the prepuce) being directed toward the examiner, thereby exposing the protruded portion for a more prolonged examination. This posture can often be held for a few seconds as long as the tip of the penis does not contact the cow. Wherever possible, more than one collection should be made, especially if the first is of poor quality. Moreover, in some cases an even greater number of collections may be required to satisfy the collector that the bull has worked well and that the series of samples obtained is as representative as possible. Only experience allows this judgement.

Experience of collector: There are considerable variations between how bulls cope with the use of an artificial vagina and the experience of the collector can help considerably in obtaining a good ejaculate as opposed to a poor one. It is difficult to rationalize just what the

collector does to ensure a good collection. Firstly, there is the judgement as to whether to try and collect when the bull first mounts. Quite often the first mount will be 'premature' with a poor erection of the penis and in most cases it is best just to deflect the penis by using pressure on the prepuce and let the bull dismount. While this carries the risk of putting the bull off mounting again, this is unlikely in bulls with normal libido. Time and effort spent in teasing (even to the point of removing the bull or the cow from the scene temporarily) are usually rewarding and eliminate any doubts that can arise when a poor sample is obtained at the very first mount. Secondly, there is the process of actually allowing the penis to enter the artificial vagina. In some cases, where the bull will not immediately thrust, it may be induced to do so by a short, quick, back and forward movement of the artificial vagina. This should be firm but gentle. Related to this is the decision as to the length of the artificial vagina, the pressure of the water in the liner, the type of liner and temperature. For example, few bulls will thrust well with an artificial vagina temperature less than 42°C, but equally there is no need for it to be more than 55°C. The use of a very warm artificial vagina with a rough liner can leave the penis looking very red! It is vital to remember that the tip of the penis is highly sensitive, and that an ejaculatory thrust is usually induced immediately it enters a properly prepared AV.

Other techniques of semen collection: Occasionally, the collection of an ejaculate by artificial vagina proves impossible and it is deemed necessary to examine a semen sample. In such circumstances, if the bull will mount and serve an oestrous cow then the removal of semen and vaginal mucus from the vagina of the cow and examination of the spermatozoa in the mucus is, in our opinion, more sympathetic to the bull's welfare than electro-ejaculation. It is for this reason that the cow should not be served prior to the visit. Semen can be collected by massage of the ampullae *per rectum* (McGowan *et al.*, 2002) and can be done without a teaser cow in oestrus.

In the last resort, and in our opinion only if it is felt *absolutely* necessary, one should collect semen by electro-ejaculation. This technique depends on electrical stimulation of the sacral segments of the spinal cord, which are mainly parasympathetic nerves emerging from the pelvic plexus. This stimulation will often cause a form of erection (possibly incomplete) and ejaculation. The ejaculate often differs from a 'normal' ejaculate by having a considerably greater volume and a lower sperm concentration (even in the 'sperm-rich' portion). This is due to the excessive contribution of the accessory glands, in particular the seminal vesicles.

Another disadvantage of this technique is that, at least with some machines, the animal shows tetanic con-

tractions with each series of pulses and these increase in strength with voltage. The bull may raise his tail, rock gently to and fro and, if the probe is incorrectly positioned, lift one hind leg and, if excessive stimulation is applied, the bull will go down. It has been suggested that the bull be sedated in some circumstances. However, our experience is that the danger of the bull going down means that the technique is best used without sedation. Sexual rest before electro-ejaculation seems to improve the likelihood of obtaining a representative sample.

In our experience the latter techniques are only of value if one obtains an ejaculate with motile spermatozoa and can study their morphology. Failure to obtain an ejaculate does not mean the bull is infertile! Even then concentration is so variable that at least in our experience it cannot totally be relied upon as representative of naturally ejaculated semen.

Assessment of ejaculate: While there has been, and still is, considerable research into the prediction of fertility on the basis of tests upon semen (Linford *et al.*, 1976; Miller & Hunter, 1987), the general form of on-farm semen examination is still largely based on the pioneering work of the early AI industry. In particular, the reader is referred to the study by Bishop *et al.* (1954).

A full ejaculate examination generally entails observing and recording the following:

- Volume
- Initial motility of semen
- Progressive motility of spermatozoa
- Morphology of spermatozoa
- Presence of other cells
- Concentration of spermatozoa
- Final overall assessment

The first three measurements above are usually carried out on the farm, followed by an initial assessment of the results. Smears of semen are also prepared on farm, but not necessarily examined; this is essential for the nigrosin–eosin stained smears. Samples and smears are then returned to the laboratory for completion of the other tests followed by the final overall assessment. The ejaculate should be returned to the on-farm laboratory as quickly as possible after collection. It must not be allowed to become chilled until after the first three steps and preparation of the nigrosin–eosin smears are completed.

Volume: Use a graduated collecting tube.

Initial motility of semen: A small drop of semen is placed on to a warm slide, which is put on a warm microscope stage (35–37°C) and examined ($\times 100$) as soon as possible after collection. It is scored on a scale of 0–5, ranging from 0 being completely static to 5 being vigorously active. In the bull the major criterion of scoring initial motility is wave motion, which is a func-

Table 38.3 Guide to assessment of initial motility.

| Score | Motility | Approximate % live, where density and morphology are normal |
|-------|----------------------------|---|
| 5 | Rapid vigorous waves | 90+ |
| 4 | Good wave motion | 80 |
| 3 | Sluggish wave motion | 60 |
| 2 | Active sample, but no wave | 40 |
| 1 | Some motile sperms | 20 |
| 0 | No movement | 0 |

tion of concentration, proportion of motile sperm and their activity (see Table 38.3). This simple test, if applied correctly, correlates quite well with fertility. Any bull that consistently produces semen with a score of less than 2 should be suspect.

Progressive motility of spermatozoa: Progressive motility, the percentage of motile spermatozoa moving in a forward direction, is best estimated by diluting the semen (roughly 1:50 depending on concentration) in a prewarmed (37°C) physiological solution (see p. 601) and examining this at $\times 400$ magnification under a warm cover slip. A figure in excess of 50 per cent is certainly desirable. High percentage progressive motility generally also means rapid progressive movement. Examination at this power ($\times 400$) will also allow some initial observation of the morphology of the spermatozoa and the presence of unusual cells in the semen.

Morphology of spermatozoa: The morphology of the spermatozoa is closely related to testicular function and the appearance of head, midpiece and tail should all be studied. A general morphological examination entails the observation of spermatozoa (and other cells) under high power ($\times 1000$), noting any abnormalities and expressing these as the number of abnormal spermatozoa/100 spermatozoa counted. This is best done quietly away from the farm although a cursory on-farm look at $\times 400$ will allow tentative prognosis for the owner and also satisfies the collector that the smear is acceptable. The use of at least two different staining techniques is recommended: one entailing dilution of the semen prior to making the slide and the other using a direct smear, which is stained after fixation. These are described more fully below.

(1) *Nigrosin–eosin stain* (Figs 38.4, 38.5). Freshly collected semen should be mixed with prewarmed stain in a small test tube roughly according to spermatozoa concentration (average 1[semen]:10 [stain]) and allowed to incubate at $35\text{--}37^{\circ}\text{C}$ for one minute. One small drop is then taken and smeared thinly across a prewarmed slide (using the same technique as would be employed

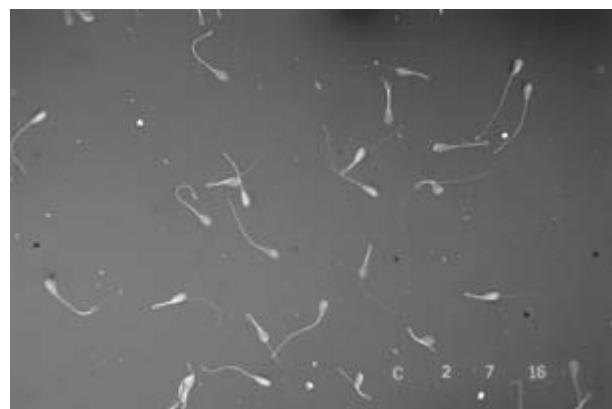

Fig. 38.4 Spermatozoa morphology (nigrosin–eosin $\times 400$). The reflected tails are artefactual, possibly due to chilling during staining and smear preparation. There is no evidence of cytoplasm in the bend of the tail and Giemsa-stained air-dried smears did not show the defect.

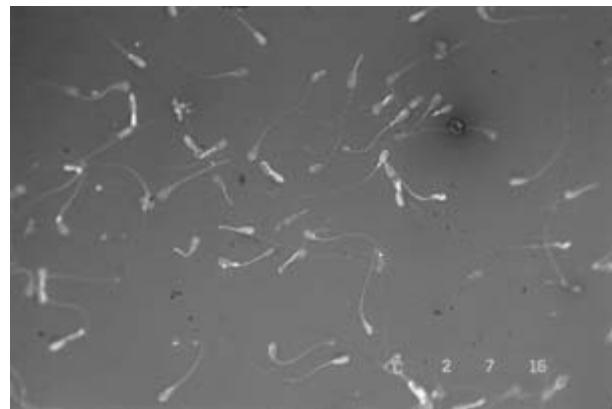

Fig. 38.5 Spermatozoa morphology (nigrosin–eosin $\times 400$). A range of defects including proximal cytoplasmic droplet, dag defect, reflected tail, detached head and microhead.

in the preparation of a blood film) and allowed to dry in the warm cabinet or on the warm stage. Chilling during preparation can lead to artefactual effects on sperm morphology. This stain will also allow the computation of the live:dead ratio since eosin is a vital dye, staining so-called dead (or immotile) spermatozoa pink, but leaving live spermatozoa unstained and pale, almost white. The percentage live figure correlates well with percentage progressively motile and not surprisingly gives similar correlation coefficients with fertility.

(2) *Indian ink smear*. This can be prepared in the same way but does not show ‘vital staining’.

(3) *Giemsa* (Fig. 38.6) and *methylene blue stains*. In this case at least three direct smears of the semen are made on warmed slides and allowed to air dry and this

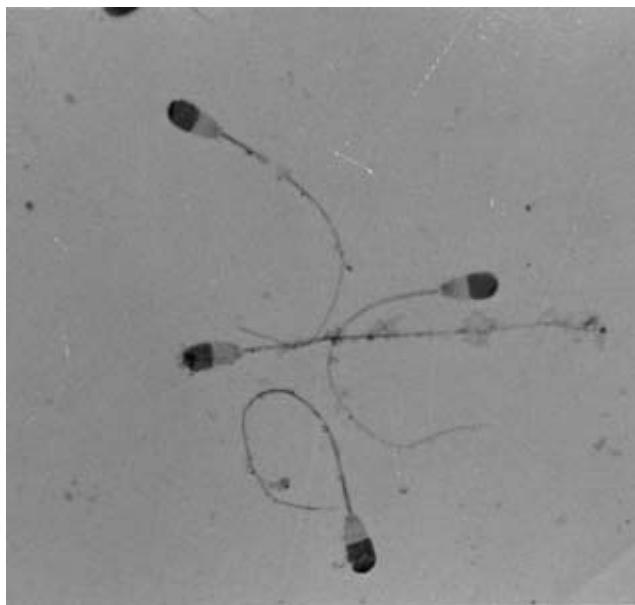

Fig. 38.6 'Knobbed sperm', an inherited defect of the Friesian breed (Giemsa) ($\times 700$).

would usually be done on the farm. On return to the laboratory one is fixed using 10 per cent formal saline (buffered), one using methanol and the third by gentle heat. After the first two have been washed in water they are stained in a simple buffered 10 per cent Giemsa solution for approximately three hours. Depending on its source, ordinary tap water will do. This stain should highlight the acrosome and allow further identification of any abnormalities of this region in particular. If one brings the slides back to the laboratory before fixation the use of the two different fixes can be of particular value, since often one gives a better resolution of the acrosome than the other, presumably due to differences in the relationship of thickness of the smear, time of air drying and the fix. The heat-fixed slide is stained by methylene blue (see p. 601). Comparison of direct smears with those prepared following mixing of semen and stain (e.g. nigrosin–eosin) allows detection of artefactual morphological effects that can arise from faulty technique in preparing the latter (Fig. 38.4).

Considerable experience is required before reliable counts of morphological abnormalities can be obtained and the reader is referred to Barth and Oko (1989) for authoritative guidance on the procedures required. Overall one is aiming for at least 70 per cent normal spermatozoa. However, this needs to be qualified as the effect upon the fertility of the semen depends upon the type and extent of abnormality (Barth & Oko, 1989); thus head and midpiece abnormalities (including cytoplasmic droplets) are more important than simple reflected tails. Some abnormalities are known to be

Box 38.4. Spermatozoa abnormalities.

Table 38.4 Visual criteria for estimating semen concentration ($\times 10^6$ spermatozoa/ml) (from Logue & Greig, 1987).

| Appearance | Estimated number of spermatozoa ($\times 10^6$) |
|-------------|---|
| Thick cream | 3000 |
| Cream | 2000 |
| Milk/cream | 1000 |
| Milk | 500 |
| Water/milk | 250 |
| Cloudy | 100 |

inherited, for example the knobbed sperm. Results of morphological analysis should be presented in tabular form, showing the proportions of the various abnormalities seen (Box 38.4).

Presence of other cells: A variety of cells are normally found in semen and these cells are best observed either in the direct smear stained by Giemsa and/or a direct smear heat fixed and stained by methylene blue. The latter demonstrates leukocytes particularly well. Most of the cells are of preputial or urethral epithelial origin and are of little consequence. However, the presence of large numbers of leukocytes, small darkly staining cells that appear to be degenerating spermatids, multinucleate giant cells and so-called 'round' cells is indicative of spermatogenic disruption.

Concentration: This can be estimated using the criteria in Table 38.4. When a more accurate measurement

is needed then resource to a calibrated turbidity meter or a simple haemocytometer is needed.

Final overall assessment: There has been little study of the correlation of these commonly measured semen parameters with the fertility of bulls used under natural service conditions. For semen collected by AV and used for artificial insemination there is evidence for correlation of motility and percentage dead spermatozoa with fertility and that is why we have described these tests (Bishop *et al.*, 1954). In North America, the New Society for Theriogenology Breeding Soundness Evaluation System (Hopkins & Spitzer 1997) is based on examination of semen collected by electro-ejaculation and may not be applicable to AV collected samples. Our experience with an electro-ejaculator is that in some cases perfectly normal bulls fail to give a good sample. However, the Society suggests that to be classified as satisfactory the 'gross motility' must be at least 'fair', the 'individual progressive motility' at least 30 per cent and morphology analysis should show at least 70 per cent normal sperm cells. The Society's 'gross motility' is equivalent to the initial motility assessment described here except that a cover slip is placed on the drop of semen; 'fair' ('generalized oscillation') probably equates with a score of 2 and 'individual progressive motility' is equivalent to progressive motility. Therefore the measurements that correlate best with fertility are generally believed to be initial and progressive motility, percentage dead spermatozoa and percentage morphologically normal spermatozoa. However, volume and density are usually also recorded. Table 38.5 shows minimum reference figures used by the authors when assessing bull semen. They are based on published work and experience and are offered as a guide. However, it must be appreciated that correlation of findings in semen and the fertility of natural service bulls is an inexact science due to the paucity of published information available, which reflects the difficulties of small scale on-farm investigations of fertility. In the final

analysis semen samples tend to fall into one of three categories. Firstly all parameters are well above the minimum reference figures in Table 38.5 (the semen should be of normal fertility). Secondly the important parameters fall well below (the semen is likely to be subfertile or sterile). Thirdly the important parameters are mostly at or just below the minimum reference figures. It is the third category that causes difficulties. If there is a history of infertility and there are no other significant findings, the bull could be re-examined after three months to see if there is improvement in the semen parameters. If the semen picture is normal at this time this suggests the bull was recovering from some form of testicular degeneration at the first examination. If the semen quality has deteriorated further the prognosis is very poor. However, if the quality is similar then test mating to at least ten fertile females followed by pregnancy diagnosis is the only recourse.

Ancillary tests: Research into other attributes of semen, and particularly spermatozoa, that correlate well with fertility has been consistently directed to the development of simple cheap methods to improve the accuracy of our predictions. Unfortunately, to date, such an addition suitable for on-farm use by a practising veterinarian has not been found. The most widespread tests have been the use of sperm motion analysis using a variety of computer based packages, cervical mucus penetration tests and zona pellucida (ZP) penetration tests (the simplest of these being the number of accessory sperm 'trapped' within the ZP). All these measure the ability of the spermatozoa to gain access to the egg for fertilization more objectively. However, only a more accurate evaluation of the acrosome using phase contrast microscopy seems applicable to the practical examinations that we are discussing here and even this seems more relevant to studying the effects of processing damage upon spermatozoa stored for either AI or other reproductive technologies. Finally there are a number of laboratory investigations showing the value of a variety of fluorescent stains which can allow evaluation of the chromosome content (X or Y), DNA variability, membrane integrity, mitochondrial function and vital function (for review see Garner, 1997). In the long term some of these tests may allow an improvement in the accuracy of assessment of semen, but until that time it is still an inexact science!

Table 38.5 Minimum reference figures (with range) for assessment of ejaculate.

| | |
|---------------------------------------|--|
| Volume (ml) | 4 (2–12) |
| Appearance | White (some samples have a yellow tinge) |
| Density ($\times 10^9/\text{ml}$) | 1.0 (0.3–2.5) |
| Initial motility (0–5) | ≥ 2 |
| Progressive motility (%) | >50 |
| Total dead spermatozoa (%) | <50 |
| Total morphological abnormalities (%) | <30 |

Observation of natural service

Finally, after semen collection is completed it is very worthwhile standing back and observing the bull serving the cow naturally. Obviously, this is only possible with a cow in season and the consent of the owner, who may not wish to have the cow served. This procedure avoids the risk of declaring a bull fertile on the

basis of normal semen findings when the bull is actually unable to complete natural service.

Full physical examination of the bull

We have already suggested that the first opinion veterinarian may undertake a full examination of the bull as a preliminary to any further investigations. We recommend that even if this was done previously it is always worthwhile going through the examinations again. Hard experience has taught that *no one* is infallible and defects can either be missed or could have become more apparent between examinations! In any event a full examination of the reproductive tract is essential, as is the examination of several other aspects of the clinical appearance of the bull. Obviously, where lameness or some other defect is apparent during collection the relevant area should now be examined more thoroughly.

Mouth: Assess the age of the bull by examining the incisor teeth. This is often very helpful in impressing upon owners how immature their young bulls are. Many bulls of continental breeds have still no adult incisors at two years of age.

Eyes: It is also worthwhile examining the eyes, at the very least to rule out congenital cataracts. Severe cataracts can lead to unpredictable behaviour of the bull and are found in all breeds. A good ophthalmoscope is needed to diagnose less obvious abnormalities such as colobomata of the retina.

Penis and prepuce: Palpate around the orifice of the prepuce, the sheath itself and the penis as it runs back to the scrotum. It is also worthwhile examining the umbilicus for evidence of a hernia.

Scrotum: Palpation of the scrotum allows definition of the following structures:

- Testes
- Epididymes (head, body and tail)

- Spermatic cords
- The scrotal sac itself.

The testes should exhibit freedom of movement within the scrotum and all structures should be of normal size, shape, and free from inconsistency in outline, i.e. bumps and nodules. A simple objective measurement of testicular size is scrotal circumference. This is determined by measuring the circumference of the scrotum at its largest point with a tape measure when the testes are in (or manipulated into) a normal fully descended position. In the normal adult bull this should be between 33 and 45 cm, depending on breed and mature size (see Table 38.6). More recently, the use of real-time ultrasound has been employed as a further diagnostic aid (Figs 38.7, 38.8). It remains to be seen precisely how valuable it will be. However, it is now being used by a number of veterinarians, including the authors, and has highlighted a variety of defects including orchitis and calcinosis.

Pelvis: A rectal examination is needed to examine the accessory sex glands. Some of these are found just under the hand after it has been fully inserted through the anus and the ampullae of vas deferens and seminal vesicles can be identified. The prostate and bulbourethral glands cannot normally be distinguished. The main part of the former is found at the beginning of the root of the penis, while the latter is found just anterior to the ventral bend of the root at the bulbospongiosus muscle. Again ultrasound has an obvious application, in particular for the examination of seminal vesicles.

Confirmation of identity: The breed and physical description of the bull should be recorded along with ear tag numbers and any tattoo numbers where legible.

Collection of other diagnostic samples

The composition of the collection is influenced in part by the health status of the national herd and also by that of the herd the bull is in or has been introduced to. The

Table 38.6 Suggested minimum scrotal circumference measurement (cm) to exert selection pressure for increased testicular size for bulls by breed and age in North America (Reproduced from Coulter *et al.*, 1987 with permission from Elsevier Science).

| Age of bull (months) | Simmental | Angus and Charolais | Hereford and Shorthorn | Limousin |
|----------------------|-----------|---------------------|------------------------|----------|
| 12–14 | 33 | 32 | 31 | 30 |
| 15–20 | 35 | 34 | 33 | 32 |
| 21–30 | 36 | 35 | 34 | 33 |
| Over 30 | 37 | 36 | 35 | 34 |

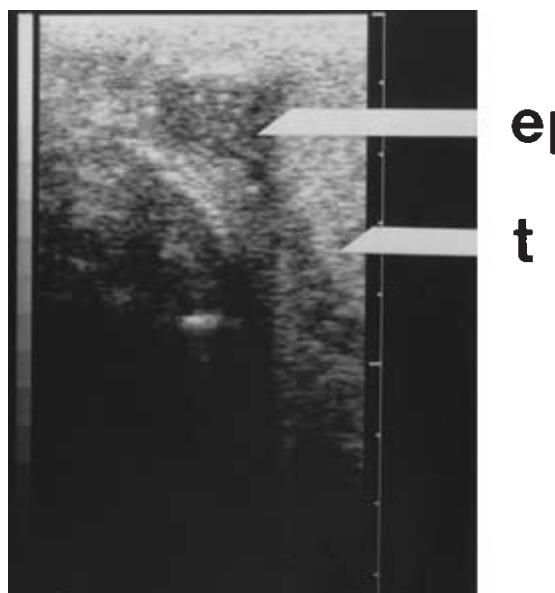

Fig. 38.8 Real-time ultrasound of the tail of the epididymis. ep:t, tail of epididymis; t, testis.

minimum routine employed by the authors in the UK is as follows (Fig. 38.9):

- (1) Preputial washing for culture and fluorescent antibody test for *Campylobacter fetus* sp.

Fig. 38.9 Samples for further laboratory investigation routinely returned from the farm by the authors. From three ejaculates in this case: nigrosin-eosin stained smears, air-dried smears and raw semen; also heparinized blood and preputial wash.

- (2) Blood for BVDV antigen and antibody, unless bull previously tested.

If indicated by history, semen findings and/or clinical signs collection of further samples, as detailed below, should be considered:

- Semen for culture of bacteria, virus or *Mycoplasma* sp.
- Blood for serology for IBRV, *Leptospira hardjo* or Johne's disease.
- Blood for biochemistry (e.g. albumin or liver enzymes) or routine haematology.
- Faeces for examination for helminth eggs, culture for *Salmonella* sp. or smear or culture for the bacterium of Johne's disease.

In some cases sampling of the females involved may also be required, e.g. vaginal mucus for VMAT for *C. fetus* sp. antibody.

Preliminary diagnosis and prognosis

Prior to leaving the farm and before all the examinations of semen and further laboratory tests have been concluded the farmer will be keen to hear a verbal preliminary diagnosis and more importantly a prognosis and some advice about what should now be done with the bull. These can usually be given, with the proviso that they are pending the outstanding test results, since any major abnormalities of the semen or physical abnormalities in the bull should be apparent before leaving the farm. Nevertheless, it is wise not to be too dogmatic, particularly with reference to the presence or absence of any form of infectious infertility.

Final diagnosis, prognosis and advice after all test results are known

Having obtained the history of the bull, examined it fully for breeding soundness (and any cows if necessary) and with knowledge of all relevant laboratory test results, a written report should be prepared. This should summarize the history, findings and any laboratory test results. It should then reach a conclusion, which should include a diagnosis, however tentative, and, if available an appropriate treatment and/or management regime to prevent or control the problem should be offered. Finally a prognosis should be given. A discussion of the aetiology of the problem can also be included. In general, the most important aspect of this conclusion is the prognosis. Effectively there are three alternatives:

- (1) No abnormality can be detected and the bull should be of normal fertility. If the history is of poor fertility recommend a 'test-mate' with at least 10 fertile females.
- (2) An abnormality consistent with a history of poor fertility has been found and the bull is considered long-term infertile or unlikely to return to normal fertility.
- (3) The bull is infertile or of questionable fertility, but it may recover. In this case, depending on the diagnosis, the value of the bull and the manner in which the farm use him the bull can be kept, treated if necessary and the situation re-evaluated in two to six months.

Further action for the herd and its future breeding management

Where any findings made in the bull are likely to impinge on the rest of the herd, now or in the future, this should obviously be mentioned in the report. Examples would include the presence of significant infectious agents or evidence of overworking a young bull.

Manifestations, aetiology, treatment and prognosis of bull infertility

The aetiology, treatment and prognosis of infertility in the bull are discussed in more detail below under each of the four manifestations.

Failure to mount

The following factors have an influence on the ability to mount.

- Age
- Genetic factors

- Season
- Social factors
- Overwork
- Nutrition
- Orthopaedic abnormalities and housing conditions.

Age

The age at which a bull is capable of mounting, protruding the penis fully and ejaculating semen (puberty) varies with the bull and breed (see p. 479). However, one would normally expect a bull of a high production dairy breed to be capable of serving a cow at 12 months of age, although usually semen production would have commenced some two months earlier. Indeed mounting behaviour would be normal in the prepubertal state. However, one would not advise use for breeding before 15 months of age. Continental beef breeds tend to mature at a later age than most dairy breeds and so more care is needed with such animals when attempting to use them at a young age, for example less than 18 months. From a behavioural point of view young bulls often display naivety and awkwardness in their approach to an oestrous cow. There is evidence that this can be affected by how young males are reared, so that young bulls raised with female calves are less likely to exhibit sexual naivety than those kept in the presence of their dams until weaning (Kilgour, 1984).

In extreme cases young bulls may go through a pronounced phase of showing no sexual interest even when presented with a cow in oestrus. This 'sexual inhibition' may be heightened by the presence of another bull. While the condition often indicates an inherently poor libido, the problem may correct itself with time. Similarly, despite being clinically normal, bulls can show a considerable lowering of their sexual drive beyond eight to ten years old (Chenoweth, 1983).

Low sexual drive may also be due to overwork or pain, either from an orthopaedic problem or possibly emanating from the reproductive tract (see p. 611).

Genetic factors

There is evidence from work with identical twins that many aspects of mating behaviour, in particular sexual drive and mode of approach to service, are inherited (Bane, 1954). Furthermore, despite the wide variation between individuals there is plenty of evidence that some types and breeds of bulls display better libido than others. For example, dairy breeds tend to show a stronger sexual drive than beef breeds and there is now evidence of a quite high heritability for libido (Chenoweth, 1983).

However, there is little evidence that variation in libido is due to differences in circulating hormone

concentrations (Bane, 1954). This was demonstrated dramatically in an endocrinologically abnormal bull with a 60, XXY chromosome complement, in which the mating behaviour was normal (Logue *et al.*, 1979).

There is little firm evidence of any relationship between poor libido in the bull and poor oestrous expression in female offspring, but there is some evidence of a relationship in sheep. Thus libido is a factor that should not be ignored in any selection programme (Chenoweth, 1983).

Season

There is conflicting evidence about the effect of season of the year, largely because of the environmental conditions in which the bulls were kept. A sluggish sexual drive has been related to periods of extreme heat, cold and light reduction (Vincent, 1972; Foote *et al.*, 1976; Gwazdauskas, 1985).

Social factors

Age, genetics and season all interact in the herd situation where the bull is running with a group of cows either as the only male or along with several other bulls as a mating team. Thus generally the oldest and largest bulls are dominant and spend most of their time in the presence of the sexually active oestrous females (Chenoweth, 1983). Subordinate bulls spend considerably less time with that group and in some cases their attempts to serve will be totally disrupted by the dominant bull.

Overwork

Bulls do become satiated. This state varies with the individual and the herd structure and in temperate climates seems more likely to present during the winter than in longer daylight periods. In simple terms, introduction of a young, totally inexperienced, 18-month to two-year-old bull to 20 cycling cows is considered to be risking overwork, while introduction to as many as 40 is foolhardy! Finally, poor female fertility can compound the problem because of returns to service.

Nutrition

High planes of nutrition result in puberty and maturity being reached at an earlier age (Salisbury & Van Demark, 1961). There is also some evidence that high energy intakes in early development are detrimental to subsequent libido. This effect has been described in both dairy and beef bulls, but without looking closely at whether the regime caused the physical defects such as laminitis in the bulls. There does not appear to be a

direct relationship between nutrition and fertility in working bulls. Nevertheless, it is widely believed by farmers that performance testing young working bulls is detrimental to their longevity as working sires.

Orthopaedic abnormalities and housing conditions

Often the bull will show intent to mount, moving to the cow and standing behind her, but does not mount because of painful or physically limiting orthopaedic abnormalities. Obviously, the level of libido of the bull mediates the extent of this effect and on some occasions the frustration becomes so great that the bull will strike the cow.

A large number of orthopaedic problems are liable to interfere with the ability to mount and serve a cow. The most common problem areas are in the foot, the hock, the stifle and the back.

The treatment and prognosis of failure to mount depends very much on the diagnosis of the clinician. Many of these problems result from injuries to muscles, tendons and joints caused by the bull slipping when attempting to serve on poor underfoot conditions or foot lameness (see Chapter 31). Thus, adequate housing and service management are prerequisites of good bull fertility. The specific requirements of the bull for service should be borne in mind and thus any prognosis should be guarded. This is because many bulls are prepared to mount before a healing process is complete, thus exacerbating the condition, and also because frequently the bull produces soft, dystrophic bone in and around the site of injury resulting in added healing difficulties with subsequent arthritis (Bartels, 1975; Weaver, 1997). Some injuries appear to be more specific bull problems, such as spinal changes (Bane & Hansen, 1962), stifle injuries (Bartels, 1975) and delayed spastic paresis (Fig. 38.10).

It should also be remembered that other less specific conditions can cause poor libido simply due to the bull feeling unwell or being in pain. This is particularly relevant if the penis and/or prepuce has been damaged (see below). Finally, other diseases such as bovine spongiform, encephalopathy (BSE) (see p. 909) and progressive ataxia (see p. 179) of Charolais cattle (Palmer *et al.*, 1972) should be borne in mind.

As already mentioned, it is most important to introduce the bull gradually to an adult workload and to monitor his progress closely at every stage. In particular, the bull should be introduced initially to quiet adult cows which are clearly in season and virtually hand-mated until the bull and his owner are confident that he can work reliably and fertility is confirmed by early pregnancy diagnosis of those females using real time ultrasound after day 26. Table 38.7 gives some general indications of workload.

Fig. 38.10 Delayed spastic paresis in the bull.

Table 38.7 Recommended workload of bull with age (running loose with females).

| Age | No. of cows |
|-----------|---------------------------------|
| <2 years | 10 cows |
| 2–3 years | 20 cows |
| 3 years | 30 to 50 cows depending on bull |

The prognosis for poor libido of indefinable origin must be extremely guarded, since, despite any mitigating circumstances, it is likely that this problem is inherent in the make-up of the bull and will recur. In young bulls of around 18 months to two years of age the prognosis is more hopeful, but a maximum time scale of six months in which to show some evidence of overcoming the condition is appropriate.

Attempts to treat low libido by a variety of hormones, either alone or in combination, have rarely proved of value and there is a dearth of recommendations apart from sexual rest in any of the common texts. In fact, matters remain as described by Lagerlöf in 1951!

Failure to achieve intromission

The majority of bulls that are presented as being able to mount, but then fail to gain intromission, suffer from a variety of conditions, which include penile or

preputial defects and orthopaedic problems. It is important not to belittle the problems of diagnosis, for example an early manifestation of either corkscrew penis or a venous drainage defect could conceivably be masked by the overzealous application of an artificial vagina. Observation of the natural service behaviour of the bull should generally avoid this error although some young bulls can display penile abnormalities intermittently. As ever prognosis, treatment and prevention depend upon the exact diagnosis.

In order to understand penile problems fully a brief discussion of the anatomy and physiology of erection in the bull (Fig. 38.11) is necessary.

Intromission can only be achieved if the penis is fully erect. This is a stiffening process brought about by the filling of the corpus cavernosum penis with blood pumped in by the ischiocavernosus penis muscle. Since drainage of the corpus cavernosum penis is very slow in normal bulls, blood pressure in the corpus cavernosum penis builds up well in excess of that in a car tyre (over 200psi) (Beckett *et al.*, 1974). This is sufficient to harden and straighten the penis and it is consequently forced out of the sheath. The latter, owing to its elastic nature, envelops the erecting penis up to the start of the free end of the penis. As the penis protrudes and reaches the point of ejaculation, it stiffens still further and spirals in an anticlockwise direction. This 'corkscrew' is caused by the fibrous architecture of the glans, in particular the dorsal apical ligament and spiral distribution of collagen fibres along the tip of the penis, allied to the rise in blood pressure in the corpus cavernosum penis at ejaculation. Further distortion may be caused by the very transitory erection of the erectile tissue at the tip of the penis. It is believed that this may be caused by pressure waves in the corpus spongiosum penis (Ashdown, 1973).

Clinically, we suggest that there are two major presentations associated with failure to achieve intromission and each can be further subdivided as follows.

- (1) The penis cannot be protruded sufficiently:
 - (a) Balanoposthitis
 - (b) Short penis
 - (c) Rupture of the corpus cavernosum penis
 - (d) Persistent frenulum.
- (2) Failure to locate vulva or enter vagina:
 - (a) Psychogenic problems
 - (b) Penile problems: fibropapilloma, drainage defects, corkscrew penis, deviations.

The penis cannot be protruded sufficiently

Balanoposthitis: Some cases of inflammation of the epithelium of the penis and prepuce can result in inabil-

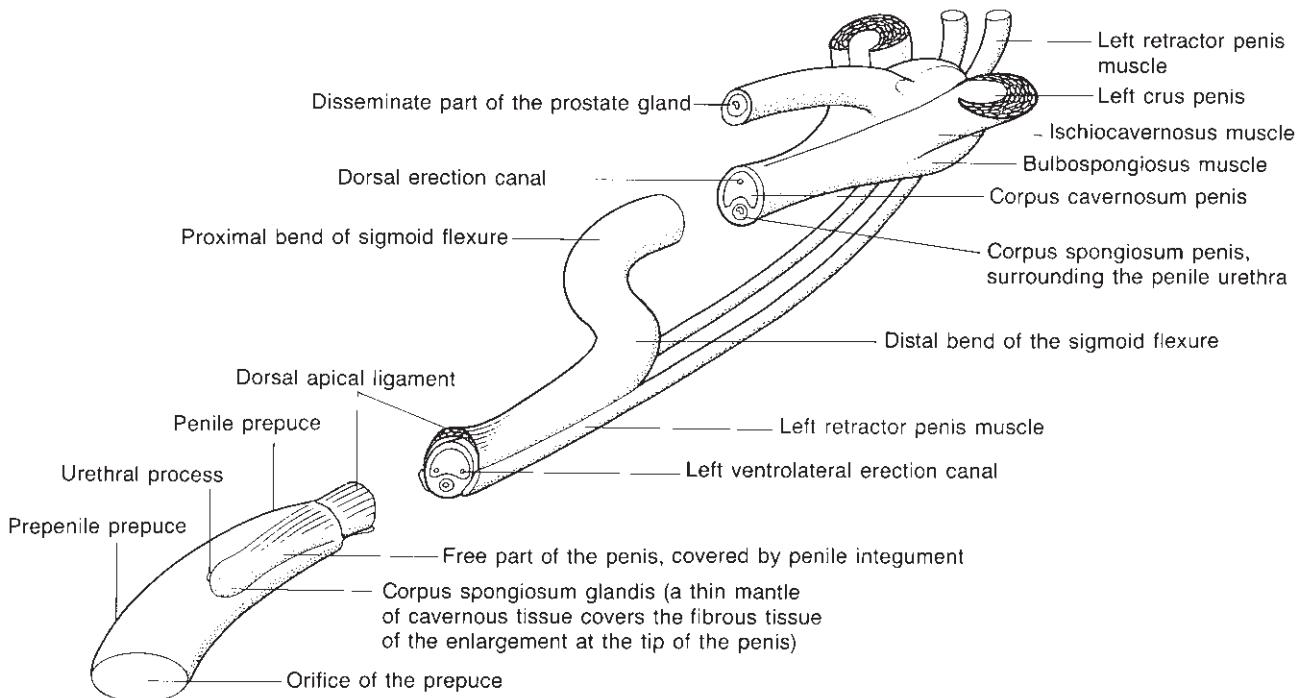

Fig. 38.11 Diagram to show the anatomy of the penis and prepuce of the bull. (Courtesy of Dr R.R. Ashdown.)

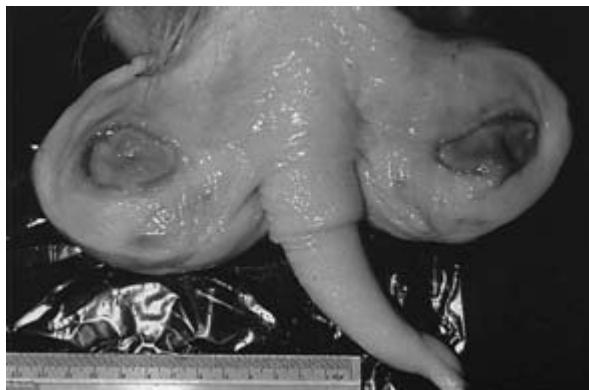

Fig. 38.12 Abscess formation of the preputial epithelium in the bull.

ity to mate because of pain or physical interference. There are three areas of damage:

- The region around the preputial orifice.
- The penile epithelium.
- The reflected prepuce which, by virtue of its extreme elasticity and mobility, stretches and reflects itself along the extended erect penis.

The region around the preputial orifice: Problems in this area may be the result of trauma with subsequent

infection (Memon *et al.*, 1980–85). An example is where the bull everts his preputial epithelium, which is then damaged and infected (Long & Dubra, 1972; Fig. 38.12). The breeds most commonly affected are the Aberdeen Angus and polled Hereford, which have no retractor preputiae muscle, and the *Bos indicus* breeds and crosses (Larsen & Bellenger, 1971). Ubiquitous organisms such as *Arcanobacterium (Actinomyces) pyogenes* and *Staphylococcus aureus* can often be isolated from such lesions. The smegma produced by the bull is very tacky and the authors know of at least one case where the problem was caused by the firm matting of the hairs over the preputial orifice due to this substance, with resultant failure to protrude the penis. Others have described hair rings around the free end of the penis, although this usually produces an annular constriction a few centimetres behind the tip of the penis.

The penile epithelium: This can be damaged either traumatically, or by infection, in particular by the virus of infectious pustular balanoposthitis (BHV-1). Damage with subsequent scar tissue can result in a failure to protrude or deviation.

The reflected prepuce: This area is extremely important because it must function properly to allow the penis to protrude (Ashdown & Pearson, 1973a). Any traumatic damage with resulting scar tissue formation

Fig. 38.13 Severe tear of prepuce.

tends to be self-perpetuating since the scar tissue often limits movement, resulting in further tearing. Furthermore, infection at such sites is common with subsequent abscessation. An extreme example of such damage can occasionally be seen after collection with an artificial vagina and in some of these cases the tear is very large indeed (Fig. 38.13). Usually the bull in question is a young inexperienced animal or one returning to work after a prolonged layoff (Monke, 1980). Treatment of this condition is largely symptomatic; however, in cases with severe scar tissue formation, surgery is the only course of action other than salvage (Larsen & Bellenger, 1971; Walker, 1980). Although a guarded prognosis is necessary the chances of recovery will depend on the site, extent and aetiology of the condition. Even in less severe cases sexual rest for at least three months is recommended to ensure adequate healing. Prevention is best effected by good bull management, regular monitoring of the bull when he is serving a cow and recording of his performance. Should the bull be part of an AI stud then the importance of collection technique must be re-emphasized.

Short penis: As the bull grows so the penis should also develop. In some cases it would appear that this does not occur and the bull becomes less and less able to protrude the penis sufficiently to achieve intromission. The exact aetiology of the problem is obscure and this presentation may even be due to several different conditions, but it does not appear to be a defect of erection since the penis appears to firm up quite normally. Fibrous metaplasia of the retractor penis muscle has been described (Arthur, 1960) and this has been successfully treated by myectomy. However, since the condition appears to be heritable surgery is probably not advisable. At its simplest, a grossly enlarged pendulous abdomen may be a cause of the problem, although

usually in such cases some of the penis can be protruded. A severe drainage defect problem could also possibly present in this manner (see later). Diagnosis is based on the increasing difficulty of the bull to protrude the penis after mounting. The penis should be felt to confirm a firm erection because the condition should be differentiated from either a drainage defect of the corpus cavernosum penis or a longstanding balanoposthitis. In our experience the prognosis is hopeless.

Rupture of the corpus cavernosum penis: As mentioned earlier, the pressures erecting and firming the penis are immense and in some unfortunate cases the tunica albuginea ruptures (Fig. 38.14). It is possible that in some cases the tunica albuginea is unable to sustain integrity because of the pressure alone, but it is more likely that it ruptures under additional strains caused by a sudden penile deflection due to an unexpected movement by the cow while service is taking place, or the bull slipping while the penis is in the vagina. Rupture generally occurs in the region of the sigmoid flexure. It is most common on the dorsal aspect of the distal bend of the sigmoid flexure but can also occur on the dorsal surface of the penis between the root and proximal bend of the sigmoid flexure. Such rupture results in a haematoma, which subsequently organizes and prevents the full erection and protrusion of the penis. Diagnosis is based on a sudden onset of an inability to serve coupled with swelling, usually in the inguinal region just above and anterior to the scrotum. Often the bull also presents with a prolapse of the prepuce and because the condition can be painful he may walk stiffly. Where this condition is presented in the acute phase and the surgical approach is adopted, immediate sexual rest followed by surgical removal of the haematoma some five to seven days later, before it can organize (Walker,

Fig. 38.14 Rupture of the corpus cavernosum penis.

1980), is indicated. In more chronic cases and in those acute cases where surgery is not adopted gradual teasing may eventually result in adhesions being broken down sufficiently to allow mating. Progress may also be assisted by frequent gentle massage in the area of the haematoma. Recurrence is quite common and, if possible, identification of the site of rupture is advisable because the prognosis is more hopeful for a rupture at the distal bend of the sigmoid flexure rather than at the proximal bend. This is because the latter is associated with drainage defects of the corpus cavernosum penis (Ashdown & Glossop, 1983). Prevention is clearly difficult but the introduction of young sexually inexperienced bulls to heifers, especially at grass, should be done with care. Service in slippery surroundings should be avoided if at all possible.

Persistent frenulum: The penile frenulum, which normally attaches the free end of the penis to the prepuce of the prepubertal bull, is normally 'lost' during early puberty, possibly breaking during play and/or masturbation. Occasionally, this does not occur and its persistence prevents the tip of the penis straightening on erection. It is usually bent ventrally and caudally. Although this is not a common condition diagnosis is easy, as is treatment, which involves simple surgery.

Failure to locate vulva or enter vagina

Psychogenic problems: There would appear to be two distinct problems:

- Neck or side mounting;
- Normal mounting, but without success, the bull being incapable of inserting the penis into the vagina despite a good erection and apparently normal seeking movements, even to the extent of touching the vulva.

The aetiology for both these conditions, especially the former, is obscure though neck mounting is not uncommon in young inexperienced bulls. However, they usually quickly move round to the rear of the cow. For the latter one could hypothesise either that this could be an early manifestation of a premature partial drainage defect of the corpus cavernosum penis or that there was an inadequate sensitivity of the penile tip (possibly acquired traumatically or by infection) resulting in a lack of appreciation of the position of the penis relative to the vulva.

A diagnosis of psychogenic depression of libido must be tentative because it is based on a failure to obtain any other. One should always bear in mind that this condition may be the result of penile damage or an early manifestation of a drainage defect of the corpus cavernosum penis, or may be of orthopaedic origin.

There is no known treatment apart from initial sexual rest for at least three to four weeks followed by hand-mating after some considerable teasing. Often collection by a small artificial vagina using a rough liner may obtain an ejaculate and start the bull working. The prognosis is very guarded.

Penile problems:

Fibropapillomata: These are generally found on or near the tip of the penis (Fig. 38.15). They are caused by a virus and are thus transmissible. They can occasionally also cause considerable problems in the female (Meischke, 1979). In the bull they usually only affect the penis of young animals less than four years of age and generally regress after a period of two to six months. In some cases, however, they persist much longer and some become eroded and infected (Walker, 1980). Treatment depends on the extent and severity of the tumour. A small single pedunculated tumour is clearly much easier to deal with than a large, sessile, cauliflower-like lesion. Most authorities advise surgery in severe cases, but it is essential to avoid weakening or rupturing the tunica albuginea (Walker, 1980), since this can result in blood escaping at service and this setback to surgery has been seen by one of the authors. Note that possible leakage from the corpus spongiosum penis (CSP) into the terminal part of the urethral lumen has

Fig. 38.15 Fibropapilloma on the tip of the penis.

also been described. This could also cause spurting of blood from the penis at service (Ashdown & Majeed, 1978). Since these lesions are transmissible, segregation of affected cattle, especially heifers, from a young bull is advisable. Contaminated bedding may infect young bulls and sexual play between young bulls may result in superficial abrasion of the penis and thus susceptibility to infection. The use of an older bull on infected females reduces the risk of infection of the bull. Prognosis should be guarded as regards both spontaneous recovery and return to service after surgery.

Drainage defects: Careful anatomical studies of the normal and abnormal penis have revealed a number of arteriovenous shunts, which allow the venous cavities of the penis to drain more quickly than usual. This results in an inability to erect fully or to sustain an erection (Ashdown *et al.*, 1979). It is now considered possible to distinguish four different venous drainage defects based on history and clinical findings. However, in the last analysis all are associated with inadequate erection in the bull and a diagnosis of venous drainage defect is probably sufficient in most cases (Logue & Greig, 1985). Diagnosis is dependent on a careful assessment of the history and a thorough clinical examination of the bull while serving. It is advisable not only to attempt to collect semen by artificial vagina but also to palpate the erect penis as much as possible as the bull attempts to mate and finally, if at all possible, the bull should be allowed to attempt to mate naturally and his lack of ability to mate confirmed. Differentiation between the various categories of corpus cavernosum penis

defects is largely academic at present since there is no treatment and the prognosis for all of these is hopeless.

Corkscrew penis: This is one of the most dramatic defects and is often diagnosed by the client. Spiral deviation of the penis within the vagina at ejaculation is physiological but in the clinical condition the spiral deviation precedes intromission and so prevents service. This is most commonly seen in beef bulls of around four years of age (Blockey & Taylor, 1984). In all cases the spiral is anticlockwise and can almost comprise a complete circle. However, it does present with varying degrees of severity from intermittent spiralling (which can present problems with diagnosis) to being so severe that spiral deviation occurs while the penis is still in the prepuce and it may then prevent protrusion. Usually it does not occur until the penis makes contact with the vulva of the cow. It should be remembered that spiral deviation has been described as occurring after entry into the vagina immediately prior to ejaculation in bulls with apparently normal mating behaviour (Ashdown & Pearson, 1973b). The only known treatment is surgical and there are a variety of techniques, all of which depend on either fixing the dorsal apical ligament to the dorsal aspect of the penis or additionally stiffening it by the insertion of fascia lata or carbon fibres. The latter are placed between the ligament and tunica albuginea (Mobini *et al.*, 1982). Postoperative recurrence is quite common after apparent recovery. The problem is said to be heritable but there is little evidence other than anecdotal to confirm this.

Deviations of the penis: These deviations are largely believed to be caused by scar formation such as that following balanoposthitis or surgery (Walker, 1980). As with corkscrew penis, deviations are usually obvious. However, ventral deviations can be confused with a drainage defect of the corpus cavernosum penis and must be differentiated from these. They can usually be distinguished by the flexibility of the erect penis that is apparent in drainage defects. Some bulls can accommodate deviations surprisingly well and if they are not too pronounced, careful hand-mating may allow these bulls to learn to serve again. Surgical treatment is again a possibility (Walker, 1980) for more severe cases. A guarded prognosis is advisable even for relatively discrete deviations.

Failure to thrust and ejaculate after intromission

Occasionally, one encounters a bull that is capable of placing the penis in the anterior vagina but then fails to thrust vigorously and ejaculate. In some cases the cause may be orthopaedic, but in other cases the cause may

be neural in origin, whether due to local receptor problems causing a lack of sensitivity of the penis, which may be acquired or congenital, or due to a more general psychosomatic defect. Another possibility is that this problem might be due to either a slight defect in the drainage of the corpus cavernosus penis itself or a defect in the corpus spongiosum penis, or even of the erectile tissue in the tip of the glans. The prognosis is poor. Finally, in some cases it may just be due to inexperience where, given time, the problem may resolve but the prognosis should be guarded.

Normal service with a poor pregnancy rate

The vast majority of conditions causing this manifestation are related to problems associated with sperm production and transport. An understanding of the complexity of the mechanisms involved in governing and modifying these processes is essential. There are two basic components in the ejaculate: spermatozoa and seminal fluid. The former are produced in the seminiferous tubules of the testes by spermatogenesis and the latter from the testes, epididymis and accessory sex glands.

The clinician should consider the following items when presented with a bull that is serving normal cows satisfactorily but achieving a low pregnancy rate.

- Age
- Overwork
- Testicular hypoplasia (and testicular atrophy)
- Testicular degeneration and atrophy
- Interference with storage and transport of spermatozoa
- Abnormalities of accessory sex glands

Age

In addition to the influence of age and experience upon libido there is a gradual development towards maximum fertility in the young bull and this is under physiological control. A practical example of these effects can be seen in the increase in scrotal circumference with age (Coulter & Foote, 1978). This parameter is quite valuable as an objective estimate of normal development of the testes and epididymis. Figures from bull examinations suggest that while a scrotal circumference of 35–40 cm is desirable in a young bull (approximately 18 months old), measurements below 30 cm are likely to be linked to infertility or subfertility. However, we have collected perfectly normal semen from young well-grown bulls with scrotal circumferences around this size. We therefore recommend collecting semen from 'borderline cases' if there are likely to be other

parties involved in the future of the bull. One theory for the relatively lower fertility seen in young bulls when compared with adults is related to the development of both testes and epididymis in the young bull, which has roughly half the sperm output of an adult, but less than one-quarter of the storage available in the tail of the epididymis with probably only enough for two to three days' sperm production. Hence it is much easier to deplete the young bull. Furthermore, it will be apparent that relative to the testes the epididymis, particularly the tail, is still enlarging and just how this interacts with sperm maturation in these young bulls is not well understood (Amann & Almquist, 1976; Amann and Schambacher, 1983).

In summary, while the bull may be capable of reproducing quite early in life it is not until after three years of age, or possibly even a little later in the case of late-maturing continental bulls, that one can safely say that the fertility of the bull is unlikely to improve further. While detailed studies are not really available it does appear that fertility also diminishes with advancing age (Amann & Schambacher, 1983). In the older bull poor fertility is associated with degeneration of some of the seminiferous tubules and with the development of testicular calcinosis in the seminiferous tubules resulting in non-productive areas of testes. Testicular calcinosis can be quite marked in some older bulls; however, it can also occur in young animals (Turnbull, 1977). Clearly there is very little that the veterinarian or farmer can do to influence this factor other than limit the mating pressure to both young and old bulls as recommended earlier and this is discussed further below.

Overwork

Much of the information about semen quality and work rates come from AI centres. However, the demands upon bulls running and mating with a herd of cows are obviously very different from those at an AI centre since young active bulls may serve a cow ten times or more during oestrus. This sort of pressure (ten ejaculates in two hours) results in a diminution of total sperm numbers per ejaculate by a factor of around ten (Salisbury & Van Demark, 1961), mainly due to a fall in concentration. Concentration in such circumstances falls to as low as 100×10^6 sperm/ml, a level that, in a semen evaluation as described here, would certainly result in the fertility of the bull being questioned. However, theoretically, a complete rest of around two weeks should allow a return to normal sperm concentrations in the ejaculate. In practice this is generally the case. In other words, the main effect of overuse is to exhaust the epididymal reserves. However, at very high and sustained mating pressures a slower return to

normal number of spermatozoa per ejaculate may be found. Furthermore, it has also been noted that as the number of ejaculates increases, sperm motility tends to fall. In addition, the likelihood of an occasional azoospermic ejaculate increases (Salisbury & Van Demark, 1961). Finally, there is some information indicating that young bulls given a diet below maintenance for energy take considerably longer to replenish their sperm reserves. This is particularly relevant to young post sale bulls, which are purchased in very good body condition and then put outside with cows in a hard environment, thereby losing condition rapidly. By inference such bulls take considerably longer to replenish their sperm reserves (Salisbury & Van Demark, 1961). The history, number of cows, frequency of working and the age of the bull will generally indicate this diagnosis. At worst the semen picture will be of low concentration ($200 \times 10^6/\text{ml}$ or less), marginal initial motility (2/5), but reasonable progressive motility (60 per cent +) and morphology (<20 per cent abnormal). However, often the bull has been removed from the breeding group and rested before examination so the sample appears normal. As already indicated, treatment is sexual rest since it takes nine weeks for development from the spermatogonia stage to ejaculation as a mature spermatozoon. Hence ideally the bull should not serve for at least nine weeks before being re-examined. There is little point in re-examining a bull after less than three weeks' rest. When this diagnosis is made the prognosis is good. However, one must always be aware that such a diagnosis may be complicated by another underlying cause and so it is advisable to be 'guarded but hopeful'.

Testicular hypoplasia (and testicular atrophy)

Testicular hypoplasia is defined as the congenital presence of either one or two small testes (i.e. bilateral or unilateral). It has been closely studied in the Swedish Highland breed of cattle, where it has been demonstrated to be a heritable defect caused by a recessive gene with incomplete penetrance (Fig. 38.16). In both unilaterally and bilaterally affected cases sexual behaviour and secondary sexual characteristics are normal (Lagerlöf, 1951). It is not known whether a similar inheritance pattern applies to other breeds. It is theoretically possible that toxic or infectious agents affecting the dam at a critical stage of organogenesis of the testes could also cause hypoplasia, either bilateral or unilateral. Mention should also be made of bilateral testicular hypoplasia that is associated with the abnormal sex chromosome constitution XXY, i.e. an 'extra' X chromosome (Figs 38.17 and 38.18). Other cytogenetic abnormalities may be associated with infertility. Thus it

Fig. 38.16 Unilateral testicular hypoplasia in the Ayrshire breed. Note the adhesions on the normal testis caused by needle biopsy.

is believed that chromosomal abnormalities may interrupt the meiotic process to such a degree that infertility or reduced seminiferous tubule output is a result (Chandley, 1979). This does not appear to be as much of a problem in cattle as in man, though there is evidence of reduced fertility in cattle carrying a 1/29 Robertsonian translocation (Gustavsson, 1974; Logue & Harvey, 1978) and bulls with 61 XXY chromosomes are, as might be expected, completely sterile (Logue *et al.*, 1979). However, the nature of the bovine karyotype has meant that identification of reciprocal translocations is not easy and it is likely that, with improved techniques, some will come to light. These abnormalities are more likely to be associated with infertility than the Robertsonian translocations, which are not uncommon in the cattle family.

Although testicular atrophy should be dealt with under degeneration from a clinical point of view it is also being considered here because unless one has a firm history of the previous size of the testes it can be extremely difficult to differentiate between testicular hypoplasia and testicular atrophy, especially in the bilateral state. Both present as the 'small testes syndrome' (Fig. 38.19). Testes that have been affected by atrophy subsequent to a severe local infectious condition or trauma may feel small, firm and nodular on palpation, while those affected by hypoplasia are usually less firm and more uniform. Frequently, one is left in genuine doubt about the diagnosis.

Scrotal circumference measurement can be helpful in giving an objective guide to testis size, as it is a simple, highly repeatable, measurement. In other species it has been related to spermatozoa production and, intriguingly, ovulation rate in the female offspring (Land, 1978). However, from a practical point of view it is sufficient to note that those males with a below normal

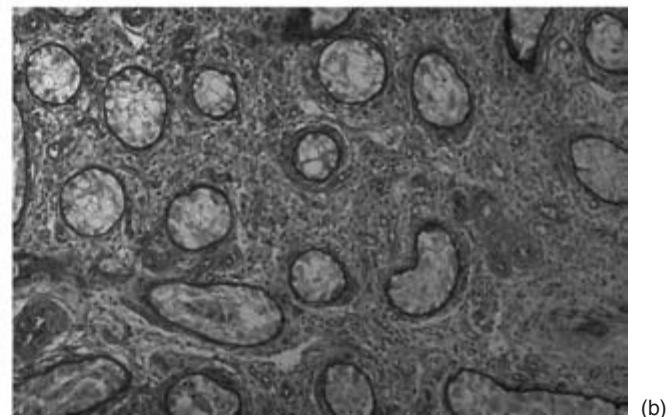

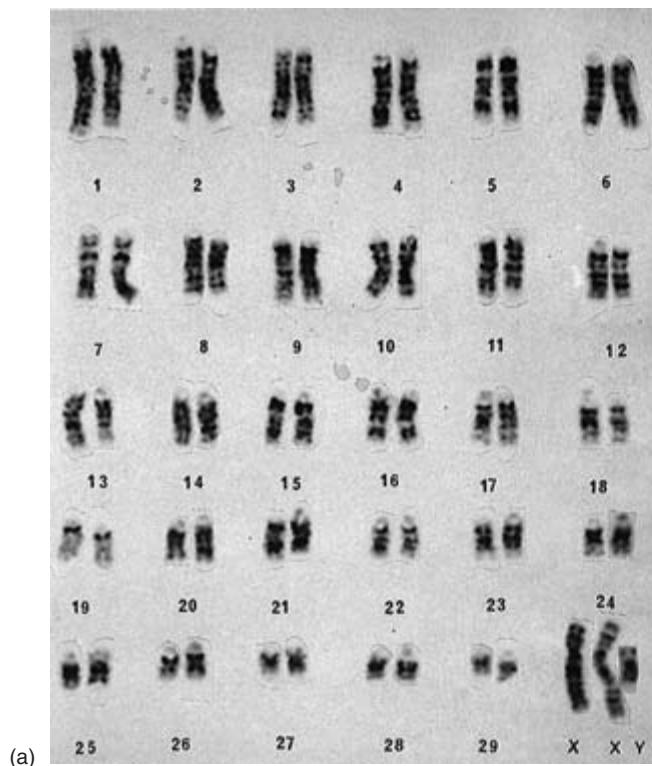

Fig. 38.17 (a) G-band karyotype 61XXY. (b) XXY bull. Tubules lined by Sertoli cells only, Leydig cells moderately increased in proportion (Masson $\times 195$). (Courtesy of the *Veterinary Record*.)

Fig. 38.18 A 61XXY bull with bilateral testicular hypoplasia.

scrotal development have a greater likelihood of being infertile. A further diagnostic aid that may prove of value is the determination of the chromosomal constitution of the animal.

As already mentioned, care must also be taken not to jump to conclusions. Surprisingly good quality semen has been collected from bulls with disappointingly small scrotal circumferences. However, such occasions are rare, so that in general the prognosis for the 'small testes syndrome' is poor. As far as the unilateral condition is concerned this is more problematical since the animal is often fertile. Here every attempt to obtain as reliable a history as possible should be made in order to differentiate between hypoplasia and atrophy because of the strong evidence of the heritable nature of hypoplasia. If the diagnosis is hypoplasia the owner should be advised that such stock are only fit for the production of 'slaughter generation' animals.

Testicular degeneration and atrophy

In many infertile animals the main histological finding is the absence of dividing spermatogenic cells, the Sertoli cells and interstitial cells still being present. This is often the result of testicular degeneration. Evidently,

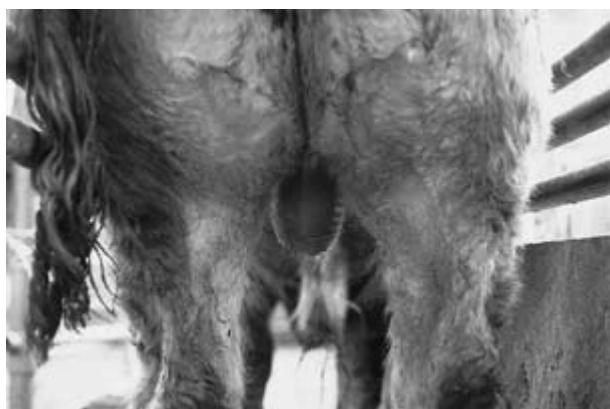

Fig. 38.19 'Small testes syndrome' (scrotal circumference 24 cm) in a Limousin bull aged 2 years with no previous history of fertility. The bull also intermittently displayed spiral deviation of the penis. Semen density was very low ($4.0 \times 10^6/\text{ml}$).

Fig. 38.20 Severe acquired testicular abnormalities in a Charolais bull aged 5 years. Chronic orchitis of the left testis manifested as atrophy, fibrosis and adhesions. The right testis whilst of normal size was very soft in consistency. The bull showed a complete absence of libido.

however, histology does not show the defects of function, in particular the delicate interaction between the cells of the testes and their hormonal influences from, and feedback to, other hormonal control centres. Spermatogenesis is a very sensitive process and can be easily upset. Nevertheless, it can also recover, particularly if the insult has been transient. Studies in the rat have shown firstly that Sertoli cell function was disrupted by a whole variety of noxious stimuli and that one side effect of such damage was an increase in serum follicle stimulating hormone (FSH) concentrations due to a decreased output of inhibin. Secondly, the Leydig cells were also affected since serum luteinizing hormone (LH) concentrations were higher and testosterone concentrations lower. Finally, there was evidence of a reduced response to human chorionic gonadotrophin (hCG) (de Kretser, 1979). The inference is that damage to the spermatogenic epithelium interferes with androgen binding protein (ABP) and inhibin release leading to an increased FSH concentration, which in turn alters the balance of testosterone-oestradiol synthesis towards the latter with a subsequent alteration in LH concentrations. Since there is evidence that LH can directly affect the Leydig cell, testosterone release and so ABP release by the Sertoli cell, it can be hypothesized that if events are prolonged or extreme these effects may accumulate and eventually result in a permanent derangement. However, it is of considerable interest to veterinarians in the field that immunization of bulls to gonadotrophin-releasing hormone (GnRH) is generally reversible (Robertson *et al.*, 1982). This then implies that in many clinical cases where such a regeneration of the seminiferous epithelium does not occur the underlying aetiology is more than just a simple hormonal dysfunction.

Insults to spermatogenesis causing temporary or permanent testicular degeneration can be categorized as either local or systemic.

Local:

Scrotal sac disruption: Obviously, severe trauma to the scrotum can have a direct effect upon the testes and epididymes, but one of the main functions of the scrotum is temperature control and any disruption of this can interfere with spermatogenesis. The first area of spermatogenesis affected is meiosis; the spermatogonia tend not to be affected and, after removal of the insult, regeneration within six weeks is to be expected providing the Sertoli or nurse cells are not damaged also. These are the most resistant to insult (Kumi-Diaka & Dennis, 1978). While weather conditions are capable of insult and cause variations in semen quality (Parkinson, 1987), it really requires trauma, a severe skin infection, an allergic reaction with scrotal oedema, a scrotal hernia or a deformity of the pampiniform plexus (so-called varicocele) to produce serious infertility. Diagnosis should be determined by a clinical examination. The most obvious problems are varicocele and inguinal herniation. Care needs to be taken when making the latter diagnosis as a pad of fat can lie above the pampiniform plexus and feel very like a hernia. The treatment and prognosis both depend on the cause. Thus for a simple skin infection one would be more hopeful of a return to normal fertility than for a varicocele or a hernia.

Orchitis/epididymitis: Inflammation of the testes is commonly a purely local problem and frequently it only involves one testicle. However, often the infection so interferes with the temperature gradient of the scrotum that the remaining testicle is indirectly affected (Fig. 38.20). A similar effect is seen with epididymitis,

although in this case there is the further problem of obstruction of spermatozoa and testicular fluid on the affected side. Often orchitis and epididymitis are concurrent. The causes of orchitis/epididymitis infection are not well documented. In many cases *Arcanobacterium pyogenes* can be isolated from the affected testes, but whether this is the original pathogen is uncertain. Other bacteria, such as those of the *Haemophilus/Histophilus* group, have been implicated in spermatogenic damage as have a number of viruses.

These conditions should also be relatively easily diagnosed by a clinical examination. Confirmation can be obtained from the semen findings. Generally, there will be low concentration of spermatozoa, poor/marginal motility and poor spermatozoan morphology, especially of the head. There will also be increased numbers of white blood cells and other cells indicative of damage such as large multinucleate cells, so-called 'giant cells'. Culture of semen may allow the identification of a causative micro-organism. However, the findings will to some degree depend on the time scale. Thus a bull with a spermatocele (see later) on the head of the epididymis could have been affected several years previously and the effects of the lesion subsided, allowing the semen quality of the bull to return to normal.

Treatment by antibiotics is usually ineffective and the main aim should be to prevent testicular degeneration of the sound testis and epididymis. The strategy adopted depends on the severity of infection. Thus assuming the remaining testis is not affected the removal of a grossly infected testis is the most straightforward remedy. Unfortunately, even then the local, and possibly systemic, damage to the other testis may be sufficient to cause a permanent derangement of semen production. Thus the prognosis, even in animals that have recovered either after surgery or after conservative treatment, should be guarded. The owner should be reminded that the daily sperm output may be affected in apparently recovered animals and that they should carefully monitor the cows that have been served in the bull's first series of matings to ensure that the proportion of returns to service is acceptable.

Systemic:

Systemic illness: Severe illness can disrupt spermatogenesis by one or all of three routes: firstly, by interfering with the temperature gradient of the testes, secondly as a consequence of toxæmic damage to the spermatogenic epithelium and finally by interfering with the complex hormonal secretions which control spermatogenesis and their interactions. The roles of bacteria and viruses in the aetiology of this condition are not well understood. For example, a few apparently infertile bulls have been found to be persistently

infected with BVDV or to have high antibody titres to *Leptospira hardjo*. However, in some cases the animals have subsequently proved fertile; this includes BVDV viraemic animals (Logue, D.N. & Cranshaw, N.M.C., unpublished information). It should again be remembered that the bull might be presented some time after the incident when recovery is taking place. This can take a considerable time – at least some two to three months. Finally one interesting condition, worthy of mention, is idiopathic angioneurotic oedema. This is occasionally seen in young bulls, particularly of continental breeds, and generally occurs soon after introduction to grazing. There is often tremendous oedema of all the dependent areas, especially the scrotum, with consequent azoospermia. The latter is presumably due to a temperature effect. In our limited experience recovery is usually complete, however with other illnesses this is not always the case, especially in older bulls. Treatment and prognosis are dependent on the history, the origin of the insult and the age and type of the bull.

Drugs: Although therapeutic products are subject to very stringent safety screening there are certain drugs that might affect male fertility. Anabolic steroids given to young growing bulls have been shown to have an undoubtedly effect upon spermatogenesis, resulting in a reduced testicular size and delayed development of the seminiferous tubules and interstitial cells (O'Lamhna & Roche, 1983; Deschamps *et al.*, 1987a,b). Although it was suggested that these effects were temporary, in fact there was a delay in puberty and the effect was more severe in younger animals (these studies have only involved animals of up to 15 months and may not truly reflect the field situation). In addition there was evidence of interference in the hypothalamic–pituitary axis and the size and structure of the testes and epididymis. Finally, the fact that the studies were relatively short term makes one very wary of such a claim. The only problem that might arise is with clandestine and improper administration of a drug, such as an anabolic steroid or β agonist, with the intent of improving the appearance of the bull or even liveweight performance test results. It is possible to test for residues. It is possible that a bull could suffer from an adverse reaction to one of the common treatments, although such cases are rare. The diagnosis is dependent on the history and the treatment. Given the effect of anabolic steroids, by inference treatment with corticosteroids is also likely to affect semen quality (Li & Wagner, 1983), and indeed some slight changes have been described short term. However, administration to adult Holstein bulls did not appear to cause any practical spermatogenic problems (O'Connor *et al.*, 1985). Nevertheless, there is more recent evidence that some non-steroidal anti-inflammatory drugs such as flunixin could have an

effect (Archibald *et al.*, 1990). Treatment of such adverse reactions is symptomatic while the prognosis depends on the exact form that the adverse reaction takes. Field experience has also failed to show any fertility effect associated with the administration of the commonly used antibiotics. However, again the periods of administration were relatively short. Abbott *et al.* (1984) reported that neither dihydrostreptomycin sulphate nor oxytetracycline hydrochloride had any real effect upon reproductive function, even when given in greater than normal therapeutic doses.

The diagnosis of testicular degeneration is dependent upon a history of fertility, followed by infertility with the latter being confirmed by the collection of a semen sample of poor spermatozoa motility, concentration and morphology. In addition there will sometimes also be small, darkly staining, degenerate spermatids, which in some cases 'raft' together in clumps. In the extreme case the sample may be aspermic. In cases of testicular degeneration the testes may be smaller than normal due to atrophy, but often they are within the norm. While collection of semen is the main diagnostic tool many workers have desired to examine the seminiferous tubules. A number of authors have attempted to use a testicular biopsy as a means of obtaining histological evidence of spermatogenic dysfunction (Galina, 1972). This technique is hazardous even when one uses a modern disposable biopsy needle due to haemorrhage (the testis is very vascular), spermatogenic disruption and adhesions. However, with time, good spermatogenic recovery can occur (Galina, 1972; Logue, 1975).

Because testicular degeneration can be either temporary or permanent, it is impossible to be certain of the prognosis on the basis of a single semen examination. However, some guidelines can be obtained by looking at the length of infertility and the semen picture. Should the time scale be relatively short, say three months, and there is evidence of normal motile spermatozoa, albeit at a low concentration, then it is worth waiting another three months for a re-examination. Where the degeneration of the seminiferous epithelium is permanent then this may result in a gradual diminution in size of one or both testes, i.e. testicular atrophy. Unfortunately, unless one had prior knowledge that the affected bull had previously had normal-sized testes in the bilateral condition this small size could quite easily be considered to be testicular hypoplasia. Where there is good evidence of testicular atrophy being present then the prognosis is very poor.

Interference with transport and storage of spermatozoa

It is generally impossible to differentiate clinically which of the local and systemic effects mentioned

earlier have an effect solely upon the epididymis, since, as already mentioned, any disruption of testicular function frequently interferes with epididymal function.

The epididymis, unlike the testis, develops from the mesonephric (Wolffian) ducts and is prone to several congenital malformations (Blom & Christensen, 1960). Aplasia of part of the epididymis, ductus deferens and seminal vesicles has been described as a congenital defect in the bull. The aplasia is usually unilateral and can be very specific. It is generally associated with spermatocele formation (so-called sperm granulomas) proximal to the aplasia (Blom & Christensen 1960). These are swellings of the epididymis reflecting a rupture of the tubules and the consequent foreign body reaction to the escaped products of the testes and are most commonly seen on the head of the epididymis. While they have been described as being a result of segmental aplasia (see above), in some cases spermatoceles arise in this position apparently spontaneously. Spermatocele formation has been diagnosed in the field following a sudden failure to mount and thus, by inference, it is painful in the acute phase (Logue & Greig, 1986). Since this was the only behavioural demonstration of pain it could be that any discomfort is only appreciated during sexual arousal. The exact relationship of the spontaneous condition to segmental aplasia is uncertain but one cannot ignore the possibility of an infectious condition causing an epididymitis and subsequent spermatocele. However, epididymitis resulting from infection by *Brucella* sp. and the *Haemophilus/Histophilus* group appears to occur most frequently in the tail of the epididymes. *Mycoplasma* infections have also been implicated in epididymitis (La Faunce & McEntee, 1982).

Unilateral spermatoceles need not necessarily cause sterility since once the inflammatory reaction has settled the remaining testicle can produce an apparently normal ejaculate. However, it is clearly not advisable to use such an animal with a large number of females, as in two cases known to the authors, where the bulls involved were at an AI centre and the concentration of the ejaculate never returned to the level seen before the incident. In one of these bulls the epididymis of the other testis also later suffered the same problem and the bull had to be destroyed. No significant micro-organism could be found (Logue, D.N. & Hignett, P.G., unpublished information). Ease of diagnosis depends on the site and the extent of the problem. Should there be a spermatocele then this is generally easily palpated provided one is careful and palpates the entire epididymis. However, some defects can be very small and ultrasound may well prove a very useful diagnostic aid. Treatment is usually symptomatic and certainly in the early stages antibiotic administration is probably worthwhile.

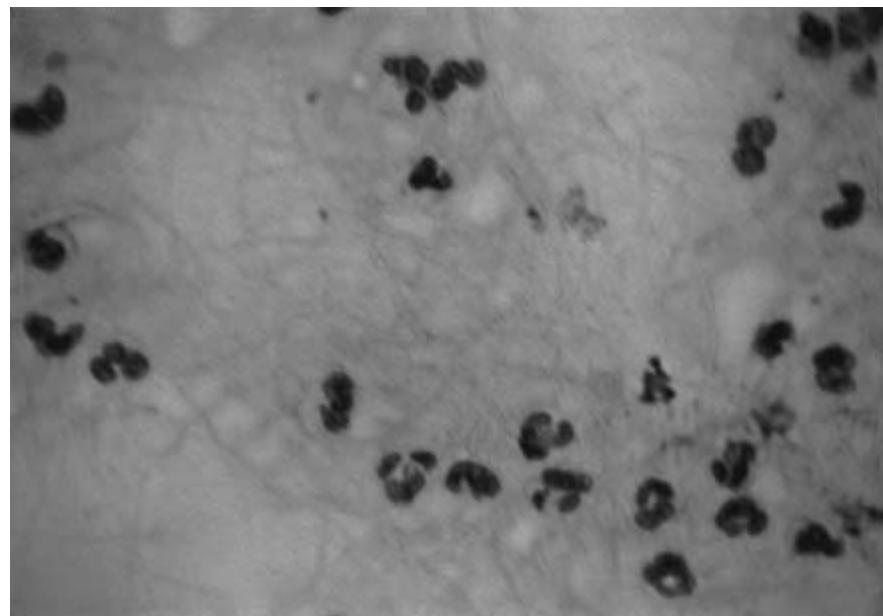

Fig. 38.21 White blood cells in semen (methylene blue) ($\times 700$).

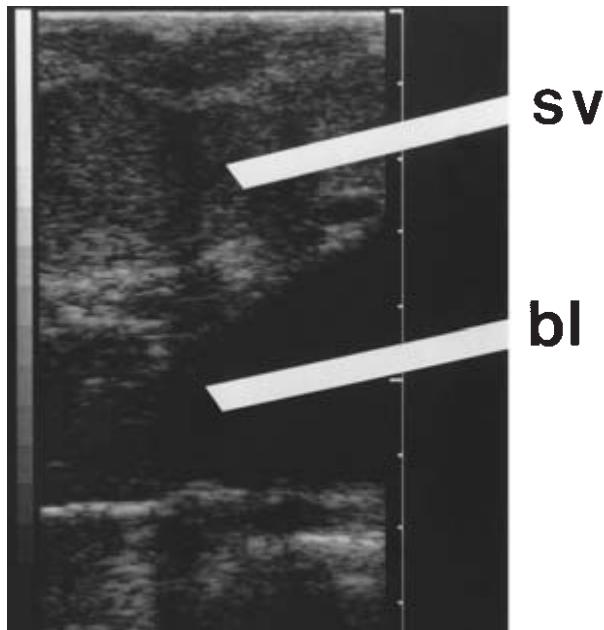

Fig. 38.22 Real-time ultrasound of the seminal vesicle. sv, seminal vesicle; b, bladder.

In some cases small compact masses up to the size of a pea, so-called cysts, can be felt both on the epididymis and on the spermatic cord itself. They are developmental in origin and of no consequence as long as they do not interfere with sperm transport.

Abnormalities of the accessory sex glands

The accessory sex glands consist of the seminal vesicles, ampullae, prostate and bulbourethral glands.

As already mentioned, abnormalities of the seminal vesicles are the most commonly diagnosed condition. Segmental aplasia of the seminal vesicle occurs and often appears to be related to a congenital defect (Blom, 1979a,b). Numerous infectious agents have been isolated and implicated in the aetiology of seminal vesiculitis in the bull, such as members of the *Chlamydia* group, *Mycoplasma bovigenitalium* and *Mycoplasma bovis* (La Faunce & McEntee, 1982). However, in severe clinically recognizable cases the most common organism isolated is *Arcanobacterium pyogenes* (Arthur, 1960; McCauley, 1980). Some authors believe that these infections of the seminal vesicles are secondary to congenital defects. Diagnosis of these abnormalities is firstly dependent upon rectal palpation (where enlargement, firmness, pain and adhesions may be detected in the case of seminal vesiculitis) and ultrasonic scanning; and secondly upon laboratory tests, particularly the examination of semen for white blood cells which indicate the presence of inflammation (Fig. 38.21). Hopefully, ultrasound scanning will prove of value in the reliable diagnosis of severe seminal vesiculitis and also of segmental aplasia of the seminal vesicle (Fig. 38.22). However, as mentioned before, the application of the technique is still in its infancy (Little & Woods, 1987). Treatment of an infectious condition obviously requires antibiotic, preferably one with a broad spectrum, and given that there is no evidence of severe effects upon the structure of the seminal vesicles, prognosis is good.

Conditions affecting the other smaller accessory sex glands of the pelvis in the bull have rarely been recognized clinically, but this may yet be possible using ultrasound.

Conclusion

The investigation of infertility in the bull is one of the most interesting examinations in farm animal practice. The approach is standard and success is dependent upon attention to detail in all the facets mentioned in this chapter. One of the main advantages the general practitioner has compared with the specialist is an intimate knowledge of the farm, the ability of those involved as stockworkers and also a fair idea of the reliability or otherwise of the history and records. On the other hand, the major disadvantages are the small number of cases that the practitioner will see in a year, so limiting the experience that can be built up, and the standard of equipment, particularly microscope, required. Finally the amount of time and flexibility of time that need to be devoted to such work must be balanced against other, possibly more remunerative, demands of a busy practice.

Introduction

Large scale artificial insemination (AI) for cattle was started in Russia at the beginning of the twentieth century (1909) by the stimulating impetus of Professor Ivanovich Ivanov. Verbal history says that it was used for genetic improvement, but mainly to avoid transmission of venereal diseases. These diseases were transmitted from infected cows to cows on different farms by travelling bulls used for natural service. Using extended (diluted) semen the great number of offspring by one bull also produced more information on its breeding value. The main goal of AI is to improve the genetic potential of cattle, and considerable progress has been made since its applications.

Semen is shipped all over the world, and consequently must be free from infectious diseases. Relevant regulations apply in all parts of the world, but may differ slightly between countries. The EU regulations concerning semen production are laid down in Directive 88/407; semen imported into the EU from other countries must also conform to this standard.

Semen is only safe beyond doubt if produced by bulls that were proved to be free of infectious diseases 21 days after its production. International regulations current at the start of the twenty-first century do not fulfil this requirement.

Semen processing

After collection and application of extenders (specific diluents), semen must be cooled to 5°C over a period of 2–5 hours before freezing in liquid nitrogen. During this period metabolism of the spermatozoa continues and metabolic products are excreted into the liquid of

the ejaculate. Extenders are applied to improve the buffering action of the media surrounding the spermatozoa for protection against toxic metabolic substances (mainly lactic acid), and secondly to increase the volume in order to serve as many cows as possible with one ejaculate.

Between 300 and at least 1000 straws can be produced from one ejaculate, depending on the concentration needed in one dose. Fertility after insemination is often expressed as the non-return rate (NR): the percentage of cows that are not rebred within a certain period (usually 56 days). This information can be used to optimize the concentration of spermatozoa per dose. Each dose is delivered in a straw (0.25 ml in Europe, 0.5 ml in the USA) containing on average 15×10^6 sperm cells. However, fertility results differ between bulls. The average NR in the Netherlands is 68 per cent; some bulls score above and others below the average. Thus the semen concentration of each bull is altered to produce the average NR and thereby allow an optimal number of cows to be served and become pregnant with each ejaculate. Fertility of bulls can only be judged after insemination based on NR. The criteria in the laboratory do not have predictive value for fertility: very often disappointing results are obtained with semen that was considered of excellent quality in the laboratory, while conversely excellent fertility has been obtained after natural service with bulls that did not fulfil the standards for AI bull approval.

Technique of artificial insemination

The technique in itself is easy to perform, cheap and applied world-wide rather uniformly by technicians and veterinarians. Insemination is routinely performed by the recto-vaginal technique. One arm is introduced into the rectum of the restrained cow in heat, grips the cervix and stretches the vagina. After careful cleaning of the vulval area, the AI gun is inserted into the vagina and through the cervix for the deposition of three quarters of the semen into the corpus uteri (uterine horns are too deep) and, after limited withdrawal of the AI gun, the remaining quarter is deposited in the cervix at the

first insemination after parturition. At the second or higher number of inseminations the semen must be deposited in the cervix only, because a limited number of cows show signs of heat in the presence of an embryo. Introduction of the gun into the corpus uteri might interrupt the integrity of the embryo and thus interfere with pregnancy.

The proper time for insemination is in the last period of the standing heat. Cows are selected for insemination by observation of the herd at least twice daily during moments of quiescence: observation during periods of even limited excitation (for example during collecting for milking) can lead to the insemination of cows not in heat and thus to disappointing fertility results. Several aids have been applied to improve heat detection such as electronic pedometers, heat mount detector pads, spotter bulls, etc. However, careful observation of the herd and proper records of heat periods undoubtedly form the backbone of good fertility results (see Chapter 41b). Harmful side effects of improper insemination are infections and/or injuries of the genital tract, which are dealt with in Chapter 36.

Diseases transmissible by semen (and/or mentioned in trade certificates)

Table 39.1 summarizes the diseases in this category.

Foot-and-mouth disease (FMD) (see also p. 700)

This is a highly contagious disease of cloven-hoofed animals characterized by high fever followed by vesicles on the mucosa of mouth and tongue, the feet and the udder. FMD is caused by a picornavirus comprising seven serotypes; infection with one serotype does not induce immunity to other serotypes. In order to prevent spread of the disease in a country immediate recognition of the clinical picture is essential. For a positive diagnosis the demonstration of FMD viral antigen by indirect sandwich ELISA techniques, preferably in the epithelium of unruptured or freshly ruptured vesicles, is sufficient. The agent is very resistant to environmental factors and may be spread over long distances by air and/or vehicles and/or man. FMD virus is easily transmitted by semen.

Infectious bovine rhinotracheitis/infectious pustular vulvovaginitis (IBR/IPV) (see also pp. 289, 579)

This is a disease of the upper respiratory tract or of the genital tract, respectively. IBR is characterized by clinical signs such as high fever, nasal discharge, ocular

discharge and abortion in up to 30 per cent of pregnant animals. The disease has a high morbidity but a low mortality. However, the disease might follow a more severe course if complicated by bacterial infections. IPV is characterized by erosion in the vagina or on the penis, leading to adhesions. The disease is caused by bovine herpes virus type 1 (BHV1) which can be subdivided in strains with preference for the respiratory or genital tracts respectively. Diagnosis is made by demonstration of the virus in secreta from respiratory and/or genital tracts up to 14 days after infection, and by serology. However, sensitivity and specificity of serological tests applied in various countries differ considerably. The agent may survive in favourable conditions (high relative humidity, low temperatures) for 30 days in the environment. BHV1 is easily transmitted by semen. AI centres in the EU must be free of IBR: only serologically negative animals are allowed as BHV1 infections lead usually to latency. Latently infected animals are the source for new epidemics. Latently infected animals are serologically positive for BHV1, but some seronegative latently infected cows have also been reported. However, the sensitivities of the tests applied in these animals are doubtful. Straub (see Horzinek, 1990) described seronegative latently infected animals after the application of a one hour incubation serum neutralization test with a limited sensitivity: the animals would probably have been positive with sensitive tests. It is thought that seronegative latently infected animals develop during the period of maternal immunity after an infection with a very low dose of BHV1 and they should exist in very low prevalence in endemic areas. However, Switzerland, Denmark and Austria became free of IBR: these countries eliminated the virus from their cattle populations without unexpected disease outbreaks caused by serologically negative latently infected animals. The straightforward isolation of positive animals was successful. So the problem of serologically negative latently infected animals is very limited or even non-existent.

Bovine virus diarrhoea (BVD) (see also pp. 578, 853)

BVD is observed clinically as transient diarrhoea during three to ten days after infection in at maximum 5 per cent of infected animals; in exceptional cases severe diarrhoea, fever, ulceration of the buccal mucosa, haemorrhages and death occur. The remaining 95 per cent of the infections pass unnoticed. When infected in the first four months of pregnancy, cows may deliver persistently infected (pi) calves that shed the virus during their lifetime. The disease is caused by the pestivirus bovine virus diarrhoea virus (BVDV). Bovine virus diarrhoea is endemic world-wide. Diagnosis is by antigen ELISA or culture of the virus from

Table 39.1 The main characteristics of infectious diseases that could be transmitted by semen or artificial insemination.

| Disease | Incubation period | Reservoir | Excretion mainly by | Period of transmission/viraemia | Transmission by semen/AI ^a |
|--|------------------------------------|--|---|--|---------------------------------------|
| FMD | 2–8 days | Animals in the acute phase Chronic carriers (cattle) | Saliva Other secreta | <14 days Carriers for up to 2 years | ++ |
| IBR/IVP | 2–5 days | Latently infected animals | Nasal discharge | 2–20 days | ++ |
| Rinderpest | 4–15 days | Cattle in the acute phase | All secretions and excretions | 21 days or longer | ++ |
| BVD | 2–15 days | Persistently infected (pi) cattle Cattle up to 56 post infection | Saliva All secretions and excretions of pi animals | Variable, usually 2–15 (but up to 56) days | ++ |
| MCF | From a few days to year(s) | Sheep during lambing period | Unknown | Unknown, not cow to cow | 0 |
| Akabane virus | ?? | Biting insects | Viraemia | Viraemia during prolonged periods | 0 |
| Bluetongue | 3–6 days | Biting insects | Viraemia | Viraemia, mostly <14 days | 0 |
| Enzootic bovine leukosis (EBL) | Up to 35 days | Chronically infected cattle | Intact blood Lymphocytes | During lifetime after infection | 0 |
| Genital campylobacteriosis | <3 days | Chronically infected cattle: bulls without symptoms | Copulation | During lifetime after infection | ++ |
| Bovine brucellosis | 14–120 days | Chronically (latently) infected animals | Vaginal discharge Fetal membranes | Prolonged periods | + |
| Bovine tuberculosis | >3 weeks | Chronically infected cattle | Nasal discharge | During lifetime after open tuberculosis | + |
| <i>Leptospira hardjo</i> | <7 days | Chronically infected cattle | Urine | Prolonged periods after infection | + |
| Johne's disease | Occasionally 12; usually 24 months | Chronically infected cattle | Faeces | From 18 months before overt clinical disease onwards | 0 |
| <i>Mycoplasma mycoides</i> (contagious bovine pleuropneumonia: CBPP) | 2–6 weeks | Chronically infected cattle | Nasal discharge Urine | During lifetime after infection | + |
| <i>Haemophilus somnus</i> | ?? | Harboured in genital and respiratory tracts in healthy animals | Nasal discharge Effluents from genital tract | During lifetime after infection | + |
| Genital trichomoniasis | <3 days | Chronically infected cattle: bulls without symptoms | Copulation | During lifetime after infection | ++ |
| Query-fever (Q-fever) | ?? | Ticks Environment (dust) Chronically infected cattle (animals) | Fetal membranes Vaginal discharge | Prolonged periods | 0 |
| Bovine spongiform encephalopathy (BSE) | 4 years | CNS of contaminated cattle | Contaminated food | No transmission reported | 0 |

^a 0, unlikely; +, possible; ++, easily.

??, no experience and no information found in the literature.

the peripheral blood or organs after death, and by serology. Persistently infected animals transmit the virus during their lifetime and infect sentinel animals easily. Transiently viraemic animals, however, transmit the disease to a limited extent. These primary infections might lead to prolonged periods of viraemia (up to 40 days), the presence of virus in bronchoalveolar washings (up to 56 days after infection) and in semen even after seroconversion has taken place. Therefore, the risk for transmission of BVDV by semen is substantial. One exceptional bull has been described that shed BVDV in the semen over prolonged periods (11 months), although the animal was serologically positive. This unusual pattern might be explained by a primary infection during puberty or an intrauterine infection around the time of maturation of the immune system. There is information that this phenomenon might occur more frequently. The agent survives for some days in the environment. Transmission by semen is easy. AI centres only accept bulls that are not persistently infected. However, because some infectious routes for the introduction of BVDV are not completely understood, in endemic areas BVDV might infect bulls in an AI station. Where there is unintended infection of AI bulls the infection passes subclinically and, as this disease is easily transmitted by semen, it is very important to test for BVDV. Monthly tests for serologically negative donor bulls and, in the case of seroconversion, ensuring the semen is free from BVDV might be the only solution.

Enzootic bovine leukosis (EBL) (see also p. 693)

EBL is found clinically by enlarged lymph nodes or other lymphosarcomas, or by lymphocytosis in the peripheral blood in the minority (some 30 per cent) of infected animals. Infections for the greater part pass completely unnoticed. The disease is caused by the retrovirus bovine leukemia virus (BLV), which may be demonstrated in the blood by PCR techniques. Routine diagnosis is performed by serology (ELISA, AGID). The agent does not survive in the environment. Only intact lymphocytes are infective: the infection is transmitted by blood. Transmission by semen is very unlikely.

Rinderpest (see also p. 707)

This is a very contagious disease of mainly cattle and buffaloes. The disease is characterized by high fever, erosions on the gums, tongue and palate together with nasal and ocular discharge, and diarrhoea. Rinderpest is caused by a Morbelli virus that can be demonstrated in blood or lymph nodes and spleen, mainly by culture. Transmission is mainly directly by infected animals and

can occur via the semen. The virus survives in the environment for limited periods.

Malignant catarrhal fever (MCF) (see also p. 935)

MCF is a sporadically, almost invariably fatal disease of cattle of all ages. The disease is characterized by high fever, bright red coloration of all mucous membranes, enlarged superficial lymph nodes and very often diarrhoea. A herpes virus (BHV3) causes the disease. Diagnosis in live animals is by clinical signs, and by PCR on heparinized blood. Culture of the virus is not possible, therefore information on the resistance of the virus against environmental influences is not available. Cow to cow transmission has never been reported. Transmission by semen is therefore very unlikely.

Bluetongue (BT) (see also p. 691)

BT occurs mainly in small ruminants but may occur in cattle as well. If clinically overt (many infections pass unnoticed in cattle) the disease is characterized by fever, facial oedema, haemorrhages and ulceration of the mucous membranes. An orbivirus consisting of 24 serogroups causes the disease. The virus is identified by culture and by PCR techniques on blood samples of febrile animals. The agent is transmitted by insects of the genus *Culicoides*; transmission from cow to cow has not been reported. Transmission by semen is very unlikely.

Akabane virus (see also p. 580)

Infections of Akabane virus were shown to cause sporadic epizootics of premature births and developmental deformities in the new born (arthrogryposis-hydranencephaly) in cows, sheep and goats. The disease has been reported in Southeast Asia, the Arabian Peninsula and the Middle East and African countries. Diagnosis is done retrospectively by serology in adult animals, and by culture techniques in abnormal fetuses and calves. Biting insects transmit the agent. After experimental infection in bulls, Akabane virus was not demonstrated in the semen; transmission by this route is therefore unlikely.

Bovine genital campylobacteriosis (see pp. 568, 582)

This is a venereal disease characterized by infertility, early embryonic death and abortion. In bulls, infections are inapparent. The disease is caused by *Campylobacter fetus* ssp. *venerealis*, which in bulls can be cultured from preputial washings. Serological methods are unreliable. The organisms survive in the environment for limited periods (hours). Mating and/or semen mainly

cause transmission. Virgin bulls are absolutely free of this agent. This agent was the impetus for the worldwide application of AI techniques and for the obligatory addition of antibiotics to the semen. If this procedure is properly executed, semen is free from this bacterial agent. Bull stations should be free of this agent, but the low transmission rate makes testing more often than once a year useless. However, when a positive result is obtained, all semen batches after the last negative result should be checked for the presence of the agent and positive ejaculates destroyed.

A very similar agent, *Campylobacter fetus* ssp. *fetus*, is associated with abortion storms in sheep. In cattle, after oral uptake, this agent infects the gastrointestinal tract and is shed by the faeces. In exceptional cases, oral infections in adult pregnant cattle may lead to bacteraemia and in limited numbers to infection and expulsion of the fetus. This agent is not transmitted by mating or semen. Giacoboni *et al.* (1993) isolated *Campylobacter fetus* ssp. *fetus* from the faeces in 26.5 per cent of young calves, and in 15 per cent of older cattle. Excretion by the faeces leads inevitably to contamination of the environment and thus to the risk of contamination of the prepuce. In The Netherlands, *Campylobacter fetus* ssp. *fetus* was isolated from the prepuce of AI bulls ranging in age from 10 months to 5 years that had never served naturally.

Brucellosis (see also p. 580)

This is manifested by abortions in the last third of pregnancy. The causative organisms are excreted in abundance with uterine discharges and with milk. The disease, which is a zoonosis, is caused by *Brucella (B.) abortus*, occasionally by *B. melitensis* (lower numbers of aborting cows in the herd) and exceptionally by *B. suis*. The disease is diagnosed by culture of the causative organism from uterine discharge and milk, by serology (CFT, BUA, ELISA) or by a specific skin test. The organisms survive in the environment in favourable circumstances for prolonged periods. Transmission by semen is possible.

Bovine tuberculosis (see also p. 862)

This passes unnoticed in the early phases after infection, but in advanced cases emaciation, coughing and enlargement of the lymph nodes develop. It is caused by *Mycobacterium (M.) bovis* and occasionally by *M. tuberculosis* (the human tuberculosis strain) when an infective human source is present. Tuberculosis in live animals is diagnosed by a specific skin test, gamma-interferon assay using peripheral blood lymphocytes, serology (ELISA) and by culture from nasal secretions. The organism is resistant to environmental influences

and may survive for several months and transmission by semen is possible. Tuberculosis is a zoonosis.

Leptospirosis (see also p. 735)

Leptospirosis is a contagious disease of animals and humans. Many *Leptospira* species exist, each with their specific carrier host (reservoir) in which infection leads to diseases of limited severity and prolonged excretion. Infection in other animal species (end hosts) leads to very severe, life threatening disease symptoms. Clinically, infections in susceptible end hosts are characterized by fever, icterus, haemorrhages, uraemia and blood tinged urine. After recovery, the *Leptospira* are completely eliminated from the end host's body and transmission by semen is very unlikely. Infections in the carrier hosts pass with minor clinical problems and may even pass unnoticed.

Cattle are carriers for *Leptospira hardjo*, but end hosts for other *Leptospira* species. Infection with *L. hardjo* in cattle leads to prolonged or intermittent excretion with urine (and semen) and therefore may be transmitted by semen. *Leptospira* may survive in the environment in humid and warm conditions (summer) for longer periods. Attention in AI stations should be concentrated on *Leptospira hardjo* infections. *L. hardjo* is a zoonosis and causes milker's fever in man.

Contagious bovine pleuropneumonia (CBPP) (see also Chapter 49b)

CBPP is characterized by fever, dyspnoea, coughing, nasal discharges and anorexia. It is caused by *Mycoplasma mycoides* ssp. *mycoides*, which can be demonstrated in nasal secreta and bronchoalveolar washings or in pleural fluids collected after puncture by culture in appropriate media. The agent is vulnerable for environmental influences and is transmitted by infective animals over limited distances. Transmission by semen is possible.

Johne's disease (paratuberculosis) (see also p. 857)

This disease is chronic enteritis of ruminants, characterized in cows by severe diarrhoea, emaciation and submandibular oedema. It is caused by *Mycobacterium (M.) avium paratuberculosis*, which only leads to clinical disease and excretion after infection at a very young age. Infection leads to progressive thickening of the gut wall, causing a protein losing enteropathy with diarrhoea in the final stages after 24 months or longer. *M. paratuberculosis* was found in the semen of bulls that suffered from severe clinical disease.

In the clinical stages, the agent can be demonstrated in faeces and exceptionally in milk and the fetus by

culture and/or PCR techniques. The use of PCR on the faeces lacks sensitivity. For the detection of subclinically infected animals a skin test, ELISA and CFT are applied. Each method has the disadvantage of limited specificity and sensitivity.

Transmission by contaminated semen or semen from contaminated bulls has never been demonstrated. Johne's disease is endemic in most countries of the world. The prolonged incubation period and test systems with low sensitivity lead inevitably to the introduction of infected calves into the AI centres. However, excretion by semen does occur only after prolonged excretion by the faeces, and shedders can be traced by the application of annual faecal culture tests from the age of two years. Furthermore, there is no evidence that contaminated semen infects cows after insemination. Johne's disease might be a zoonosis (Crohn's disease in man).

Haemorrhagic septicaemia (HS) (see also p. 728)

HS is a highly fatal disease characterized by initial fever, respiratory signs and terminal septicaemia leading to recumbence. It has been reported from Asia and Africa, and is caused by certain strains of *Pasteurella multocida*. The agent can be cultured from blood and from internal organs. *P. multocida* is moderately resistant to environmental influences. Transmission by semen is very unlikely.

Query fever (Q-fever) (see also p. 586)

In cattle, Q-fever is characterized by abortion, retained placenta, metritis and infertility. The disease is caused by *Coxiella (C.) burnetti*. Diagnosis is established by microscopy of fetal membranes or aborted fetuses, or by culture of this agent in embryonated eggs from uterine effluents. Routine diagnostic tests are made by serology (CFT, ELISA). The agent is extremely resistant to environmental influences. Transmission is caused by biting insects or by inhalation of contaminated dust. Transmission by semen is limited or unlikely. Q-fever is a zoonosis.

Bovine genital tritrichomoniasis (see also p. 584)

This is characterized by infertility and abortion. Bulls may be infected without clinical signs. The disease is caused by the protozoan *Tritrichomonas fetus*, which comprises three serotypes of equal pathogenicity. The agent can be cultured from uterine discharges and preputial washings. *Tritrichomonas* is rather resistant to environmental influences. Mating and/or semen mainly cause transmission. Virgin bulls are free of this agent. However, if an infection with tritrichomoniasis is

diagnosed, no treatment is available and the bull and its semen must be destroyed.

Bovine spongiform encephalopathy (BSE) (see also p. 909)

BSE is a fatal neurological disease of cattle with a long incubation period. Clinically, behavioural changes and locomotion disturbances such as ataxia manifest the disease. Feed is generally regarded as the most likely source of infection. After (oral) uptake of abnormal protein some of the body protein is stereometrically altered, making the protein invulnerable to proteases and thus leading to intracellular accumulation of prions. This stereometrical change leads to death of brain cells, resulting in the aforementioned. No diagnostic tests for live animals are available, although some promising results have been reported. The prions are extremely resistant to environmental factors. BSE prions have never been demonstrated in the genital organs of diseased bulls or in the semen and experimental insemination of susceptible cows with semen from BSE-contaminated bulls has not been shown to induce BSE in the cows or progeny. There is no proof that prions might be present in the semen. At present the risk of BSE transmission by semen is thought to be negligible and so restrictions on semen trade due to BSE should be minimal or none. BSE is considered to be a zoonosis (new variant CJD).

Other infectious agents

Ubiquitous agents that might be or are present in semen, e.g. *E. coli*, *Proteus* spp., *Pseudomonas* spp., *Haemophilus* spp., *Campylobacter* spp. except *C. fetus* spp. *venerealis*, *Mycoplasma* spp., and *Ureaplasma* spp., should not hinder the semen trade: the addition of appropriate antibiotics after proper procedures is a sufficient guarantee for safety.

Semen safety

For safety testing of semen, two approaches can be applied: examination of the end product or continuous surveillance of the bulls before and after semen production. The tests for the presence of infectious agents in the semen completely depend on one single investigation and therefore rely on the sensitivity of the test methods only. The continuous surveillance of the semen donors for infectious diseases before and after semen collection is based on sequential investigations, increasing the reliability by the application of multiple tests. In terms of semen safety, testing the donor for the absence of infectious diseases 21 days after semen collection is

beyond doubt the best method. Therefore the bulls in AI centres must be negative for the diseases mentioned above. The very first step is to accept only virgin bull calves negative for these diseases. Most AI centres in Europe that release semen for the EU market collect their bull calves before the age of six months. There are no concerns about diseases from which the area is officially declared free. An annual check on the health status will suffice if the country in which the AI centre is situated remains negative. However, if diseases are endemic, theoretical risks exist for the introduction of disease agents into AI studs. Preventive measures should concentrate on optimal hygiene for humans entering the premises (showering and changing clothes), on 48-hour storage periods (including forage) or on disinfection of materials before admittance into the station, the use of mains water, and on the eradication of vermin. One risk factor remains, however infectious particles transported by air and/or birds. Only large distances (more than 1 kilometre) between the AI station and other cattle in the area will suffice.

The next step is to minimize the consequences of the unintentional introduction of agents into AI centres. Regular checks must be performed for the presence of disease agents that might be transmitted by semen: animals found positive must be separated or destroyed immediately. The system for checking the disease-free status of the bulls depends on the transmission routes and transmission rate. Highly contagious diseases with a high risk for transmission by semen should be checked regularly (monthly). The rates at which diseases are transmitted to other animals depend on a number of characteristics of the pathogen, the host and of the contact structure between animals. An important parameter related to transmission is the basic reproduction ratio, i.e. the number of animals that are infected by one typical infectious animal during its entire infectious period. This number depends greatly on the number of effective contacts between animals. A contact is effective when the pathogen is transmitted from one infected animal to another (excretion titre above the minimal effective dose). These contacts might be either direct (animal-animal) or indirect (by air, people, equipment, etc.). High transmission rates in AI stations will be achieved when the number of effective contacts is high and the length of the incubation

period is short. For diseases with high transmission rates (e.g. IBR) monthly checks of 20 per cent of the donor bulls give a certainty of 99.9 per cent for semen safety. This method is applied in one centre in The Netherlands.

Introduction

Although considered a recent technology, Walter Heap performed the first successful embryo transfer (ET) in rabbits over a hundred years ago. A further six decades elapsed before the first embryo transfer calf was produced in 1951, in the USA, by Willet and his colleagues. The first commercially acceptable results were recorded in cattle in 1969 by Rowson and his colleagues. In 1973 Wilmut and Rowson produced the first calf born from a frozen-thawed embryo and five years later Willadsen succeeded in producing commercially acceptable results for cattle embryo freezing.

Now ET technology is widely used in pedigree cattle breeding offering breeders a number of opportunities:

- Increased numbers of progeny from genetically superior dams.
- The possibility of progeny of the other sex from dams that previously may have only produced calves of one sex.
- Increased diversity for marketing herd genetics including international trade.
- Banking of frozen embryos to accommodate seasonal breeding or longer term breeding strategies.
- As a diagnostic technique for infertility cases, especially in diagnosing blocked oviducts.
- As a method of continuing breeding from animals unable to do so naturally.
- Improved disease control applicable to high health status herds and international trade by reducing the number of individual animal movements.

The principles of embryo transfer

As previously described (see Chapter 33), follicular dynamics result in either two or three waves of follicle development during the oestrous cycle. In each wave a dominant follicle suppresses the development of subordinate follicles until at the end of the cycle the corpus luteum (CL) is lysed, allowing the dominant follicle of the last wave to become the ovulatory follicle.

Superovulation utilizes commercially prepared follicle stimulating hormone (FSH) to encourage a group of developing follicles to overcome the dominant follicle suppression and continue developing to ovulation with concomitant maturation of the oocytes. The FSH is commonly administered as a twice-daily injection regime over four days, commencing mid-cycle (days 9–14). Incorporated in this regime is a prostaglandin F_{2α} (PGF_{2α}) injection, usually given alongside the fifth FSH injection, to return the donor cow to oestrus. The onset of oestrus and subsequent ovulation are accelerated in superovulated animals and oestrus occurs usually 48–56 hours after the PGF_{2α} treatment, with ovulation occurring as early as the onset of oestrus (cf 12–18 hours post oestrus in non-superovulated cows). Accordingly it is usual to inseminate the donor cow soon after the onset

of oestrus (e.g. the afternoon of the day of oestrus, with a second insemination the following morning).

Embryo collection is performed on day 7 of the oestrous cycle (day 0 = day of oestrus). Embryos enter the uterine lumen from the oviduct at approximately day 4 of the oestrous cycle and, although embryos can be collected successfully from the uterus between days 5 and 9, a day 7 collection allows recovery of the most flexible stages of the embryo for both freezing and fresh transfer. Collection (flushing) is a non-surgical procedure requiring catheterization of the uterine horns.

Two types of embryo collection catheter exist:

- Two-way, which has two tubes within it. One allows inflation of a latex cuff near the tip of the catheter, whilst the other enables the flushing media to enter and leave the uterine horn. Greater volumes of media are required as a larger segment of the uterine horn is flushed (Fig. 40.2).
- Three-way, which consists of three tubes. One allows inflation of the cuff situated 10 cm behind the tip. Another tube allows media to enter the uterine lumen from the tip of the catheter and a one-way flow is created by the media returning down the third tube via its entry hole at the level of the cuff (Fig. 40.3).

The flushing media, Dulbecco's phosphate buffered saline (PBS), is infused into the uterine lumen to allow slight distension before drainage by gravity flow along with the embryos and ova into a collection filter. The filter contains a metal or plastic micromesh with a pore diameter approximately half that of an embryo (embryo diameter 140–170 µm), allowing excess media to run through whilst retaining the embryos.

Embryo searching is performed once both uterine horns have been flushed. The contents of the filter are emptied into a petri dish and examined under a stereoscopic microscope at between $\times 6$ and $\times 10$ magnification. Recovered embryos are placed in embryo holding solution (Dulbecco's PBS with bovine serum albumin, glucose and antibiotics), classified (Fig. 40.1; Plate 40.1) and graded (Box 40.1). Embryo holding solution is also known as ovum culture medium (OCM). Embryo evaluation is by subjective visual assessment under $\times 50$ stereoscopic magnification. Embryos can survive on the bench at ambient temperature (20°C) for up to eight hours with little drop in pregnancy rate, but they are best frozen or transferred within three hours of collection (Wright, 1985).

Embryo freezing involves, initially, partial dehydration of the embryo in a cryoprotectant to prevent freezing damage. Two main factors influence the success or failure of freezing cells:

- Solution effects: the solute concentration within a cell increases due to dehydration and causes cell

Box 40.1 Description of embryo grading. Source: *IETS Manual*, 3rd edn (Stringfellow & Seidel, 1998).

Grade 1: Symmetrical and spherical embryo mass with individual blastomeres (cells) that are uniform in size, colour and density. The embryo is consistent with its expected stage of development. Irregularities should be relatively minor and at least 85 per cent of the cellular material should be an intact, viable embryonic mass. This judgement should be based on the percentage of embryonic cells represented by the extruded material in the perivitelline space. The zona pellucida should be smooth and have no concave or flat surfaces that might cause the embryo to adhere to a petri dish or a straw.

Grade 2: Moderate irregularities in overall shape of the embryonic mass or in size, colour and density of individual cells. At least 50 per cent of the cellular material should be an intact, viable embryonic mass.

Grade 3: Major irregularities in shape of the embryonic mass or in size, colour and density of individual cells. At least 25 per cent of the cellular material should be an intact, viable embryonic mass.

injury, particularly when cooling is slower than optimum.

- Intracellular ice: this results in physical damage when cooling is faster than optimal.

Cooling rates of 0.3°C/min to 0.6°C/min are considered rapid whereas 0.1°C/min is considered slow. The cryoprotectants lower the temperature at which intracellular ice forms, reduce the amount of ice present in extracellular fluid, moderate the solute effect and help stabilize the cell membrane. Some cryoprotectants themselves may cause osmotic injury to cells and need to be added or removed gradually. The cryoprotectants most commonly used commercially are 10 per cent glycerol and 1.5 M ethylene glycol. Stepwise addition or removal is required for 10 per cent glycerol in increasing or decreasing gradients of concentration respectively, whereas one-step thawing of embryos frozen in ethylene glycol can be performed as it crosses cell membranes more rapidly. Embryos are frozen in 0.25 ml plastic straws which must be identified with the donor name, sire name, collection team code, breed code and date code. The straws are sealed either by a plastic plug or are heat-crimped.

The cooling curve to be used is preprogrammed into the freezing machine and the straws are subjected to a controlled rate of freezing as this progresses to ensure optimal survival of the embryo. A process called 'seeding' is performed when the freezer chamber temperature is at -6°C (some programmes -7°C). This nucleates the freezing medium with an ice crystal when

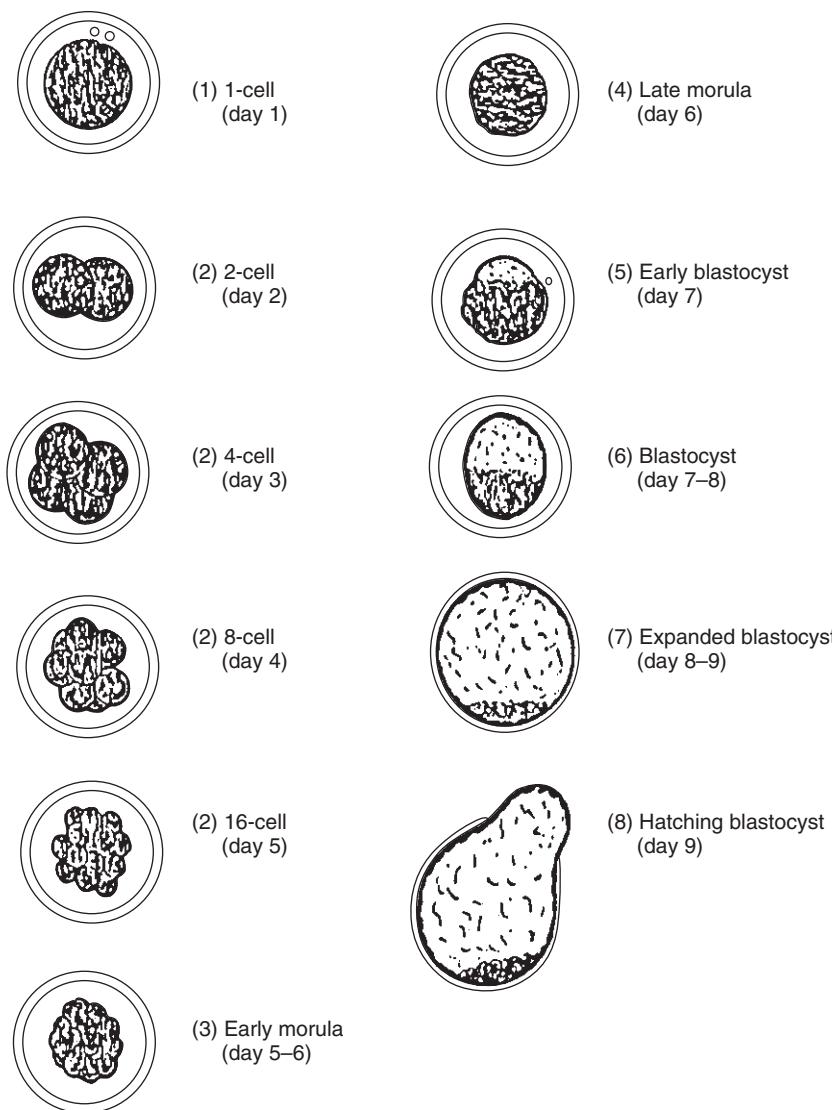

Fig. 40.1 The code for stage of development is numerical. Number 1 identifies an unfertilized oocyte or a one-cell embryo. Number 2 identifies embryos with 2 to 16 cells (approximately day 2 to day 5). Number 3 identifies an early morula, and numbers 4 to 8 (inclusive) identify post compaction stage embryos as illustrated above. In commercial embryo transfer, embryos are collected on days 6 to 8 of the oestrous cycle (morula to blastocyst).

1 or 2°C below its freezing point, preventing supercooling and excessive temperature rise from the release of latent heat in the cooling process. At the end of the freezing programme the straws are plunged directly into liquid nitrogen before being placed in plastic goblets and stored under liquid nitrogen in cryogenic flasks.

Thawing of the straws is a reversal of the previous procedures. The straws are thawed in a flask of warm water and if frozen in 1.5M ethylene glycol are then ready for immediate transfer. Those frozen in 10 per cent glycerol must first have this extracted from the embryo. The embryos are removed from the straws they are frozen in and passaged through decreasing concentrations of glycerol until finally they are placed in embryo holding solution, re-examined, their grades

checked and then they are reloaded into straws for transfer.

The *embryo transfer* procedure for the recipient is the same for fresh or frozen embryos. Recipients need to have been synchronized to display oestrus on the same day as the donor cow or within a 24-hour period either side of that day. For frozen embryos the recipients are synchronized to be in oestrus six, seven or eight days prior to the day of transfer. Before transfer of the embryo the recipient's ovaries are examined by manual rectal palpation or ultrasound scanner for the presence of a CL. Note is also made of which ovary has the CL. Recipients receive an epidural anaesthetic and, after the perineum has been cleaned, the transfer gun is passed through the cervix and guided along the uterine horn ipsilateral to the corpus luteum before depositing

Table 40.1 Analysis of results achieved from 1110 commercial embryo collections. Source: Ovaflow Embryo Transfer.

| Overall results per collection | |
|--|--------------|
| Total ova (includes unfertilized ova, degenerate embryos and viable embryos) | 10.08 (mean) |
| Total viable embryos | 5.03 (mean) |
| Fertilised ova (includes viable and degenerate embryos) | 58.6% |
| By classification | |
| Blastocysts | 11.3% |
| Early blastocysts | 15.2% |
| Morulas | 73.5% |
| By grades | |
| Grade 1 embryos | 88.0% |
| Grade 2 embryos | 11.7% |
| Grade 3 embryos | 0.3% |

the embryo. Historically embryos were transferred surgically, involving paravertebral anaesthesia and laparotomy of the sublumbar fossa, but for welfare reasons surgical transfers have been superseded by the non-surgical technique.

Results

Donors

In superovulated animals an estimate can be made of the likely number of ova by counting the corpora lutea on the ovaries. Manual estimation is poor if there are more than ten CLs on an ovary, but if there are fewer then estimates have a higher accuracy. Some discrepancies can be accounted for by luteinized follicles which histologically show an enclosed oocyte with the cumulus cells dispersed and luteinization in the granulosa cells (Monniaux *et al.*, 1983). Heifers can exhibit large responses to superovulation (based on palpated CLs) with high fertilization rates of the recovered ova but lower recovery rates than parous animals (Hasler *et al.*, 1983). Examples of results achieved commercially are given in Table 40.1.

Recipients

Successful pregnancy rates are influenced by a number of factors, both embryonic and maternal.

Embryonic factors

Although some young embryos (days 3–6) have been shown to have abnormal karyotypes (7 per cent) no

| By dam breed | |
| Beef (grade 1) | 59.3% |
| Dairy (grade 1) | 64.5% |

anomalies were found in day 7, 8 or 9 embryos, suggesting embryos with abnormal karyotypes were non-functional by that stage. Whilst embryos from donors over 15 years old have shown lower pregnancy rates (Hasler *et al.*, 1987), the biggest single embryo factor affecting pregnancy rates is embryo quality. Good quality embryos give better pregnancy rates (Donaldson, 1985). By day 16 well-developed embryos produce significantly more interferon, thus fully inhibiting luteolytic PGF_{2α}, than do poorly developed embryos at that stage.

Maternal factors

The best pregnancy rates are achieved when the synchrony is close (± 24 hours) between the embryo's stage of development and the recipient's uterine environment (Donaldson, 1985; Newcomb & Rowson, 1975). Transfer of the embryo to the uterine horn ipsilateral to the corpus luteum with deep placement of the embryo, rather than placement at the level of the intercornual ligament, gives the best pregnancy rates (Christie *et al.*, 1979). The CL ensures a source of progesterone but maternal progesterone concentrations can

show considerable diurnal fluctuations. Progesterone is required in the first half (approximately 12–14 days) of the oestrous cycle to suppress the oxytocin receptors. Inhibition of the oxytocin receptors is less effective in cows with a low progesterone concentration, meaning that the luteolytic mechanism develops earlier allowing less time for the conceptus to produce sufficient trophoblastic interferon to create an adequate block to luteolysis. Remsen *et al.* (1982) and Northey *et al.* (1985) demonstrated maximal pregnancy rates (PR) when plasma progesterone concentrations were in the ranges 2–5 ng/ml (PR 74 per cent) and 2–6 ng/ml (PR 68 per cent), respectively. However Hasler *et al.* (1980) and Smith *et al.* (1996) found no correlation between pregnancy rates and progesterone concentrations. A review of mean pregnancy rates that can be achieved commercially is given in Table 40.2.

Embryo collection: practicalities

Forward planning is the key. Careful animal preparation and attention to detail will improve success.

Donor selection criteria

Donor heifers:

- Body condition score approximately 2½ (assessed over the range 1–5; Lowman *et al.*, 1976; see also Chapter 2);
- Regular oestrous cycles;
- Age 15–18 months.

Donor cows:

- At least six weeks calved;
- Clean uterus and returned to regular oestrous cycles;
- Preferably two heats since calving;
- Maintaining or increasing liveweight (body condition score 2–3).

Nutrition

It is now recognized that the time required for a primordial follicle to develop to an ovulatory follicle is 60–90 days and the environment that the cow is in during that time can influence not only the vitality of that oocyte but also the subsequent embryo (Webb *et al.*, 1999). In particular there is a correlation between follicular development and plasma levels of insulin and peripheral levels of insulin-like growth factor-1 (IGF-1), with elevated levels of insulin being associated with enhanced ovulation rates. Research continues into identifying the mechanisms and pathways involved in

this relationship, but since diet supplementation can raise insulin levels nutrition has an important role. Donors should be on a rising plane of nutrition for six to eight weeks before flushing. All adjustments must be gradual without any sudden changes. The timing of housing and turn-out needs to be planned carefully as either event occurring in the middle of a superovulation programme can have a disastrous effect on the success rate. Careful attention to mineral supplementation is also important. Apart from ensuring a balanced level of minerals, consideration should be given to molybdenum toxicity. Embryo donors on a high molybdenum diet (15–20 mg Mo/kg dietary DM) produce greater numbers of abnormal embryos, suggesting that elevated dietary molybdenum will retard embryo development. In addition, diets containing 5 mg Mo/kg DM decrease conception rates and cause anovulation and anoestrus in cattle. Protection against molybdenum toxicity is achieved by providing adequate supplies of copper. Although copper can be supplied by injection or orally as powdered mineral, drenches and capsules it seems, from some studies, that the use of intraruminal boluses is more efficacious (p. 298).

Superovulation

Gonadotrophins such as equine chorionic gonadotrophin (eCG) and human menopausal gonadotrophin (hMG) have been used in the past to superovulate cows, but due to the undesirable effects from extended activity of the luteinizing hormone (LH) fraction they have been superseded by purified FSH. This is available as a freeze-dried product with diluent which, when mixed, produces a solution with controlled amounts of LH activity. These commercial FSH products are sourced principally from ovine and porcine pituitaries.

It is best to start superovulation from a known reference heat so that the injections commence at a known point in the oestrous cycle. A superovulated response can be achieved starting anywhere in the cycle, given good control of the follicular wave, but the most repeatedly consistent results are achieved when the FSH injections commence between days 9 and 14 (Hasler *et al.*, 1983). This same review found no differences in the number of ova (11.6 versus 10.2) or viable embryos (6.2 versus 6.4) recovered from donors superovulated following prostaglandin-induced reference heats versus natural reference heats, respectively. The use of intra-vaginal devices to mimic the hormone levels found mid cycle can supply an exogenous source of progesterone. Although less consistent than starting from a known reference heat, the results from this method are satis-

Table 40.3 Examples of commercial superovulation regime for cattle.

| | | Maiden heifer | Mature cow |
|-------------------|----|--|--|
| day 12 | am | 2.25 ml FSH solution | 3.0ml FSH solution |
| | pm | 2.25ml | 3.0ml |
| day 13 | am | 1.75 ml | 2.5ml |
| | pm | 1.75ml | 2.5ml |
| day 14 | am | 1.25 ml + double dose of PGF _{2α} | 2.0ml + double dose of PGF _{2α} |
| | pm | 1.25ml | 2.0ml |
| day 15 | am | 0.75ml | 1.5ml |
| | pm | 0.75ml | 1.5ml |
| Total dose | | 12ml | 18ml |

Note:

At the time of publication there is one licensed FSH product in U.K. This is an ovine FSH (Ovagen, ICP, NZ) containing 0.88 mg/ml NIADDK-OFSH-17 ovine pituitary FSH.

PGF_{2α} = Prostaglandin F_{2α}

These protocols are included as examples of regimes used in commercial embryo transfer practice. Alternative protocols do exist with variations in total volume, volume of individual injections and rate of decline of dosage regime.

factory even if few or no behavioural signs are seen at the time of the reference heat.

When a twice-daily injection regime is used the injection interval is ideally 12 hours, but as long as the interval is no less than eight hours satisfactory results will still be achieved. Product manufacturers advocate that the total dose be split into eight equal injections, but the use of a declining regime with higher dose volumes at the start gives superior results. Responses to the same superovulation regime will vary from donor to donor and there are also breed differences in sensitivity to the treatment with the Simmental breed being particularly sensitive. In addition, body condition, nutrition and environmental factors will all influence the response to treatment. A generalization can be made that maiden heifers will respond satisfactorily to a lower total dosage of FSH than that required for a mature cow. Although aged cows can be successfully superovulated the oocyte quality may be compromised in these cows, especially if over 15 years old, so that fertilization rates of these ova or pregnancy rates of subsequent embryos may be poorer. An example of a standard commercial programme used for maiden heifers and mature cows is shown in Table 40.3.

Between animals there can be a substantial variation in their superovulatory response to a given dose of FSH. What can be an effective dose in one animal may result in either too low or too high a response in another. Animals which fail to respond sufficiently (fewer than two ova is a non-response and fewer than five ova is a low response) can usually be improved by increasing the dose on a subsequent occasion. Increasing the total dose in 2ml increments (0.25ml per injection) is usually an acceptable approach. The objective

is to improve the superovulatory response without creating an over-response, because as the number of follicles stimulated increases there is a negative effect on the viable percentage of the recovered ova. Generally this happens once the total CL count rises above 20. As numbers increase above this level there is a tendency for a rise in numbers of unfertilized and degenerate embryos and a decline in viable embryos, often to zero. However, some donors can still perform successfully with CL counts in the range of 20–30. It is, however, the author's opinion that a preferred target is a superovulatory response yielding a total ova count in the mid teens, which can result in 8 to 12 viable embryos (fertilization rate 50–60 per cent). As Table 40.1 demonstrates real results are lower than this. This can be partly attributed to some donors being consistently successful, but others being consistently poorer performers. Studies of donor populations corroborate this, but such profiles can only be built up over time and on the strength of a single flush a donor cannot be categorized simply as good or bad other than for that single event.

Cleanliness at the time of injection is important as contamination of the stock solution can result in loss of potency of the FSH. New sterile syringes and needles should be used for each injection. In animals that have high body condition scores the superovulatory response is improved if the injections are given into the neck muscle.

Insemination (see also Chapter 39)

The number of straws of semen recommended can vary from operator to operator, but given good quality semen three straws given in two insemination periods

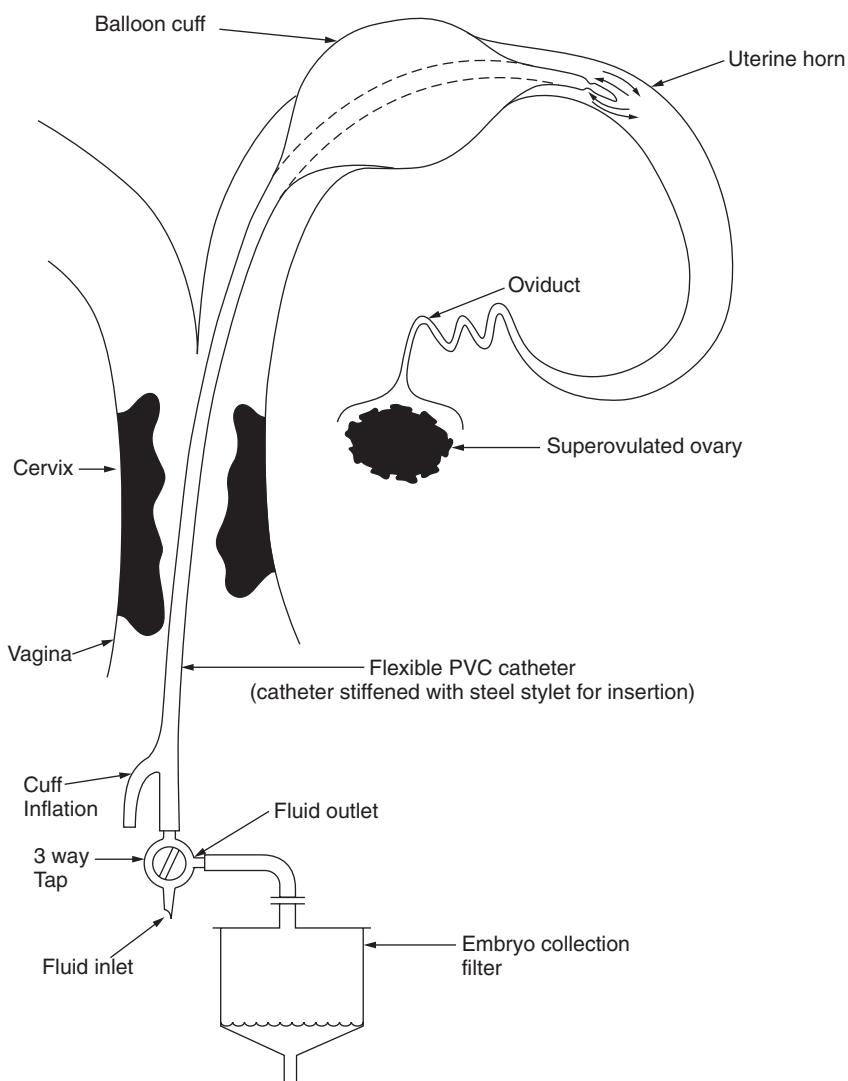

Fig. 40.2 Two-way embryo collection catheter.

are usually adequate, firstly the afternoon of the day the donor is in oestrus and again the following morning. The precise timing of this action can be dependent on the time of onset of oestrus. If the donor is in standing oestrus in the morning then artificial insemination (AI) at mid afternoon that day with two straws and again the following morning with one straw is sufficient. If the donor only comes into standing oestrus later in the day then the first AI can be delayed. This is easily done if DIY AI is used, but may be awkward with a technician service. The time of onset of heat is usually directly proportional to the size of the superovulatory response. If a cow is in standing oestrus the night before she is expected then a large superovulatory response can be assumed and an extra AI session using an additional two straws of semen should be planned for the morning of the first day of AI. If, through

previous experience, the semen is known to be of poor quality then extra straws may be used (e.g. three sessions utilizing two, two and one straws of semen). A mix of semen from two different bulls can also be used when quality is questionable. It should be confirmed that the Breed Society rules permit this practice and all progeny produced will need to be either blood-typed or DNA tested to confirm parentage. Equivocal evidence exists as to whether heterospermic interaction in this scenario will synergistically enhance fertilization rates. Published data suggest enhancement in a range of 2 to 10 per cent, dependent on whether two bulls (same breed) or three bulls (different breeds) were used respectively. Natural service can also be used and the bull should be allowed to serve the donor as soon as she comes into oestrus. Consideration must be given to the health status of bulls used

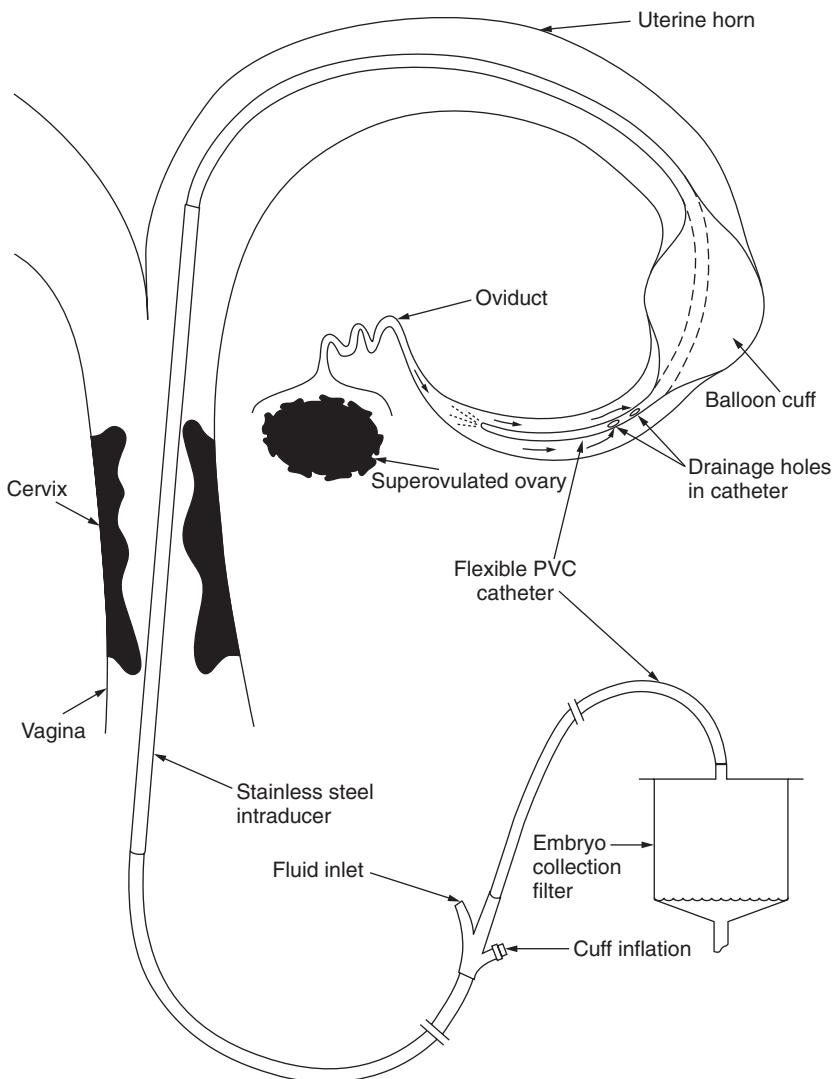

Fig. 40.3 Three-way embryo collection catheter.

for natural service to avoid transmission of venereal and other diseases.

Embryo collection

Cleanliness of the epidural site and the perineum is important and cotton wool swabs damped with surgical spirit are ideal for this. All instruments, catheters, tubing and filters must be sterile. Metal instruments, silicone tubing and glass tubing can be autoclaved, whereas catheters and filters are usually gas sterilized with ethylene oxide. No disinfectants or harsh cleansing solutions that may persist on surfaces and be harmful to the embryos should be used. All equipment sterilized by ethylene oxide must be aired for a minimum of seven days before use.

A successful recovery rate requires good catheter position and good media flow. These conditions are most easily met if the epidural completely abolishes rectal peristalsis. The ideal position for a two-way catheter is to have the cuff inflated at least 5 cm past the level of the intercornual ligament (ICL) (Fig. 40.2). In the three-way system the stainless steel cannula, down which the catheter passes, is inserted to the level of the ICL. Upon removal of the centre, the catheter is passed down the cannula and along the uterine horn until the tip is about 10–15 cm from the end of the horn (Fig. 40.3). Inflation of the cuff should be enough to anchor it in position without damaging the endometrium; usually 2 ml of air and 4 ml of sterile water will be sufficient in most donors. The two-way system will use more media than the three-way because a larger

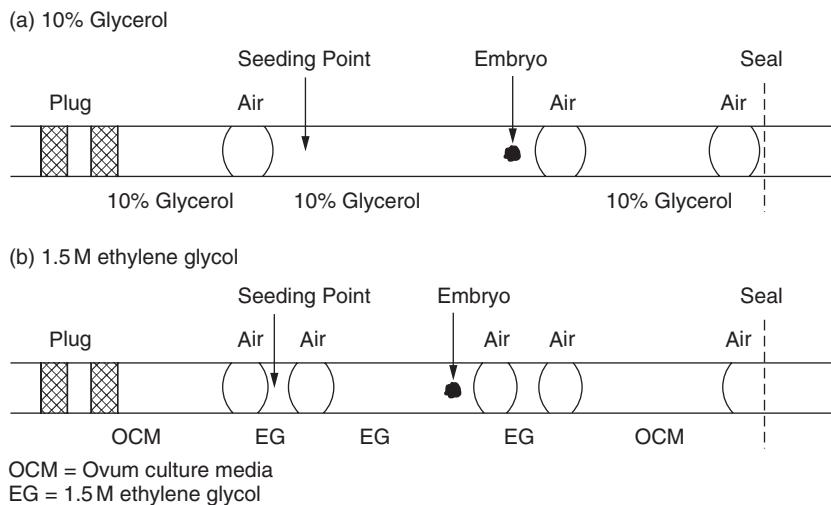

Fig. 40.4 Methods of loading straws for freezing.

volume of uterine horn is being flushed. Generally the two-way system will require about 350–500 ml per horn compared to the three-way system using 180–200 ml per horn. Care must be taken not to overdistend the horn and aliquots of approximately 30 ml in a three-way system would be sufficient. To aid successful drainage of the media down the catheter it is important to lift the tip of the uterine horn gently so that it is not curled under the body of the uterus. The bovine uterus is a fragile organ and rough handling or excessively forceful actions can result in damage to the endometrium or perforation of the wall.

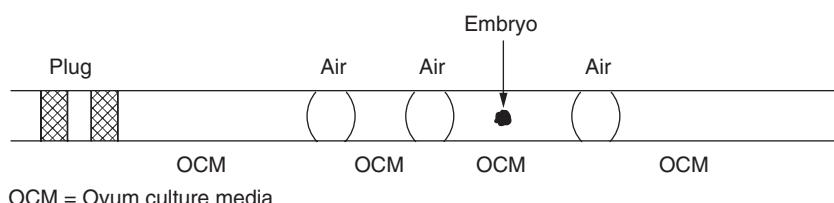

Best practice is to return the donor animals to normal cycles after the flush. This ensures termination of skunking embryos and reduces opportunities for development of cystic ovarian disease after superovulation. This can be done by injection of PGF_{2α} or by using a combined progesterone releasing intravaginal device with PGF_{2α}. When using PGF_{2α} alone a higher dose than normal is required to lyse the luteal tissue present on superovulated ovaries. Consequently a one-and-a half times or double normal dose of PGF_{2α} is used. If donors are to be repeat flushed they should be allowed two oestrus events between flushes to optimize the repeat results (Hasler *et al.*, 1983). In practice this translates to an eight-week interval between flushes.

Embryo processing

Examination of the embryos requires a good quality stereoscopic dissecting microscope with at least $\times 10$, $\times 25$ and $\times 50$ magnification. Disposable plastic Petri dishes should be used. Once retrieved from the flushing solution, embryos should be kept in embryo holding solution at a constant ambient temperature (approximately 20°C) and out of strong light until the next procedure. Ideally, embryos should be frozen or transferred within three hours of collection. Although the law requires embryos to be washed ten times prior to freezing it is good practice to wash all embryos whether destined for freezing or fresh transfer. An outline of this procedure is given in Box 40.2 and a more detailed account can be found in the *Manual of the International Embryo Transfer Society* (IETS) (Stringfellow & Seidel, 1998). The ten-times washing regime will remove a number of viruses from the zona pellucida whilst other more persistent ones can be removed by including a wash with trypsin in the procedure. Box 40.3 lists viruses and bacteria which can be successfully removed by standard washing procedures and trypsin washing.

Embryo freezing

Prior to freezing the embryos are partially dehydrated in cryoprotectant. Ready-to-use 10 per cent glycerol

OCM = Ovum culture media

Box 40.2 Embryo washing procedure. Source: *IETS Manual*, 3rd edn (Stringfellow & Seidel, 1998).

- Only embryos from a single donor should be washed together
- Ten or fewer embryos should be washed at one time
- Only zona pellucida intact embryos should be washed
- Only embryos free of adherent material should be washed
- A minimum of ten washes is necessary, ensuring gentle agitation in each wash
- Use a new sterile micropipette each time embryos are moved from one wash to the next
- Regulate volumes so that each wash is at least a 100-fold dilution of the previous wash, achieved by using 1 ml droplets of Dulbecco's PBS and a 10 µl micropipette to move embryos

and 1.5 M ethylene glycol are available commercially, which have the benefit of being quality controlled and screened for viruses. Prior to freezing the embryos need to be allowed time to equilibrate in the cryoprotectant. This state is achieved after 5 to 10 minutes immersion in 1.5 M ethylene glycol, but with the 10 per cent glycerol the embryo needs to be passaged step-wise through increasing concentrations of the solution. A common method is to allow 5 minutes in 5 per cent glycerol (10 per cent glycerol diluted with an equal volume of embryo holding solution) followed by 15 minutes in 10 per cent glycerol. After the required equilibration time in the cryoprotectant the embryos are loaded into straws (Fig. 40.4), sealed and labelled before being put in the freezing machine. It is important not to greatly overextend the equilibration time as the cryoprotectants themselves are embryo-toxic if overexposure is allowed. At the appropriate time in the freezing protocol the cooling process is paused to allow seeding.

Seeding is easily performed using a metal rod, e.g. brass; the rod is supercooled in liquid nitrogen then gently and briefly touched against the straw (Fig. 40.4). The seeded medium immediately becomes opaque as it nucleates. Embryo damage can occur if too long a period of time elapses at seeding (overseeding) or if too large an area is seeded. The use of a brass rod is therefore preferable to tweezers for this reason. Once all straws are seeded the cooling process continues and at the end the straws are swiftly plunged into liquid nitrogen (-196°C). Straws containing embryos (especially the column of medium in the straw in which the embryo lies) should be kept submerged in liquid nitrogen and should not be exposed to air until thawing. The straws should be handled with tweezers, not fingers. The easiest method to check identities on the straw labels is to place the whole goblet containing the straws in a wide-mouthed insulated flask containing liquid nitrogen. Thus the labels/plugs can be read while the

straws are still submerged. If long-term storage is envisaged, separate into two groups and store in different cryogenic flasks.

Embryo thawing

Thawing of the straws is a reversal of the previous procedures. Once the straws have been removed from the liquid nitrogen they are placed in a flask of warm water. Some protocols require a short period of air thawing prior to entering the water. The water temperature (22–37°C), the duration of submersion (7–30 seconds) and the inclusion of air thawing (none–10 seconds) are all dependent on the method and programme protocol used for freezing. Most embryo transfer companies provide recommended thawing protocols along with the embryos. Labels must be checked and the details recorded. Straws with embryos frozen in 1.5 M ethylene glycol can be loaded into the transfer gun for immediate transfer. Embryos frozen in 10 per cent glycerol must be removed from the straws they were frozen in and passaged through decreasing concentrations of glycerol; they are then placed in embryo holding solution, re-examined and their grades checked before they are reloaded into straws for transfer (Fig. 40.5). This step-wise removal of the 10 per cent glycerol is aided by the inclusion of sucrose in the solutions to prevent too rapid an ingress of water to the cells. One brand of ready-to-use solutions passages the embryo from 10 per cent glycerol through 5 per cent glycerol, 0.5 M sucrose (5 minutes) then 2.5 per cent glycerol, 0.5 M sucrose (5 minutes) and finally 0.6 M sucrose (5 minutes) before immersion in embryo holding solution/OCM prior to reloading.

Embryo transfers: practicalities

For successful results forward planning is essential.

Recipient selection criteria

Recipient heifers should be:

- At least 15 months old;
- At least 370kg (dairy heifers);
- At least 400kg (beef heifers);
- Of a suitable frame size to carry to term and to calve naturally an embryo calf of the breed to be transferred;
- Body condition score 2–2½; (assessed over the range 1–5; Lowman *et al.*, 1976; see also Chapter 2);
- Displaying regular oestrous cycles.

Recipient cows should be:

- No more than a fourth calver;
- Of a good breeding history;
- At least six weeks calved;
- Clean and returned to regular oestrous cycles post calving;
- Maintaining or increasing liveweight;
- Body condition score 2½–3;
- Of a suitable frame size to carry to term and to calve naturally an embryo calf of the breed to be transferred.

Nutrition and management

It is important that recipients are on a rising plane of nutrition for six to eight weeks before transfer and that this continues for at least another six weeks post transfer. This is of particular relevance around the time of housing and turn-out and ideally these two events should not occur in the middle of a programme but should be completed either two months before the transfer date or delayed until at least six weeks post transfer. The ration should be checked to confirm that it is providing an acceptable balance of energy and protein with sufficient levels of roughage. As with the donors, a suitable supply of minerals is important. If molybdenum toxicity is likely to be a problem then a suitable supply of protective copper should be made available (e.g. intraruminal boluses) (see pp. 254, 298).

Purchasing recipients, mixing groups and routine procedures, such as worming, bolussing, vaccination, freeze-branding and foot-trimming, should all be completed at least six to eight weeks before the transfer date to minimize stress.

Disease control

A number of infective agents can severely affect the success of an ET programme. The principal culprits are bovine viral diarrhoea virus (BVDV), leptospirosis and infectious bovine rhinotracheitis (IBR). Vaccination is possible for all three agents but there is a risk of persist-

ence of virus from the live IBR vaccines which may cause problems for ET progeny destined for export (including Northern Ireland) or for entry to semen collection centres. IBR marker vaccines (p. 1010) may alter the situation but this will depend on recognition by the importing country and importer. If BVDV is known to be a problem on a farm then screening of the recipients prior to vaccination may be desirable to identify and remove any persistently infected animals. When leptospirosis is a known problem on a farm then treatment of the recipients with 25 mg/kg of dihydrostreptomycin (British Cattle Veterinary Association (BCVA), 1992) at the time of first vaccination may be required to reduce the infective load of this bacterium. As the epidemiology of *Neospora caninum* becomes better understood (see Chapters 19, 37) it may be prudent to screen potential recipients for this agent, especially if vertical transmission of this protozoan from recipient to fetus could affect the reproductive performance of any resulting ET heifers.

Oestrous synchronization

(see also Chapter 42)

For successful pregnancy to be achieved the recipients need to be tightly synchronized to come into oestrus one week before the embryo is transferred. Therefore a tight synchrony period is required. A good method is to use a progesterone releasing intravaginal device or progestage implant in combination with a prostaglandin injection. The device chosen can be inserted for 9, 10 or 11 days and the prostaglandin injection given 24, 48 or 72 hours before removal. This gives a tight synchrony with the peak of activity 28–56 hours after device removal. In the author's opinion a double prostaglandin injection protocol will not provide a tight enough synchrony to maximize recipient usage. The stockperson should observe recipients for oestrus the week before transfer. Observation should be performed at least three times a day for a minimum duration of 20 minutes per observation period. Observations should occur for the three days following the day the synchrony devices are removed.

Transferring the embryo

Having checked for the presence of a CL, and recorded which ovary it is on, the recipient is prepared for the embryo transfer. Cleanliness of the epidural site and the perineum is important and cotton wool swabs damped with surgical spirit are ideal for this. After traversing the cervix the transfer gun is guided along the uterine horn ipsilateral to the corpus luteum. Pregnancies can be achieved if the embryo is placed at the level of the ICL, but results improve if the site of transfer is further up the horn. Ideally a position of 10 cm or more past the ICL is desirable. It is important to be as

gentle as possible and avoid manoeuvres which result in endometrial damage. Sometimes in fatter animals with large dependent tracts it is necessary to accept that the site of placement is not ideal in preference to over-handling the tract, resulting in inflammation or physical injury to the endometrium.

Hormone supplementation

Exogenous hormonal supplementation has taken three main forms in an effort to provide support to the pregnancy. Firstly, exogenous progesterone or progestagen has been used. Progesterone injections have improved pregnancy rates in asynchronous recipients. However, the use of progesterone releasing intravaginal devices produced non-significant negative effects on pregnancy rates when these devices were *in situ* from day 7 to 19 and had direct deleterious effects on embryo development when two devices (double dose) were used from day 7 to day 21. The use of exogenous progestagen treatments (Norgestomet), inserted on day 7, increased pregnancy rates (57.3 per cent control vs 67.8 per cent treated). Norgestomet treatment in acyclic cows did support pregnancies, but by day 38 of pregnancy in cyclic animals there were no significant differences between treated and control groups. It has been observed that too much exogenous progesterone can depress the secretion of LH and result in a reduction in luteal mass. This depresses the luteotrophic support of the endogenous CL, leaving it unable to produce sufficient progesterone for continued support of the pregnancy when the devices are removed. The conclusion is that only discrete (as yet unidentifiable) categories of animal may benefit from this treatment and careful consideration will need to be given to the dosage levels and timing of progesterone supplementation before applying it as a blanket treatment.

The second form of hormonal supplementation has been the administration of human chorionic gonadotrophin (hCG) given at various times and for varying durations. Christie *et al.* (1979) used multiple injections between days 13 and 35 of pregnancy, whereas others used a single injection given on either the day of transfer, day 14 or day 15. All showed a non-significant improvement in pregnancy rates in the treated animals over controls.

The third method of supplementation has been the use of a GnRH analogue (buserelin) given between days 11 and 13. This has been shown to increase pregnancy rates significantly (MacMillan *et al.*, 1986). In cyclic cows treated with buserelin on days 11 and 13 of the cycle the plasma oestradiol concentrations were significantly reduced, suggesting that the mode of action is to reduce the strength of the luteolytic mechanisms, so improving the embryo's chance of inhibiting luteolysis; however, the

suppression was transient. Thus if the GnRH analogue is given too soon the luteolytic mechanism may have time to recover, resulting in a temporary benefit, but with some pregnancies being lost at a later date.

These observations indicate that although hormonal supplementation has a tendency to improve pregnancy rates, the concept of a blanket treatment for groups of cattle needs to be considered carefully as inappropriate or mistimed treatments may at best have no benefit but at worst could be detrimental to pregnancy results.

Record keeping

Box 40.4 lists the important records that should be kept for donors, recipients and embryos. Legislation requires that records are maintained for 12 months.

Legislation

Trade in embryos between member states of the European Union (EU) and importation of embryos from approved third countries, including the associated collection, processing, production and storage, is governed

Box 40.4 List of necessary records to be maintained by licensed ET teams for 12 months after collection/production of an embryo. Source: Ministry of Agriculture, Fisheries and Food (1995).

Donor

Breed, pedigree name, ID no., herdbook no. and date of birth
Superovulation drug, dosage regime, dose, batch no.
Date of collection, place of collection
Superovulatory response, number and category of embryos recovered, number and grades of viable embryos
Details of processing procedures for embryos (including freezing, transfer, micromanipulation and *in-vitro* fertilization and culture as appropriate)

Recipient

Breed, age and ID no. of recipient
Date and place of transfer
Identification of embryo transferred and its source (if known)

Storage

Identification of every embryo stored
Date of entry/departure of every embryo
Place of origin of embryo prior to arrival
Destination of embryo on departure

IVF storage

In addition to above:
IVF embryos can be identified on a batch basis
Must contain details of the date and place of collection of the ovaries/oocytes
Must identify the herd of origin of donor animals

Box 40.5 Troubleshooting: in the event of poor superovulatory responses or embryo recovery.

| Problem | Issues to consider | Solution options |
|--|--|--|
| No reference heat | Poor heat detection Poor behavioural signs Poor synchrony | Abandon programme and restart Provide artificial CL through exogenous progesterone supplementation Re-attempt |
| Poor superovulatory response | Nutrition Mineral status Type of FSH Drug dose/regime | Check ration and adjust nutrition Check mineral status and adjust supplementation Try alternative type of FSH Increase drug dose or alter regime |
| Unfertilized ova | Semen quality Insemination technique Semen handling/thawing Donor/bull interaction Insemination timing Poor ovum quality Overstimulation Defective uterine environment Superovulation drug | Check bull history/try different sire Check technique Check technique Try different sire Add additional AI session and extra straws Check nutrition/mineral status/body condition loss Reduce FSH dose Infection – antibiotic therapy and/or return to oestrus Hormonal – difficult to identify/resolve Try alternative product |
| Poor recovery (normal breeding history) | Catheter position Leakage past cuff Inadequate flow Luteinized follicles | Check technique Check cuff inflation/integrity of cuff Raise tip of uterine horn higher than cuff position If above fails reposition catheter (Note: risk of embryo loss in this procedure) |

by EU Council Directive 89/556 of 25 September 1989, amended as appropriate by the relevant Council Directives and Commission Decisions. Within most member states this European legislation is supported by domestic legislation.

In the UK the statutory instrument is the Bovine Embryo (Collection, Production and Transfer) Regulations 1995. This covers the licensing of ET teams and premises, legislation relating to disease control and welfare and also record keeping. The above EU and UK legislation along with the *Manual of the International Embryo Transfer Society* (a procedural guide and general information for the use of embryo transfer technology emphasizing sanitary procedures) are essential reading for anyone planning to become involved in practical embryo transfer.

Troubleshooting

Embryo collection results will vary between donors and pregnancy results can fluctuate between batches of recipients. Boxes 40.5 and 40.6 summarize factors that

should be considered in assessing poor results in superovulation of donor cows or pregnancy rates in embryo recipients.

Advanced technologies

Embryo splitting

This technology was promoted in the early 1990s as a commercial application. Its appeal was that it could give proportionately more pregnancies from a collection of embryos than could be achieved by simply transferring the embryos whole. It involved bisecting the embryo with a microblade or a specially designed glass microneedle. These instruments were operated via a micromanipulator which converts gross movements by the operator at the controls to very fine micromovements at the level of the embryo. One disadvantage is that this is a relatively expensive piece of equipment. Inevitably the production of these demi-embryos resulted in some blastomere damage of the embryo so that split embryos tended to have lower pregnancy rates

Box 40.6 Troubleshooting: in the event of poor pregnancy rates.

than contemporary whole embryos (split embryos 57 per cent versus whole embryos 65 per cent). Even though an increased number of calves could be produced (an increase of the order of 13 per cent) the technique was never really accepted commercially by either the ET operators or the cattle breeders.

In-vitro fertilization (IVF)

This technology involves the creation of embryos in the laboratory. A source of immature oocytes is required. These can be harvested from ovaries removed from a slaughtered animal as long as the ovaries are submitted to the laboratory within four to six hours. Alternatively oocytes can be collected from the live animal by ultrasound-guided ovum pick-up (see later). The immature oocytes must first be matured, which takes approximately 18 hours. After this fertilization takes place by mixing capacitated sperm with the embryo. Following fertilization the embryos are cultured to a stage of development equivalent to day 7 *in-vivo* embryos, when they can then be transferred fresh or frozen. Pregnancy results with IVF embryos tend to be lower than from those originated *in vivo* (IVF 40–50 per cent versus *in vivo* 50–60 per cent). Another potential problem linked to IVF is that of the ‘large calf syndrome’. Although it can also be associated with asynchronous timing of embryo transfer and progesterone supplementation early in the oestrous cycle of the dam, it was documented in the early 1990s as being associated with IVF calves. The results of various IVF laboratories worldwide showed that a significant number of ET pregnancies could be affected. There was consider-

able variation between laboratories, but the incidence in some cases was up to 20 per cent. The syndrome manifested itself as giving large calves at birth (up to 75 kg) with increased birthweights greater than could be accounted for by extended gestation length alone. This was associated with an increased incidence of dystocia and a higher mortality rate. Another feature was enlarged placentae in some of these pregnancies, on occasion with a mean weight 25 per cent greater than those of untreated contemporaries. Additionally, in some cases, there were congenital malformations and problems with altered allometric coefficients for the liver, kidney and heart which eventually left these calves unable to survive. Interestingly, despite differences in birthweight, the mean liveweight at one year for these animals can be similar to controls. The effects on the pregnancies did vary depending on the laboratories from which the embryos came. Therefore it was deduced that a factor in the maturation or culture method was significant. The resultant worldwide research effort is helping to elucidate the mechanisms involved. To date, one widely observed finding is that the use of synthetic oviduct fluid (SOF) in the system as opposed to serum reduces, or eliminates, the incidence of large calves.

Ovum pick-up (OPU)

This is the technique that allows the collection of oocytes for IVF from the ovaries of live donor animals. It utilizes an ultrasound-guided transvaginal needle. The operator places one hand in the rectum to allow manual manipulation of the ovaries. The ultrasound

probe is placed in the vagina so that the ovary can be visualized with only the vaginal wall between the ovary and the head of the probe. Usually a 7.5 MHz curvilinear probe is used. On visualization of a follicle on the ovary a 60 cm needle (18–21 gauge) is passed down a special channel in the probe. It punctures the vaginal wall and enters the follicle on the ovary. A dotted line on the scanner screen indicates the line down which the needle will transect the ovary, allowing the operator to line up the follicle with the intended path of the needle. At the point of entry the operator uses a foot-pedal to apply a vacuum pressure to the collection line attached to the needle. Too high a pressure results in stripping of the cumulus cells from the oocyte and these denuded oocytes are less developmentally competent. On average, ten oocytes can be collected from both ovaries per session and it is possible to perform a collection session weekly or twice weekly (van der Schans *et al.*, 1991). This usually translates, after developmental losses and fertilization failures, to two transferable embryos per collection session. On average, 70–80 per cent of oocytes recovered are suitable for further processing. Of these, 70 per cent will be successfully fertilized and start to cleave and ultimately 40 per cent of the cleaved embryos will blastulate to become transferable embryos. With an average pregnancy rate of 50 per cent this means that approximately one pregnancy will result from each OPU session.

Embryo sexing

Many methods have been tried over the years to find a simple, easy-to-use way of sexing embryos. The most widely used technique in the UK was developed in Finland (Bredbacka *et al.*, 1995). It involves taking a biopsy of a few cells from the embryo and lysing them to release the DNA content. This DNA material is then mixed with enzymes and multiplied using a polymerase chain reaction (PCR). A stain is included in the solutions which binds to the Y chromosomes, making them fluoresce under UV light. On completion of the PCR cycle the tubes containing the biopsies from male embryos are identified by this fluorescence. Non-fluorescing samples are deemed to be female. This technique is 95 per cent successful in identifying females and 100 per cent in identifying males. The discrepancy is due to errors when biopsies are not placed correctly in the sample tubes.

New technology allows the production of correctly sexed embryos through the use of sexed semen. X chromosomes contain more DNA than Y chromosomes. The semen is mixed with a stain which is taken up by DNA and fluoresces in a laser beam. X chromosomes with higher DNA content will fluoresce more brightly. A flow

cytometer/cell sorter utilizing a laser can then sort the sperm on the basis of their DNA content (Cran *et al.*, 1993). At present the technique is 90 per cent accurate, but only small quantities of sperm can be processed at a time and the resulting sexed semen is more successful in fertilizing ova if used for deep uterine AI (Seidel *et al.*, 1998). New freezing protocol advances for sexed semen may obviate the need for deep uterine AI.

Cloning

Cloning results in the production of genetically identical offspring. The simplest form of cloning is twinning (bisecting an embryo). Further advances in the technology resulted in the technique of nuclear transplantation. This involves several procedures including enucleation of ova and the electrofusion of blastomeres from donor embryos. In essence, unfertilized ova are used as recipients for new genetic material. The new genetic material is supplied, in the case of embryos, from a donor embryo which is between the 16 and 64 cell stage (32 blastomere stage at approximately day 5). These blastomeres are disassociated and an individual blastomere (genetically identical to the other 31 blastomeres) is introduced into the enucleated recipient ovum. This new blastomere nucleus is then electrofused to the recipient ovum's cytoplasm and the resultant embryo is cultured to day 7 prior to transfer to a recipient animal. Alternatively, at day 5 the whole procedure can be repeated using blastomeres from the cloned embryo to create another generation. There are reports of this recloning process being used to produce second and third generation embryos. The difference between this procedure and that used to produce the late Dolly the sheep is that, for Dolly, the donated nuclear material was recovered from an adult somatic cell which was then 'reprogrammed' to be capable of differentiation and subsequent organogenesis.

Currently, however, these procedures are too inefficient for commercial production of large numbers of cloned animals and are only justified for biomedical applications. This has resulted in some commercial companies utilizing the technology to produce cloned animals for production of specific proteins for biomedical purposes.

Acknowledgement

The author would like to thank all who assisted with research for this chapter and particularly David McNee for the illustrations, George Seidel Jnr and Richard Bowen of Colorado State University for the pictures and Seonaid Grimmer, Mike Kerby and Arthur Redpath for constructive comments on the manuscript.

Introduction

Beef cattle fertility must be considered as a separate entity from dairy cattle as they are managed under entirely different circumstances. Usually they are managed as a herd or group and so do not receive the same individual attention as do dairy cows. In general, clinical infertility problems do not appear to occur to the same extent. However, with the dairy herd supplying fewer cross-bred female replacements and the ever increasing importance of biosecurity, many herds are breeding their own replacements. This results in a need for careful planning of breeding in order not to lose fertility and longevity that is achieved with heterosis (Table 41.1).

Veterinary involvement in most commercial suckler herds is often limited, as these herds are run as low

input and low output enterprises. In the UK, consumer concerns about food safety and the BSE crisis mean that cull cows are of relatively low value and so the main income derives from the progeny, from either sale as store or finished cattle (see Chapter 3). Calving interval is thus one of the most important measures of reproductive performance. One of the main effects on reproductive performance in beef cows is the adverse effect of marginal nutrition. Inefficient suckler herds are unlikely to survive in the present economic climate and, in Britain, marketing of progeny may become increasingly difficult following the 2001 foot-and-mouth disease (FMD) outbreak. There is likely to be increased legislation concerning the movement of FMD susceptible stock which may well affect public auction at livestock markets, thereby reducing the potential number of outlets for farm animals.

In some beef herds cows and bulls are together all the year round and there is little attempt to control fertility or the season of calving. In better-managed herds a seasonal calving pattern is adopted and the calving pattern itself becomes an important assessment of reproductive performance. An excellent review of suckler cow management in the UK has been published (Lowman, 1988) and this paper is recommended if the reader requires further detail after reading this chapter.

Determinants of reproductive performance

In the UK, beef cows traditionally calve either in spring or autumn. The trend in gross margins has decreased over recent years (1995 to 1999); although there has been a marginal increase in stocking rate, sale price has reduced significantly (see Table 41.2).

Autumn-calving herds tend to produce higher gross margins than spring-calving herds under UK conditions (see Table 41.3). Spring-calving herds tend to be stocked more heavily, but there is greater financial output from autumn-calving herds.

The calf is essentially the sole product of the beef herd, therefore the rate of calf production (calves born

lw, liveweight.

alive and reared) is even more critical than it is in the dairy herd. In order to illustrate this a comparison between the worst and best performing (in terms of gross margin/cow) suckler herds recorded by the Meat and Livestock Commission (MLC) (2000) is shown in Table 41.4. The most important factors causing the differences were

- (1) The number of calves reared/100 cows and
- (2) The calf weight at sale/transfer.

Put more simply, the most successful herds sold more heavier calves than the worst.

Calf weight and age at sale/transfer are reflections of health and growth rate; obviously, calf weight is further dependent, to a major extent, on the breed of the sire and breeding programme used. The heavier breeds such as Charolais and Simmental produce calves with a high weight. However, this has to be balanced against a higher risk of dystokia and possible calf mortality (see Table 41.5), but it must be remembered that there is considerable variation within a breed.

| Stocking rate (cows/ha) | 1.5 | 1.6 |

^a For 90 per cent of calvings.

Also, the gestation period and hence the calving interval can be influenced, to a limited extent, by the breed of sire.

When breeding replacements for the suckler herd, two aspects must be considered: mature body size and breed composition. Mature body size must be matched by feed resources. The larger the cow, the more difficult it is to maintain good body condition and this will reduce fertility. In order to maximize hybrid vigour the cross breeding system can be worth up to 23 per cent more weight of weaned calf per cow put to the bull (Meat and Livestock Commission, 2000).

An important index of reproductive performance in the suckler herd is the length of calving season. A 365-

M = male, F = Female.

Table 41.6 Theoretical relationship between conception rate and the calving period in a 100 cow herd (adapted from ICI computer simulation by Allen & Kilkenny, 1980).

| Herd conception rate (%) | Service period for 90% of cows to be pregnant (days) | Length of calving period (days) | No. of cows calving in first month |
|--------------------------|--|---------------------------------|------------------------------------|
| 30 | 245 | 260 | 12 |
| 40 | 140 | 155 | 28 |
| 50 | 100 | 110 | 41 |
| 60 | 70 | 85 | 54 |

day calving interval is optimal, but a compact calving season is also desirable because:

- More cows calve early in the period, therefore the age and weight of calves are higher at the time of weaning and sale.
- The impact of calf disease and mortality may be reduced if there is little variation in calf ages.
- Cows are all at a similar stage in the production cycle, therefore feed can be rationed more precisely and the cows managed more conveniently.
- When cattle are sold they can be batched to produce groups of similar size, weight and condition.

The calving season is almost directly dependent on the pregnancy rate to service and the length of the breeding or service period. Obviously, the higher the pregnancy rate, the shorter the service period required to ensure pregnancy of all or the majority of the cows. A

theoretical relationship between the conception rate, the service period and the calving period was calculated by ICI and is shown in Table 41.6.

Factors affecting reproductive performance

Infectious disease

In some cases of low herd reproductive performance there may be an underlying infectious disease. Although the UK is officially brucellosis-free there is always the potential for its re-introduction; indeed, this has happened. Following the use of artificial insemination (AI), campylobacteriosis and *Tritrichomonas fetus* have almost been eliminated, but *Campylobacter* may be a problem in some suckler herds where a bull is used (Caldow & Taylor, 1997). Additionally, some viral dis-

Table 41.7(a) Recommended target body condition scores of beef cows at various stages of the reproductive cycle (Lowman, 1988).

| | Calving | Mating | Weaning |
|-----------------------------|---------|--------|---------|
| Autumn-calving suckler cows | 3.0 | 2.5 | 2.5 |
| Spring-calving suckler cows | 2.5 | 2.0 | 3.0 |

Table 41.7(b) Relationship between body condition and reproductive performance (Kilkenny, 1978).

| Herd average mating scores | Calving interval (days) | Calves weaned per 100 cows mated |
|----------------------------|-------------------------|----------------------------------|
| 1–2 | 418 | 78 |
| 2 | 382 | 85 |
| 2–3 | 364 | 95 |
| 3+ | 358 | 93 |

eases may result in poor reproductive performance, for example bovine herpes I (BHV1) infection (see pp. 289, 579) and bovine viral diarrhoea (BVD) (see pp. 578, 853).

Obviously, it is essential to rectify any infectious problem before attempting to improve herd reproductive performance by other means.

Nutritional management

Nutritional status is of major importance in the maintenance of a high rate of reproductive performance. The nutrition of cattle is covered more comprehensively in specialized texts and only the basic principles are described here.

Whilst specific deficiencies of micronutrients are common under particular circumstances and can affect fertility, under normal conditions dietary energy appears to be the main factor limiting reproductive performance. However, other nutritional deficiencies occur but are usually confined to localities or even individual herds. These include problems with manganese, selenium and cobalt (see Chapter 18) and some vitamins, particularly A and E. For a fuller account of this problem the reader is referred to Chapters 9 and 21.

The technique of body condition scoring has been developed as a simple semi-objective monitor of cows' energy status. The principle depends on the manual palpation of the thickness of subcutaneous fat cover on various parts of the body (see p. 10).

Methods have been developed for both dairy (Mulvaney, 1978) and beef cows (Lowman *et al.*, 1976) and although the finer details vary slightly the overall principle is the same. The thickness of fat cover over the lumbar and tailhead area is estimated and assigned a score, usually from 0 (emaciated) to 5 (very fat), although different scales are sometimes used. Descriptions of the various categories on the 0–5 scale are given on p. 10.

An additional guide to body condition can be obtained by palpating over the hip bones, ribs and either side of the tailhead. With a little experience an

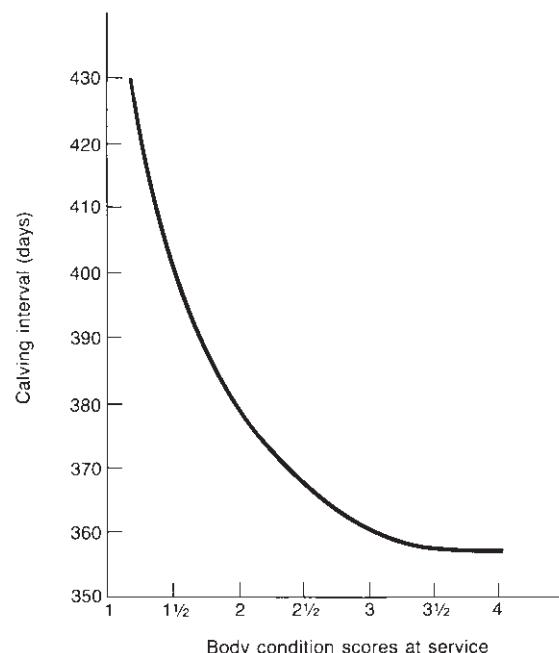

Fig. 41.1 The relationship between calving interval and body condition score at service in beef cows (Kilkenny, 1978).

operator can assess the body condition of cows to within one half-unit. Optimum body condition scores for beef cows have been worked out for the various stages of the reproductive cycle and these are shown in Table 41.7a. The target body condition score at service is the most critical as this is very closely related to overall reproductive performance. The calving interval has been shown to be negatively correlated with body condition at the time of mating in beef cows, although the true relationship is probably curvilinear (see Fig. 41.1) and affects the number of calves weaned (Table 41.7b). This target score is also most difficult to achieve in autumn-calving cows as they are mated during mid-winter when they are lactating and when good quality feed is expensive. In a survey, approximately half of the

Table 41.8 Financial effects of a high culling rate (after Allen & Kilkenny, 1980).

| | Normal culling policy | High culling rate | | |
|-----------------------|-----------------------------|-------------------|--------|--------|
| | | Year 1 | Year 2 | Year 3 |
| No. of cows | 90 | 78 | 86 | 88 |
| No. of replacements | 13 | 36 | 20 | 16 |
| Calving spread (days) | 150 | 100 | 100 | 100 |
| Average calf sale | | | | |
| Weight (kg) | 285 | 285 | 305 | 315 |
| Gross margin/ha (£) | 219 | 174 | 233 | 257 |

autumn-calving beef cows failed to reach the target condition score at mating (Kilkenny, 1978). In contrast, the nutritional drain of lactation is offset in spring calvers by the plentiful supply of grazing.

Cows should be fed to calve at a condition score of 2.5–3 and should lose minimum condition until conception (see Table 41.7a). Cows calving in fatter condition may have calving difficulties, which in turn may lead to delayed involution, reproductive tract damage, susceptibility to infection of the tract or a combination of these problems. Also, cows with a score of 4 or more are likely to mobilize their fat reserves excessively during the early postpartum period.

Beef cows calving in a low condition are also likely to undergo a prolonged period before the re-establishment of ovarian cycles, undernutrition being one of the major causes of failure to ovulate after calving. Consequently, pregnancy is likely to be considerably delayed in such cows.

As pregnancy progresses the lactational demand for a high level of dietary energy decreases. This enables the cow to replace body energy reserves that were lost during early lactation. Thus the cow can be brought back towards the target body condition for the next calving and subsequent mating.

Controlling the length of the calving season

There are a number of ways in which a compact seasonal calving pattern may be established and maintained in a healthy seasonally calving beef herd. These include feeding policy, culling policy and postpartum induction of ovulation.

Feeding policy

It is very difficult to restore compact seasonal calving patterns by nutritional management in herds that have a grossly extended calving season, since this would

necessitate the achievement of calving intervals in late-calving cows of well below 365 days. However, it is important to remember that proper nutritional management is vital for the maintenance of a compact seasonal calving pattern.

Culling policy

This is the most extreme but probably the most effective method of modifying a herd's calving pattern. As discussed above, the length of the calving period is highly dependent on the herd pregnancy rate. For example, a five-month calving period is approximately equivalent to a pregnancy rate of 40 per cent. In this situation approximately 70 per cent of cows will calve in the first two months and 30 per cent in the next three months. Therefore, the 30 per cent late calvers should be culled and replaced. Many producers are reluctant to adopt such a high culling rate due to the high cost of purchasing or rearing replacement heifers, particularly during the first year or so. However, such a policy can be of eventual financial advantage due to a decrease in the spread of calving and the consequent management economics as discussed above (see Table 41.8).

Post partum onset of ovarian cycles

A delay in the onset of ovarian cycles can lead to extended calving intervals and possibly increased variation in calving intervals between cows within a herd. This will result in increases in the length of the calving season.

Factors affecting the post partum acyclic period

Suckling

Many studies have shown that the onset of ovulation and/or oestrous behaviour is delayed in either dairy or

beef-type cows that suckle calves, relative to milked animals, particularly where more than one calf is suckled per cow. In suckling beef cows kept under UK conditions the average time to resumption of ovarian cycles has been reported as 59.9 ± 2.5 days after calving (Peters & Riley, 1982a), but there was considerable variation both within and between herds. Weaning of calves, either temporary or permanent, or at least the prevention of suckling has been reported to shorten the acyclic period.

Nutrition, body weight and condition and the post partum period

Long post partum acyclic periods in suckling cows may be reduced by the provision of increased dietary energy (e.g. Dunn *et al.*, 1969). Energy intake appears to be more critical than protein intake in the maintenance of reproductive function as positive relationships between energy intake and reproductive performance have been demonstrated in several studies. Low energy intake in prepartum and post partum cows increases the length of the anoestrous period and in heifers it has been shown to result in fewer ovarian follicles, lower progesterone levels and lower conception rates (Hill *et al.*, 1970).

Nutritional status at and before calving appears to be more important than that during the post partum period, since Peters and Riley (1982a), using body weight as an index of nutritional status, found a significant negative correlation between body weight at calving and the length of the acyclic period in beef cows, whilst body weight change after calving had no effect. Also, an increase in energy supply to pregnant beef cows has been shown to accelerate the return of ovarian cycles after calving. Target body condition scores are given in Table 41.7a.

Season

In the temperate latitudes seasonal variations in conception rates and a longer interval between parturition and first oestrus in the winter and early spring have been reported (e.g. Thibault *et al.*, 1966). Furthermore, spring-calving beef and dairy cows have been reported to undergo longer periods between calving and first ovulation than autumn calvers (Bulman & Lamming, 1978; Peters & Riley, 1982a). Most authors have suggested that such seasonal effects are related purely to nutritional management; however, strong effects of season have been demonstrated after adjusting statistically for the effects of body weight at calving (Peters & Riley, 1982b). Evidence for seasonality in cattle has now been accumulated from Europe, North America, Canada and New Zealand. Thibault *et al.* (1966) have

suggested that photoperiod might play some role in seasonality of reproductive activity in the cow and a negative correlation between daily photoperiod during pregnancy and the onset of ovarian cycles after calving has been demonstrated (Peters & Riley, 1982b). It is possible that a vestigial sensitivity to photoperiod may be present in the domestic cow and that in feral cattle this pattern would predispose towards calving during the late spring to early summer, the optimal time for food supply.

In summary, a variety of factors affect the onset of ovarian cycle in the post partum beef cow. The order of importance is probably nutrition, suckling and season. However, it is normally impossible in the practical situation to quantify these effects so that the time to first ovulation can be predicted.

Induction of ovulation in beef cows

Most evidence to date suggests that delay in ovulation during the postpartum period is mediated by a low rate of gonadotrophin release; most work has been done on luteinizing hormone (LH), but follicle stimulating hormone (FSH) is probably equally important. Such endocrine changes occur as a result of external factors (some discussed above) acting via the hypothalamus to suppress the release of gonadotrophin-releasing hormone (GnRH).

A reliable hormonal method of inducing ovulation in acyclic cows would obviously be advantageous but it is probably true to say that an ideal treatment has not yet been devised.

Gonadotrophins of non-bovine origin in the form of either pregnant mare's serum gonadotrophin (PMSG) and human chorionic gonadotrophin (hCG) have been extensively used for this purpose in the past but results have been variable; hCG has largely LH-like activity whereas PMSG has mainly FSH-like activity and may result in the development of multiple follicles. However, Penny (1998) suggests a dosage of PMSG which in one study did not produce multiple ovulations (see Table 41.9).

The injection of oestrogens in cows results in pre-ovulation surges of gonadotrophin release (depending on dosage) and oestrous behaviour. However, ovulation may or may not follow such treatment. The response is generally too unpredictable for this to be a useful method of inducing ovulation.

Progestagens have been used extensively to synchronize ovulation in cyclic cows, but may also be used to induce ovulation after calving. Roche *et al.* (1981) reported that 10-day treatment of beef cows with the progesterone-releasing intravaginal device (PRID) resulted in ovulation in about half the cows treated, whereas Bulman and Lamming (1978) reported a 75

Table 41.9 Dose of PMSG at implant removal (Penny, 1998). Reproduced with permission of The British Cattle Veterinary Association.

| Type of animal | Conditions | Dose of PMSG at progesterone withdrawal |
|------------------|-----------------|--|
| Beef suckler cow | Calved <55 days | 400iu |
| | Calved >55 days | Poor body condition score (<2) 400iu Good body condition score (>2) 250iu |
| Beef heifer | | None required under normal conditions |

PMSG, pregnant mare's serum gonadotrophin.

per cent success rate with a 12-day PRID treatment in dairy cows. However, in the latter study the conception rate in the responding cows was only 50 per cent and treatment did not affect the mean calving-to-conception interval. Other workers (Ball, 1982; Drew *et al.*, 1982) have reported a reduction in the calving-to-conception interval of up to 14 days following the use of PRID; however, the calving-to-conception interval of PRID treated beef cows was reduced only if used before day 30 after calving (Peters, 1982).

Mulvehill and Sreenan (1977) have reported the best success in induction of ovulation in beef cows by injecting 750iu PMSG at the time of progesterone withdrawal. However, as a small number of twin and triple ovulations did occur, Penny (1998) suggests a lower dose and a maximum of 400iu (Table 41.9).

Gonadotrophin-releasing hormone

The injection of GnRH in cattle induces release of both LH and FSH. There have been many attempts to induce ovulation in post partum cows by single intramuscular injections of 100–500µg GnRH and these have given variable results. In order to apply these treatments in practice, more consistent responses would be necessary.

At the above dose levels, LH release of pre-ovulatory surge magnitude usually occurs, depending on the responsiveness of the pituitary. However, ovarian follicles appear to require a two to three day period of rising plasma LH concentrations in order to mature fully prior to ovulation. Therefore, a pre-ovulatory LH surge will induce ovulation only if a follicle at the appropriate stage of development is already present. Alternatively, the induced LH release might cause premature luteinization of an unovulated follicle and transient secretion of progesterone sufficient to initiate ovarian cycles.

Two injections of 500µg GnRH at an interval of 10 days were advocated by Webb *et al.* (1977). Moreover,

this treatment regime has been particularly successful in large-scale field trials with beef cattle (Mawhinney *et al.*, 1979). A short-lived rise in progesterone concentrations following GnRH injection has been reported by several authors and may be compared to that occurring naturally in some cows prior to the onset of normal ovarian cycles. There has also been interest in longer-acting administration of GnRH, but no product is yet commercially available.

Oestrous synchronization and AI in beef cattle (see also p. 678)

The full exploitation of genetic progress cannot be made in beef cattle without the use of AI. AI is not very widely used in beef cattle, but as oestrus synchronization techniques have improved the number being artificially inseminated has steadily increased. There are several advantages of fixed-time AI (Penny, 1998) in that it:

- Eliminates the practical problems of heat detection in beef cattle;
- Allows the use of superior sires with estimated breeding values (EBVs) (see p. 71) for important traits to improve the quality of the calf crop;
- Allows the use of tested sires to breed replacement heifers;
- Allows the use of sires selected on ease of calving, thus reducing the likelihood of dystokia;
- Helps to create a compact calving pattern;
- Can be used to eliminate venereal disease.

Anecdotal evidence suggests that AI pregnancy rate results on farm have been poorer than expected. Beef cattle tend to be less handled than their dairy counterparts. Mann (2001) suggests poor pregnancy rates in dairy cattle were in part due to impaired ovulation as a

Table 41.10 Pregnancy rates after various treatments and insemination regimens (after Smith *et al.*, 1984, with permission from the American Society of Animal Science).

| Treatment | Timing of AI after last treatment | Percentage pregnant |
|--------------------------|---|------------------------|
| Control | Observed heat | 72 |
| 6 day PRID plus PG day 6 | Observed heat | 82 |
| 7 day PRID, PG day 6 | Observed heat | 73 |
| 2 × PG | 80 hours | 52 |
| 7 day PRID, PG day 6 | 84 hours | 66 |

PRID, progesterone-releasing intravaginal device; PG, prostaglandin.

result of 'stress'. In order to maximize the success of synchronized AI, Penny (1998) advises the following:

- Ensure that the animals are handled and that the handling facilities are safe and efficient.
- As nutrition has probably the greatest influence on the success or failure of oestrous synchrony, ensure that target calving condition scores are achieved and minimize body condition score loss between calving and first service. This will result in the majority of cows cycling prior to the synchrony programme. Sudden changes in the plane of nutrition may reduce pregnancy rates due to nutritional 'stress'.
- Avoid major management changes during the programme, e.g. turning out, housing, mixing groups and treatments such as vaccination.
- Ensure that adequate bull power is available for repeats and, to reduce the risk of introducing venereally transmitted diseases, avoid hired or shared bulls.

Methods

Both prostaglandins and progestagens may be used in beef cows (Peters, 1986). Fixed time AI is not generally recommended, however. Programmes which have produced acceptable pregnancy rates utilize a combination of progesterone and prostaglandin (Table 41.10). Prostaglandin administered 24 hours prior to progestagen removal has the effect of synchronizing the decline in progesterone concentrations from endogenous and exogenous sources. Progestagen may either be in the form of a synthetic progestagen implant, e.g. Norgestomet, or a progesterone intravaginal release device.

Penny *et al.* (1997) described a triple synchrony protocol (Table 41.11) in a spring-calving, single-suckled beef herd used over a two year period. Natural service was not used and AI was at fixed times. Repeat insemina-

inations 56 hours post progestagen removal were to cows which had a milk progesterone concentration of <3.5 ng/ml. Overall pregnancy rates, for the two years, were 58 per cent and 53 per cent. However, the barren rate was 17 per cent and 20 per cent (Table 41.12).

Stevenson *et al.* (2000) compared combinations of GnRH, Norgestomet and prostaglandin F_{2α}. Fig. 41.2 shows the experimental procedure for oestrous synchronization. They found that prior to 60 days post partum, programmes involving GnRH produced a higher percentage of cows in oestrus and higher conception rates compared to the programme involving only two prostaglandin injections (Table 41.13).

Martinez *et al.* (2000) compared oestrous synchronization and pregnancy rates in beef cattle given progesterone in the form of a controlled internal drug release device (CIDR-B), prostaglandin F_{2α} and oestradiol or GnRH. Two experiments were conducted to determine oestrous response and pregnancy rate in beef cattle given a CIDR-B device plus prostaglandin F_{2α}

(PGF) at CIDR-B removal, and oestradiol or gonadotrophin releasing hormone (GnRH). In experiment 1, cross-bred beef heifers received a CIDR-B device and 1 mg oestradiol benzoate (EB), plus 100 mg progesterone (E + P group; $n = 41$), 100 µg gonadotrophin releasing hormone (GnRH group; $n = 42$), or no further treatment (control group; $n = 42$), on day 0. On day 7, CIDR-B devices were removed and heifers were treated with PGF. Heifers in the E + P group were given 1 mg EB, 24 hours after PGF, and then inseminated 30 hours later. Heifers in the GnRH group were given

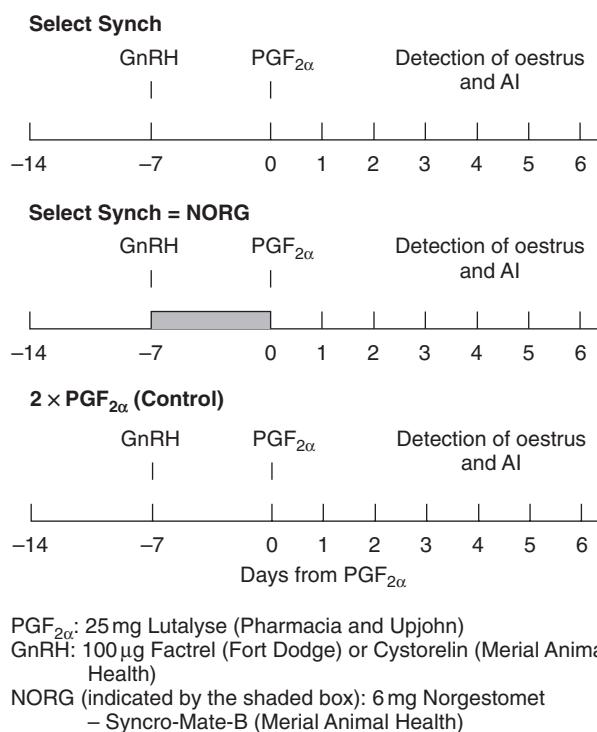

Fig. 41.2 Experimental protocol for oestrous synchronization (Reproduced from Stevenson *et al.*, 2000 with permission from the American Society of Animal Science).

100 µg GnRH, 54 hours after PGF, and concurrently inseminated. Control heifers were inseminated 12 hours after onset of oestrus. The oestrus rate was lower ($p < 0.01$) in the GnRH group (55 per cent) than in either the E + P (100 per cent) or control (83 per cent) groups. The mean interval from CIDR-B removal to oestrus was shorter ($p < 0.01$) and less variable ($p < 0.01$) in the E + P group than in the GnRH or control groups. Pregnancy rate in the E + P group (76 per cent) was higher ($p < 0.01$) than in the GnRH (48 per cent) or control (38 per cent) groups. In experiment 2, 84 cows were treated similarly to the E + P group in experiment I. Cows received 100 mg progesterone and either 1 mg EB or 5 mg oestradiol-17 β (E-17) on day 0 and either 1 mg of EB or 1 mg of E-17 β on day 8 (24 hours after CIDR-B removal), in a 2 \times 2 factorial design, and were inseminated 30 hours later. There were no differences among groups for oestrus rates or conception rates. The mean interval from CIDR-B removal to oestrus was 44.2 hours, $sd = 11.2$. Conception rates were 67 per cent, 62 per cent, 52 per cent, and 71 per cent in groups E-17 β /E-17 β , E-17 β /EB, EB/E-17 β and EB/EB, respectively. In cattle given a CIDR-B device and estradiol plus progesterone, treatment with either EB or E-17 β effectively synchronized oestrus and resulted in acceptable conception rates to fixed-time AI (Table 41.14).

Penny and Lowman (2002) have designed a triple synchrony system for beef cows which relies on fixed-timed AI and not on natural service. The programme allows cows up to three service opportunities over a 46 day period (Table 41.14). Double insemination improves pregnancy rate by 10 per cent compared to a single insemination. GnRH (10 µg Buserelin) at the time of CIDR insertion gave an improvement in pregnancy rate of 12 per cent in treated cows. Cows which were in a body condition score <2 (1–5 scale) or calved <55 days at first AI were injected with 400 iu PMSG. PMSG was administered to maiden heifers and produced a first service pregnancy rate of 74 per cent,

which was better than untreated heifers (pregnancy rate not published). The authors postulate that anoestrus may be a real problem in 15 month-old heifers of later maturing beef breed crosses. They conclude that a target of 90 per cent calving rate is achievable and repeatable in a 46 day breeding period and leads to a sustainable compact calving period.

As beef cattle are less used to being handled they can become fractious when being confined and restrained. At times of hormonal treatments it is essential to provide suitable handling facilities and sufficient experienced labour. If these are not provided there is considerable danger to both animals and humans. Where programmes involve progestogen implants, either as ear implants or intravaginal devices, it must be remembered that these may be lost prior to their planned removal. There are also welfare considerations and consumer concerns when subjecting animals to injections and implants.

Management of heifers (see Chapter 5)

Heifers should be bred to calve three to four weeks before the adult herd. Heavy breeds of bull likely to cause dystokia, e.g. Charolais and Simmental, should be avoided. Oestrous synchronization may be used to

advantage in heifers along with fixed-time insemination if required, although a bull would still be necessary to serve non-pregnant animals subsequently.

Monitoring reproductive performance in the beef herd

This is very much more difficult in beef cattle than in dairy cows because of the nature of the management systems.

Even in the best-managed units, records of reproductive events may be quite rudimentary, possibly including only date of calving. Since bulls are widely used few records of service may be kept. The bull would normally be left with the cows for a length of time that corresponds to the aimed length of the calving season. Whilst it is advantageous to identify barren cows at the end of the bulling period, in many cases it is not desirable to cull those animals because they are still suckling calves. However, methods of early pregnancy diagnosis are highly advantageous in the beef herd so that non-pregnant cows may be identified quickly and appropriate action taken. It is unlikely that the milk progesterone test will become popular in beef herds, even though a 'cow-side' test is available, because of potential difficulties in sample collection. However, the

use of real-time ultrasound where embryos/fetuses can be detected by day 30 (White *et al.*, 1985) or earlier offers very exciting possibilities.

It would be desirable for the practitioner to design a 'herd plan' to monitor reproductive performance in beef herds. The following could be used as a guide.

- (1) Condition-score cows at least two months before the start of the calving season, e.g. at weaning. Those below target (Table 41.7a) should receive supplementary rations to bring them up to target. Any cows above target should have their condition reduced.
- (2) Condition-score cows at calving; those below target should receive supplementary rations.
- (3) Special attention should be paid to first and second calvers since these are most likely to be vulnerable to problems, particularly extended periods of anoestrus after calving.
- (4) The producer should begin to observe and record oestrus three weeks before the bull is introduced.
- (5) Oestrus periods and services should be recorded throughout the breeding season. Particular attention should be paid to the dates when cows are expected to return to oestrus. The use of chinball markers may assist oestrous observation with cows at grass.
- (6) Pregnancy diagnosis should be carried out six weeks after the bulls are removed. Barren cows can then be culled when weaned. The findings at pregnancy diagnosis in conjunction with the service records will enable the farmer/veterinarian to estimate the likely calving dates and to plan the nutritional management.

Fertility problems arising in beef herds are likely to result from causes similar to those in the dairy herd. However, investigation is often hampered by the lack of adequate records. Clinical problems such as retained placenta, cystic ovaries and metabolic disease are much less likely to occur, but otherwise the more common problems are similar to those in dairy herds. Similarly, when problems occur they are likely to reflect herd status rather than just involving individual cows.

Analysing herd problems

The following information is likely to be of value in understanding and rectifying problems.

- Cumulative frequency curve of calvings;
- The age distribution of cows;
- The calving dates of first-calving heifers;
- The culling rate and reason for culling;

- An assessment of bull capacity including their ages and clinical histories;
- Evaluation of the other farm enterprises so that the best calving season can be chosen.

Beef cow stockworkers are capable of achieving rates of heat detection equal to those of dairy stockworkers. If reproductive performance is to be optimized then the stockworker must be prepared to observe and record the herd. For those who do so, techniques such as AI, oestrous synchronization/induction and induction of parturition will be much more successful.

The veterinarian should be able to assess the potential of a farmer and to educate and advise accordingly. This should be on a long-term basis, i.e. five years, by which time optimal targets should have been reached and advisory input can be reduced to a surveillance role.

Where herds have an extended calving pattern it may take several years of planning and reproductive manipulation before a herd achieves a two month calving period:

- Calve heifers to an easy-calving bull one month before the adult herd calve.
- Body condition-score cows regularly; if they are too thin increase feed and/or wean calves early.
- For late calving cows, manipulate oestrus and use AI soon after calving.

(b) Dairy Herds

Introduction

A fertility control programme is a system to monitor and manage reproduction, and is a well-established

element of preventive medicine in dairy herd management that is successfully practised in many parts of the world. In a successful programme the farmer gains an improved income more than the cost of implementing the programme (Esslemont *et al.*, 1985). For the veterinarian, a well-managed fertility control programme should represent a profitable outlet for specialist professional skills. In addition, regular farm visits to carry out fertility related work allow the veterinarian the opportunity to promote other aspects of preventive medicine, both within the dairy herd and also to other livestock enterprises on the farm.

Reproduction is particularly suitable for a preventive medicine approach because if intervention is delayed too long there will be an irretrievable loss of production time and thus a financial loss to the producer. Success depends on cooperation between the farmer and the veterinarian, and is based on good husbandry and consistently efficient work by the veterinarian.

Because of the effect of husbandry (feeding, housing and breeding management) and general health on reproduction, a fertility control programme should also incorporate other aspects of preventive medicine and encourage the practice of good husbandry. The development of herd health plans such as the British Cattle Veterinary Association (BCVA) Herd Health Plan over recent years (Anon, 1999) has been a significant step forward in this regard. The instigation of a herd health plan allows the veterinarian to influence all aspects of husbandry and preventive medicine within the herd. Furthermore, as most aspects of husbandry and health care will impact in some way on fertility and reproduction, this holistic approach to preventive medicine will aid and support the fertility control programme. Box 41.1 lists the main components of a fertility control programme.

Reproductive performance in the UK national dairy herd

There has been a general decline in fertility in the UK national dairy herd over recent years, emphasizing the growing need for cost-effective veterinary intervention in the form of well-managed fertility control programmes on dairy farms.

Analysis of approximately 9000 herds (National Milk Records (NMR)) representing data on around 1 million cows, between January 1997 and September 2000, shows that the average herd size has risen from 97 to 112 cows, and that the herd average yield has risen from below 5500 kg to approach 7000 kg per annum. Over the same period the mean calving to first service interval has risen from 84 to 88 days, the mean calving to conception interval from 113 to 121 days (Fig. 41.3) and the mean calving interval from 391 to 399 days (Fig. 41.4). There also seems to be a downward trend in first service pregnancy rate of approximately 3 per cent over the same period (Barrett, 2001). Royal *et al.* (2000) and Esslemont and Kossaibati (2000a) have also reported similar trends of falling fertility performance in the UK and O'Farrell and Crilly (1999) have documented

Box 41.1 The main components of a successful fertility control programme.

lowered fertility in Irish dairy herds. This declining fertility may be due to a number of factors such as high levels of peri-parturient disease (Peeler *et al.*, 1994a, b), inadequate nutrition (Webb *et al.*, 1997, 1999; Wathes *et al.*, 1998), increasing genetic merit for milk production (Nebel & McGilliard, 1993, Lamming *et al.*, 1997; Lucy & Crooker, 1999), infectious diseases or numerous other independent or inter-related factors. Specific breeding management changes such as the increase in the use of do-it-yourself artificial insemination (AI), with variable amounts of training of personnel, may also be significant (Howells *et al.*, 1999). Increasing milk yields and increasing herd sizes are almost certainly contributing to the problem. It is also highly likely that the decreasing availability of labour on farms is resulting in reduced labour hours per cow per year. The overall effect is greater difficulty in getting cows in calf and increased costs of trying to do so.

Components of a fertility control programme

Identifying herd specific goals

It is no longer possible to assume that every herd owner's reproductive targets are the same. Targets will be determined by various factors fundamental to the production system employed, for example contractual agreement with milk purchaser, seasonal milk price, milk constituent prices, feed costs, availability of labour, other farm enterprises, etc. The ultimate aim of the milk producer will almost always be to maximize financial return within the constraints of milk quota or production economics. Fundamental to achieving this is having a predetermined, and managed, reproductive pro-

gramme for the herd to ensure milk is produced at the most profitable time, maximizing financial margins per litre as well as ensuring an optimal culling rate with minimum involuntary culls and the production of sufficient replacement heifers.

Given that producers will sell their milk to different milk purchasers who have different price structures, it is important to ascertain by discussion with the farmer and his other advisors what reproductive pattern will deliver the best overall profitability. For example, a low input, low to moderate yielding herd of 5000 to 6000 l/cow per year looking to maximize the utilization of grazed grass may be looking for a tight seasonal calving pattern with a calving index (mean calving interval) of 365 days. In contrast, a farmer attempting to produce a uniform supply of milk each month, purchasing a large proportion of the feed used and running an intensive, high yielding herd of 10000l/cow per year may desire a year-round calving pattern and a calving index of 420 days. On the other hand a pedigree breeder producing embryos for sale may have general goals for the majority of his herd, but very specific reproductive objectives for his embryo donor cows. Having agreed the overall reproductive strategy that suits a given herd, herd specific reproductive targets can then be set.

Planning and setting targets

A fertility control programme requires reproductive targets. As outlined above, these are usually chosen for economic reasons but are limited by what is physiologically possible. It is the collective responsibility of the farmer, his veterinarian and others in the farm advisory team to choose the targets. However, the veterinarian should ensure as far as possible that the targets are realistic and achievable within an agreed time span.

There is no point producing targets that do not take into account bovine reproductive physiology or that are unduly optimistic concerning pregnancy rate, oestrous detection rate or the standard of husbandry on the farm. It is better to set a realistic target, achieve it and then set a more demanding target than to begin with a target that is unrealistic and totally out of reach, as this reduces stockman motivation. The farmer and his staff have to be in full agreement with the targets set, as only if they really want to achieve the selected targets are they likely to be met. The veterinarian can only help and advise the stockmen on the farm, and cannot achieve the aims of any fertility control programme alone. A team spirit has to be engendered and each member of the team must play his or her part fully.

Heifers

Dairy farmers often aim for seasonal calving for the whole herd. To achieve this, it is essential that the heifers calve early in the chosen season. As *age at first calving* has a major effect on the proportion of a cow's life that is productive, there is an optimal age for first calving and, for modern dairy breeds in Britain and elsewhere, this is usually put at 24 months old (see Chapter 5). However, farmers have to consider conditions in their own herds before they decide at which age the heifers should calve. Seasonal calving herds may have to calve heifers at approximately 24 months of age, as the alternative of 36 months is usually not economically viable (see Chapter 5). However, year-round calving herds or herds with two main calving periods can be more flexible. For example, some may elect to calve their heifers at 27 or 30 months of age.

Having chosen the desired season of first calving and the desired age at first calving, various problems arise that have to be considered. If, for example, the calving season chosen is September, October and the beginning of November and the age at first calving is to be 24 months, what is to be done with heifers that are born late in December, January or February? Will they be left until the next calving season? Will they be sold either as calves or perhaps later as in-calf heifers? Will they be made to calve even younger than 24 months old or will they be allowed to calve in January or February and extend the herd's agreed calving pattern outside the optimum time period? These are important and difficult decisions that have to be considered when the overall goals of the fertility control programme are agreed. Strategic decisions of this type have to be thought through, for example the above scenario can be avoided completely if replacements are only bred from cows and heifers served during the agreed breeding season, and repeat breeders and late calving cows are either culled or bred to a bull of a beef breed.

Once the age of calving has been decided, other consequential targets have to be considered. If a heifer has to calve at 24 months old she must become pregnant at 15 months old. To do this she has to be cycling and well grown (see p. 58). She also has to keep growing to be in a fit condition to calve down and be big enough to thrive in the dairy herd in competition with adult cows, or at least able to lactate, continue growing and get back in calf at the optimum time when managed in a group of first lactation cows. This means the farmer has to plan the growth rate from birth to meet the targets at these critical times (see p. 56). The veterinarian has an important role in reducing calf and growing cattle diseases to allow planned growth rates to be achieved.

Other breeding targets have to be established, for example an acceptable *culling rate* and the choice of sires used. One aim is to avoid dystokia and this should be considered in choosing the breed of bull and perhaps, more importantly, the individual bull to be used for service. Under conventional breeding programmes the generation interval is one of the major constraints to genetic gain. There are advantages in breeding replacement heifers out of heifers as this minimizes the generation interval and thus maximizes genetic gain within the herd (see p. 59). If proven dairy sires are used by artificial insemination (AI) they should be selected for ease of calving and be of higher genetic merit than the heifers being bred. At the present time health traits are gaining in importance in the selection of dairy cattle, and in the future they may be seen as equally, or even more important, than production traits, so in this context genetic merit encompasses both health and production traits.

It may also be a target to use beef sires on heifers, to allow the use of natural service or to avoid replacement dairy animals being produced from dams whose productivity is unknown. This approach may also be used to avoid too many dairy calves being born to the herd, particularly as pure bred dairy bull calves are of little or no value.

Cows

The most important targets are a controlled calving interval and *season of calving*, as these will impact directly on profitability by influencing the mean yield per day of life of the cows and the margin per litre of milk produced. In addition, minimizing the involuntary culling rate and allowing strategic voluntary culling are necessary.

In fertility control work, the *calving interval* is the number of days from the immediately past calving to the next. Farmers are very conscious of the need to have a controlled calving interval, but the ideal target varies from country to country, from farm to farm and indeed

Box 41.2 Factors influencing the choice of calving interval.

- Age and breed of the cow
- Yield and shape of her lactation curve
- Month of the year
- Feeding
 - Cost
 - Availability
- Calving and milking facilities
- Milk sale contract and differential pricing structures
- Milk quota
- Calf value

from lactation to lactation. In Britain the normal target for average yielding herds is a 12-month calving interval although, as discussed above, this may on occasions be extended for strategic reasons. Box 41.2 lists factors that influence the choice of calving interval.

There are two reasons why calving interval is important.

- (1) Typically, milk yield reaches a peak about five weeks after calving and starts to decline at about eight or nine weeks after calving. This is why the first part of a lactation is more profitable than later parts and the dry period. Short calving intervals result in a greater proportion of a cow's productive life being spent in this early, more profitable part of lactation.
- (2) Short intervals produce more calves over a given period of time than long intervals. In a 100-cow herd with a 12-month calving index there will be (approximately) 100 calves born per year; in a similar herd with a 14-month calving index the number of calves per year will be about 86.

However, longer calving intervals should not necessarily be considered a bad thing. If lifetime production could be maintained while reducing the frequency of calving of dairy cows there may be benefits. As many of the disease problems seen in dairy cows occur around the time of calving or in early lactation, having a system of extended lactation that reduces both disease in the cows and the numbers of low value calves produced may bring significant welfare benefits to the dairy industry (Knight & Sorensen, 1998).

It is tempting when marketing fertility control to put a money value on the loss occasioned by every day the calving interval is extended beyond the target. A figure that has remained remarkably constant over the last decade (to 2002) is £2.50 to £3.00/day. It should be realized that this (or any other generalized figure) is not necessarily applicable to any individual herd. Where possible, herd specific costings should be done

to derive the cost-benefit of any alterations in fertility parameters including an extended calving interval; the principles behind this are discussed more fully by Dijkhuizen *et al.* (1997).

Once the target calving pattern and target mean calving interval (calving index) have been chosen a series of consequential targets emerge. If the target calving index is, for example, 365 days, then the target for calving to conception must be 85 days, which is 365 days minus a mean gestation length of 280 days. It should be noted that if the most profitable calving interval for an individual cow is 365 days, then the aim in theory would be to have every cow calve with that interval. In practice what happens is that a herd calving index becomes the target. However, care should be taken to minimize the distribution around this 365-day mean figure, as cows with both longer and shorter calving intervals will be performing below their optimum. As the calving index is the mean interval between two calvings it only relates to those cows that calve again. In a herd with a 25 per cent replacement rate only 50 per cent of the herd will contribute to the calving index, as it takes no account of the fertility of heifers or cull cows, and can be manipulated greatly by culling. It is important therefore always to interpret the calving index alongside the culling rate for failure to conceive. The calving index as a measure of fertility in a herd is also too historical to be of much use in monitoring fertility, as it relates to the fertility of the herd over a year before. A better and more contemporary measure is the calving to conception (more correctly termed calving to establishment of pregnancy) interval as it relates to the current year rather than the previous year.

Account must be taken of the fact that many cows require more than one service per pregnancy when calculating the target interval from calving to first service. In an individual herd this depends on conception rate, oestrous detection rate and culling rate. In many herds a target for calving to first service of 65 days is satisfactory.

It is clear that cows must be cycling by the *target date for first service*. A target that is often taken for the start of cyclicity based on the physiology of the dairy cow is 42 days after calving.

It is quite obvious that a target of first service 65 days after calving has to be modified to become the oestrous cycle that straddles 65 days, often taken as 56–76 days inclusive (eight to eleven weeks) after calving. This modifies the target for calving to conception to the three-week period around 85 days, i.e. up to 96 days after calving. It follows therefore that cows should be served to the first observed oestrus after 56 days post calving. In other words, the voluntary waiting period in

this example should be 55 days. Shortening this period will allow cows to be served more quickly, but in general it will result in poorer conception rates.

Many farmers have as their prime target the season of calving, which tends to dictate a 365-day target calving index within a predefined service and calving period. The emphasis tends to be different from farmers aiming for a different calving index, although the method of calculation of target indices is in essence the same. The start and end of the service season is controlled by the targeted calving season. It is essential that as many cows as possible are served in the first three weeks (i.e. one oestrous cycle) of the breeding season. It is particularly important to have all the cows cycling in time and therefore the target for cyclicity is the three weeks before the start of the service period. Submission rates (defined as the proportion of cows eligible for service served in a defined time period, usually 21–23 days) during the breeding season of seasonal calving herds must be optimized, therefore oestrous detection is paramount and every effort has to be made to ensure that cows are served.

Cow identification, records, data analysis and interpretation

A clear, reliable *cow identification system* is needed to run a fertility control scheme. Good identification is needed for accurate records.

Without proper identification there will be no clear system to ensure that cows are served when planned, no way of knowing which animals fail to meet targets and dangerous confusion when animals are presented for veterinary examination. As an example of the latter point, consider a cow that has an unrecorded service, is pregnant and is presented to the veterinarian as ‘not yet seen in oestrus’. She will have a corpus luteum, and the usual treatment with prostaglandin or an analogue would cause abortion. Similarly, if a cow that was presented for pregnancy diagnosis on the basis of a known service date had an unrecorded service at a later date, even the most experienced veterinarian could make an erroneous diagnosis of ‘not pregnant’.

Although it is now compulsory within Europe that all cattle are tagged in both ears with a unique identification number, this may not allow rapid identification of cattle at pasture or within a large group during routine handling. The veterinarian should encourage the farmer to choose an identification system suitable for the conditions in which the herd is kept. Under most situations this will mean freeze branding, although other methods such as numbered collars may be utilized in some systems. Even with the advent of electronic tagging

systems there is still the need for a stockman to be able to identify each animal readily and rapidly in the herd in all housing and pastures used without risk of error or the need to resort to specialist equipment.

Record systems

A great deal has been written about record systems, ranging from simple, individual cow card-based systems, other paper-based systems and wall mounted breeding boards (Anon, 1984) to detailed state of the art computerized systems such as National Milk Records’ ‘InterHerd’ software. Simple systems for beginners are described at the end of this chapter (see p. 673).

Why are records needed?

- (1) Records are needed for efficient day-to-day running of the herd, even in herds with no thought-out plans and targets. They tell the stock-worker whether a cow that is in oestrus is due for service or should be left until the next oestrus; they indicate when a cow is expected to come in season from the recorded date of last oestrus or service and they allow the accurate selection of cows for the veterinary visit or for sampling.
- (2) Records are needed to monitor progress. It is necessary to keep an eye on herd progress as well as individual cow status. Monitoring will indicate how many cows have started cycling on time after calving, how many cows have been served on time and it will show the success rate of services and the incidence of long and short interservice intervals. Regular monitoring of herd events gives the veterinarian the chance to deal with herd problems at an early stage.
- (3) Accurate records analysed and interpreted correctly are an essential aid to the diagnosis of herd fertility problems. Records may be analysed for the whole herd, or if cows are grouped according to factors that may be related to fertility it is sometimes possible to pinpoint aetiological factors which may have temporal or other links. Examples include where one bull has a poor pregnancy rate, or the mean calving-to-first-service interval is very long in first calvers or if a seasonal effect on fertility is noted.

What are records?

Records consist of the following information written down by a farm worker: a cow number, a date and an event. Errors of two sorts occur: items are written down

Box 41.3 The main fertility/reproductive/production events to record.

Calving, oestrus, service, result of service, abortion
Veterinary reproductive findings and treatment
Other diseases
Production information
Milk yield
Feeding

incorrectly and events occur and are not recorded. The main events that are recorded in variable detail are listed in Box 41.3. Even on farms with the poorest records, many of the required data should be available. For example, the number of cows in the herd, culling records and calving records have to be recorded for statutory purposes (data required by the British Cattle Movement Service). If AI is used the AI company can provide data on service dates. This, along with a veterinary examination of each cow to determine pregnancy status, will provide enough information to calculate, or estimate, basic fertility parameters for the herd.

Problems in record analysis: There are two intrinsic, insurmountable problems in relation to data analysis.

- (1) With very few exceptions the amount of data available, when taking into account the variability of all fertility measurements, is not enough to give statistically valid information. This is particularly the case when the records are subdivided into age groups, seasonal groups and so on.
- (2) Information that is up-to-date is practically always incomplete (see below) and as a result may produce incorrect conclusions; complete information is nearly always out-of-date.

Up-to-date, incomplete information will give a more favourable result than is true in the measurement of the time from one reproductive event to another. Consider the calculation of the herd mean and spread of the interval from calving to first service. If the figure is calculated before all the cows in the calculation have been served (or marked as 'not to be served') the result will be biased because it will include only cows served soon after calving and will exclude those problem cows that will eventually be served after a long calving to first service interval. Incomplete pregnancy data based on non-return rates or on extremely early pregnancy diagnosis using progesterone assays may also distort the real picture.

These errors matter because decisions can be based on false assumptions. The actual analysis of records is further discussed in the section on periodic review and the regular evaluation of performance.

Box 41.4 Selection of cows for routine visit (the stage for examination or intervention figures are in brackets).

Cows with abnormalities at or after calving (21 days after calving); some will examine all cows about 21 days after calving, although this is probably unnecessary
Cows not seen in oestrus (≥ 42 days) after calving
Cows in target service period but not yet served (56–76 days after calving)
Cows overdue for service (≥ 77 days after calving)
Cows due for pregnancy diagnosis (≥ 42 days after last service or earlier if ultrasound examination used)
Cows seen at the previous visit and not yet served
Other problem cows, e.g.
Purulent vaginal discharge
Aberrant sexual behaviour
Repeat breeders

Regular veterinary visits

At each farm visit, the owner will have selected animals for examination based on an 'action list' generated using a system agreed between the client and veterinarian. Where a computerized data management system is in place the computer software may generate an action list based on predetermined agreed criteria. The animals presented for examination will vary from herd to herd and between practices. The groups of cows shown in Box 41.4 are examples of cows that may be presented at the regular visit.

Methods of examination, diagnosis and treatment have been discussed in Chapter 35. At each visit the clinician should spend a few minutes looking over the records with the client to pick up any problems at an early stage, to modify targets, to give information to the farm staff and to give them the chance to discuss any veterinary problem that is worrying them.

Records kept at the visit

Apart from the breeding records the veterinarian should keep a simple record sheet that records everything done and advised, an example is shown in Fig. 41.5.

Whatever method is used to transfer the veterinary findings to the records, care should be taken with cows that are found to be non-pregnant to make sure that it is clear to which service 'non-pregnant' applies. Errors arise when the cow is served later and the result 'non-pregnant' may be taken to apply to that subsequent service. Where a bull is present on the farm, a diagnosis of 'pregnancy not detected' is safer than non-pregnant.

The quality of the work done at the farm visit together with the informal discussion of progress and

| *date for pregnancy diagnosis and oestrus due **target period for first service | | | |

Fig. 41.5 Record of veterinary visit.

problems is very important. It acts not only to detect and treat problem cows and gather fertility and related data such as body condition scores, but also supports the advice given at the periodic review.

Periodic review and regular evaluation of performance

Detailed descriptions of the many different ways of gathering and analysing breeding records are easily obtained in other publications (Anon, 1984; Esslemont *et al.*, 1985; Brand & Varner, 1996a, b; Bailey *et al.*, 1999). Instead of repeating them here, attention is concentrated on what the analysis is trying to achieve and on some of the problems of interpreting records.

While at each visit an eye is kept on the progress of the herd's breeding pattern, periodically it is necessary to look more thoroughly at the fertility of the whole herd. The intervals between periodic reviews will vary with the calving pattern, with the intensity of the client's

interest and with the apparent success rate as noted at each visit. The basis of the periodic review is an analysis of the herd breeding records and an assessment of the effectiveness of all interventions. Cows in the milking herd will be considered separately from heifers.

There are so many ways of recording and analysing herd breeding records that this simple exercise can be unnecessarily confusing. There are two reasons for analysing herd records in these periodic reviews:

- Assessment of current status to establish whether there is a problem that needs attention or whether things are progressing satisfactorily.
- Discovery of any particular areas of weakness.

In the analysis of purely reproductive data (not factors which affect reproduction) there are five analyses that can be carried out, as listed in Box 41.5. The most important of these are marked with an asterisk. Even in herds where overall performance is adequate there may well be subsections of the herd where both

Box 41.5 Analysis of reproductive data.

Intervals in days between calving and subsequent reproductive events
 Calving to first observed oestrus
 Calving to first service*
 Calving to conception*

 Intervals in days from service to service (interservice intervals)
 Involuntary culling rate (reasons for culling)
 Submission rate (in herds with short breeding season)*

* Most important reproductive data.

the farmer and the veterinarian should be concentrating their efforts. Analysis of those data relating to herd subsections may reveal these areas of weakness. However, beware of overinterpreting data from a small number of animals.

The first step is to define clearly which cows are to be included in the analysis. The ideal baseline is all cows that calve in a specified period. This period has to end long enough before the day of analysis to allow every cow to have completed her reproductive cycle to the stage of pregnancy diagnosis or to the decision to cull.

Once the group to be analysed has been selected, it is important that the analysis makes it clear what has happened to every cow in the group.

Calving to subsequent reproductive events (to first oestrus, to first service, to conception)

It is simple to calculate the number of days from calving to first observed oestrus, to first service and to conception (the date of the service that resulted in a confirmed pregnancy). It is more difficult to express this information in a clear way and to interpret the results correctly.

The first thing to note is how many cows actually had a first observed oestrus, had a first service or became pregnant, in relation to the number of animals that started in the group. Culling rates of about 25–30 per cent are common in dairy herds. If the rate is much greater than this, the veterinarian should establish whether something is going wrong in the herd or whether the records are incomplete.

The next thing to calculate is the mean number of days from *calving to oestrus* (target: cycling by 42 days) to service (target: 65 days) and to conception (target: 85 days). Targets assume that the object is to have a 12-month calving interval. While the means are not completely satisfactory numbers they are worth knowing and comparing with targets.

Box 41.6 Measurement of success rate of service.

Percentage (pregnancy rate): 'successful services' of 'all services', e.g. 55%
 Ratio (services per pregnancy): 'all services' to 'successful services', e.g. 1.82
 Visually: as a cumulative sum (Anon, 1984) – visual and allows a degree of temporal analysis

The mean is of limited value because it may be made up of a wide range of values. For example, a mean calving to first service interval of 65 days may consist of very short and very long intervals (unsatisfactory) or it may be the result of most intervals being close to the target (satisfactory). If the mean is greater than the target, results are certainly not satisfactory and the mean does give some idea of the seriousness of the situation. However, calculation of a mean ± standard deviation for each parameter would be better, with the target standard deviation as small as possible.

Consequently, the concept of a 'target period' has been developed. For example, instead of a 65-day target for a mean interval from calving to first service, the target changes to having as many cows as possible served in the oestrous cycle period around 65 days, i.e. from 56 to 76 days (8–11 weeks) after calving. The target for conception is the period around 85 days, i.e. 76–96 days (11–13 weeks) after calving. For first oestrus it is best to aim for as many cows as possible seen in oestrus by 42 days.

Information about the number of animals that fall into the target period, before the target period and after it can be presented in histogram form. This is very clear, easily understood and puts the extent of the problem into exact numbers. This is particularly easy with modern software spreadsheet programs such as Microsoft (MS) Excel and some of the specialist software available for herd record analysis.

Success rate of services

The success rate of services is again quite simple to work out, but to avoid misinterpretation it is essential to understand the different ways of doing this, as shown in Box 41.6. The difficulty arises because of the different ways of defining 'all services' and 'successful services'. 'All services' can mean literally that; it can also mean all services up to a certain number of services, say five, or it can mean 'all first services' (first service is defined as the first service after calving or in a heifer's life). 'Successful services' can mean services that result in calving, or that result in positive pregnancy diagnosis by rectal palpation or ultrasound examination, or

positive pregnancy diagnosis by milk progesterone or by non-return to service at various intervals after calving.

Depending on the definitions used the success rate calculated from the same group of animals can vary enormously.

In most herds that are under veterinary supervision 'success' will be defined as positive pregnancy diagnosis undertaken by the veterinarian using ultrasound examination or rectal palpation. There are several points in favour of basing the success rate on first services rather than on all services, in particular:

- The result can be obtained earlier than if one has to wait for the result of the last repeat breeder in the group.
- Each cow contributes the same weight to the calculation.

Therefore, in herds controlled by a veterinarian, success rate is best defined as the *first service pregnancy rate*, i.e. the percentage of cows that are pregnant to first service. It should be borne in mind that an accurate figure will not be obtained until the result of the last first service is known, which may be about six weeks after that last service.

Once the first service pregnancy rate has been worked out it is compared with the target rate of between 45 and 60 per cent, the target depending on a variety of factors.

In addition to first service pregnancy rate, at the end of a breeding season it is valuable to calculate an *all-service pregnancy rate* as it is this that will dictate the number of straws of semen used and the total insemination charges. The all-service pregnancy rate will give a measure of the overall fertility within the herd, but should be interpreted in light of other information such as the culling policy for failure to conceive.

Interservice intervals

The number of days between services is worked out. These data are presented as one or two normal cycle lengths (18–24 and 36–48 days), or less than one, between one and two or more than two cycles (<18, 25–35 and >48 days). Alternatively, the figures are set out as a histogram with each day represented separately, which is satisfactory for visual presentation but difficult to describe in a report. The object of doing this is to assess the efficacy of heat detection.

- The assumption is made that most cows that do not become pregnant return to service at a normal cycle length of 18–24 days and therefore that returns longer than this represent a missed oestrus. While this is not strictly correct in all cases the proportion

of 18–24-day returns is quite useful for assessing levels of oestrous detection.

- Observation of the incidence of irregular intervals, such as <18 days and between 25 and 36 days, gives an indication of the frequency of inaccurate heat detection. However, it should be recognized that these irregular intervals may be brought about by late embryonic death or may be artefacts due to veterinary intervention to manipulate the oestrous cycle.

The proportion of cows presented for pregnancy diagnosis that are not pregnant also gives an indication of the number of missed oestrous periods because most non-pregnant cows have been in season once or twice before examination and have not been observed in oestrus. Another indicator of oestrous detection efficiency is the submission rate, defined as the proportion of cows eligible for service served in a defined time period, usually 21–23 days. This measure is particularly useful in seasonal calving herds.

Culling rate

The incidence of culling in relation to the total starting population and the stage at which the decision to cull is taken is presented as a percentage and an actual number. It is desirable to record the reason for culling.

Effectiveness of treatment and accuracy of pregnancy diagnosis

Treatment, including conservative treatment, takes place:

- At and after calving
- In the preservice period and
- At and after service.

Lists should be prepared with appropriate dates, diagnosis, treatment and outcome following treatment.

Many veterinarians who have not previously analysed their results will find the effectiveness of fertility treatment disappointing. Better results require more accurate diagnosis, careful selection of cases for treatment and improvement of the client's breeding management, so that practically all cows in oestrus after treatment are inseminated at the right time.

Heifers

Analysis of breeding records for heifers is often restricted because of lack of information, particularly where natural service is employed. Where AI is used analysis is to some extent as for adult cows. The aspects shown in Box 41.7 should be borne in mind.

Box 41.7 Analysis of heifer breeding records.

Starting population
 Percentage cycling when put to bull
 First service pregnancy rate
 Percentage that become pregnant (in defined breeding period)
 Length of calving period
 Range of ages at first calving (available from milk records)

After the purely reproductive analysis the next stage is to correlate the fertility results with factors that could interfere with reproductive efficiency.

At the periodic review a written report should be presented to and discussed with the client and his other advisors. Targets can then be reviewed and adjusted as considered appropriate.

Maintaining motivation

It is essential if a breeding programme is to be successful for all interested parties to remain focused and motivated at all times. This requires good communication between all involved and regular review of the herd's fertility performance within an economic framework.

There are considerable benefits to be gained from improvements in herd health; for example, a farmer with 77 cows, who adopted a planned approach to herd management, saw his farm profits improve by £13 000 in 2 years. It was estimated that £6000 of this came from improved fertility management alone (Esslemont & Kossaibati, 2000b). This in itself should be enough to motivate farmers to undertake schemes of this type. The economic appraisal of herd health schemes has been extensively reviewed elsewhere and will not be discussed in depth here (Esslemont & Peeler, 1993; Esslemont, 1995). However, it is important to realize that the financial benefits are often hidden and not immediately apparent to the farmer unless the herd records are analysed regularly and benefits quantified in monetary units.

Given the economic pressure on the dairy industry, farmers cannot afford to pay for services that do not bring financial benefits, nor can they afford to tolerate less than optimum fertility within their herds. In the past the uptake of herd fertility programmes has been poor in the UK (Wassell & Esslemont, 1992). If they are to become a regular feature on the majority of dairy farms then it is the responsibility of the veterinarian to ensure that they are cost-effective and to be able to illustrate this fact to his client. The use of spreadsheet programs containing herd specific economic parameters and easily interpreted graphics would make this task much easier.

Advice for veterinarians who wish to start herd fertility control programmes

Problems on the dairy farm that limit herd productivity and profitability such as suboptimal fertility usually have multiple causes and require an integrated, multi-disciplinary approach (de Kruif, 1998). The veterinary practitioner will be most effective when he or she is part of a dairy farm consultant team that includes, in addition to the veterinarian, personnel such as the nutritionist, financial consultant and other agricultural professionals who can contribute to a team approach for problem solving. If all the key advisors meet regularly on the farm and collaborate with developing solutions for farm problems, benefits will outweigh those seen if each advisor acts independently. This team approach has been advocated for many years (O'Connor *et al.*, 1985; Kelly & Whitaker, 1999), but has been slow to be recognized by some and barriers are sometime found between the different professionals. The veterinary surgeon should work to break down these barriers for the benefit of his client.

Many veterinarians who are not carrying out fertility control work for any of their clients find it difficult to get started. One problem is lack of confidence as regards skills in rectal palpation or ultrasound examination. If this is the case it has to be overcome by self-education and by undertaking suitable continuing professional development (CPD) training.

Marketing of the service is best done via practice newsletters and a special client meeting to explain to clients all that is involved in control programmes, preferably with the help of a client who is convinced of the benefits talking to others who are more sceptical. Help to arrange a meeting can be obtained from many sources, such as other (specialist) practitioners who run fertility control schemes, commercial firms or colleagues in the veterinary schools.

Beginners often have difficulty in knowing what to do on regular farm visits and particularly how to set up and use a recording system.

Reproductive record keeping and analysis

The first decision to be made on reproductive record keeping and analysis is who is to undertake this. Is it to be the farmer, the veterinarian (or his staff) or a third party? There are distinct advantages if the veterinarian offers a complete package to the farmer including record keeping. This gives the veterinarian control over which cows are presented at the regular farm visits. However, if the farmer already keeps adequate records this may result

in duplication of effort and the farmer may be unwilling to pay for something he considers he already has. Whatever system is agreed upon the farmer will be required to collect most of the data and will need some records on farm to make day-to-day management decisions.

It is essential that accurate herd records be maintained and that they are analysed and acted upon regularly (Varner & Brand, 1996; Bailey *et al.*, 1999). A computer-based system of record keeping offers many advantages, including rapid data analysis and the rapid production of action lists and high quality reports. Many dedicated herd fertility record software packages such as DAISY (Agrisoft, NMR), InterHerd (Agrisoft, NMR), Dairy-WIN (Massey University) and DairyCHAMP (University of Minnesota) are now commercially available. These offer distinct functions, which have been produced specifically to handle herd fertility data. In addition, software packages such as Herd Browser (Livestock Services UK Ltd) and Herd Management (Sum-it Computer Systems) offer some fertility recording and analysis functionality within more general software packages that have wider usage to the farmer.

While computers are invaluable in data handling and analysis it is important to realize that specific software is not essential. It is perfectly possible with limited computer skills to maintain and analyse herd reproductive data in a spreadsheet package such as MS Excel, although it will not easily generate action lists and some of the other output available from dedicated herd fertility software. The interpretation and understanding of herd records can be greatly enhanced by the use of computer generated graphs and charts, such as those quickly and easily produced by computer programs like MS Excel (Hendry, 1999).

Computerized recording will allow more in-depth and frequent analysis of data. However, it is vital that the veterinarian (and the farmer) understands fully the output of these systems and recognizes that the output is only as good as the quality of those data being entered into the system.

If for any reason the veterinarian is unwilling or unable to use a computer-based system a written record system is perfectly adequate for small herds, although it lacks the ability to rapidly produce regular record analysis, action lists and reports containing graphical representation of data. The following simple, paper-based system, which can be made up in the practice and photocopied, is suggested as a starting point. One sheet of A4 paper is marked across the top with headings that cover one reproductive cycle for each cow from calving to confirmation of pregnancy or disposal/death. The sheet is lined horizontally and each sheet will take records from about 20 cows (see Fig. 41.6).

This sheet is filled in by the farmer in chronological order of calving. It is usually impossible to obtain accu-

rate records for more than one or two months prior to starting (except those data which are required to be recorded by law) so that recording should be started at the same time as the rest of the programme. The best recording is likely in herds where there is some other recording system used, such as individual cow milk production records. Data kept in this way will require regular analysis which, if done by hand, will be time consuming and thus costly.

Many farmers find that a circular breeding board is useful to supplement this sheet (Anon, 1984; Fig. 4.29). Figure 41.6 could also be used as a template for the construction of a computer spreadsheet for data analysis.

If the client is aiming for a 12-month calving interval

Depending on the calving pattern and herd size, arrange to visit the herd say every 14 days and at each visit examine all cows that:

- Are more than 56 days after calving and have not been served;
- Were served 42 days or more previously and have not returned to service (if unsure of early pregnancy diagnosis, start later);
- Have had any problems.

Keep a record of everything you do on the farm and find out what has happened to all the cows you saw at the last visit (see Fig. 41.5).

It takes a year before the records are complete enough for sensible analysis. Make an initial analysis after six months, bearing in mind the problems discussed above (see p. 672 onwards). After that, analyse the records every six months, or other suitable interval, to show the following as a minimum:

- (1) The number of cows that calved.
- (2) Calving to service interval:
 - (a) The number that have been served since calving;
 - (b) The number not served;
 - (c) The mean calving-to-service interval;
 - (d) A simple, small histogram of distribution of calving-to-service intervals.
- (3) The same information for calving-to-conception interval.
- (4) First service conception rate (and all service conception rate).
- (5) Culling rate (and reason for culling).

If the client is aiming for a tight calving season

Use the same record system. Discuss oestrous detection. Make sure the farmer records all heats in the

three-week period before the first day of the service period.

Examine, and treat where needed, all animals that have not been in season at the end of the three-week preservice period. Visit at weekly or fortnightly intervals thereafter to examine all cows not yet seen in oestrus and to follow up treatments. Monitor the submission rate.

Carry out pregnancy diagnosis nine weeks after the first day of the service season. Remember this simplified advice covers the first steps to help beginners to get started.

Future developments in herd fertility management

The decreasing availability of staff on farms in the UK is presenting a real challenge to many farmers and veterinarians as they attempt to maintain and improve herd fertility. Over recent years there have been numerous technological developments that can help, particularly aids to oestrous detection such as the KaMaR heat mount detector, pedometers and milk progesterone assays (Peters & Ball, 1995). It is probable that in the future accurate and reliable automated systems to assess the cow's physiological state using biosensors will be developed (Koelsch *et al.*, 1994; Frost *et al.*, 1997; Mottram, 1997; Scully *et al.*, 2000). New developments in this area of technology may allow automatic milk progesterone assays, and other assays, to be performed while cows are being milked, allowing the timing of ovulation to be accurately predicted and removing the need for oestrous detection. In addition, technologies such as automated milking may become more widespread, freeing stockmen from routine mundane tasks and allowing them to concentrate on improving cow care. New methods of data recording, such as the use of palm held computers and mobile phones with internet capability, will allow data collected on the farm to be logged direct to remote computer databases in the farm office or at distant sites.

Introduction

This chapter aims to cover the manipulation of reproduction in cattle where this is not covered in the chapters on general fertility. The discussion includes control of the oestrous cycle, the establishment and maintenance of pregnancy and induction and postponement of parturition.

Control of the oestrous cycle

The control of the oestrous cycle is dependent on manipulation of the hormonal events occurring during the normal ovarian/oestrous cycle. The over-riding event controlling the development of an ovarian follicle to the point of ovulation in the cyclic cow is believed to be the process of luteolysis or decrease in progesterone secretion occurring between days 17 and 18 of the normal cycle (see Fig. 42.1). This fall in peripheral progesterone concentrations may be manipulated artificially in three ways:

- (1) By the artificial induction of premature luteolysis using luteolytic agents, e.g. the prostaglandins.
- (2) By attempting to modify the timing of normal ovarian events through a combination of trophic hormones and luteolytic agents.

- (3) By the simulation of corpus luteum function, by administration of progesterone (or one of its synthetic derivatives) for a number of days, followed by abrupt withdrawal.

The three methods are discussed in greater detail below.

Induction of luteolysis

The most potent luteolytic agents available are derivatives of prostaglandin F_{2α} (PGF_{2α}). Injection of exogenous PGF_{2α} or one of its analogues during the mid luteal phase of the cycle results in premature luteolysis and a consequential fall in peripheral progesterone concentrations. This is followed by a rise in the secretion of pituitary gonadotrophins and eventual ovulation. The fall in progesterone concentration is rapid, often reaching basal levels within 30 hours of injection. There are now several commercial analogues of PGF_{2α}. Examples of those currently marketed in the UK and elsewhere are shown in Table 42.1.

Prostaglandins have been used to control the oestrous cycle in several different ways. Some possible methods are given below:

- (1) Following rectal examination, only those cows with a corpus luteum are injected. These cows should then show oestrus and ovulate three to five days later. This method has the disadvantage that it is time-consuming and that rectal palpation involves added expense. The results also depend on the accuracy of detection of corpora lutea by rectal palpation.

- (2) All cattle are observed for oestrus over a seven-day period, serving any that show oestrus. The rest are injected with prostaglandin on the following day and may be inseminated either once or twice at fixed times or at observed oestrus. The reason for the initial seven-day observation period is that there is a period of about seven days in the cycle (day 18 to day 0 and day 1 to day 4) when the animal is unresponsive to prostaglandin, i.e. when no corpus luteum is present. After seven days, those originally between days 18 and 0 will have shown heat and been served, while those that were between days 1 and 4 will now be between

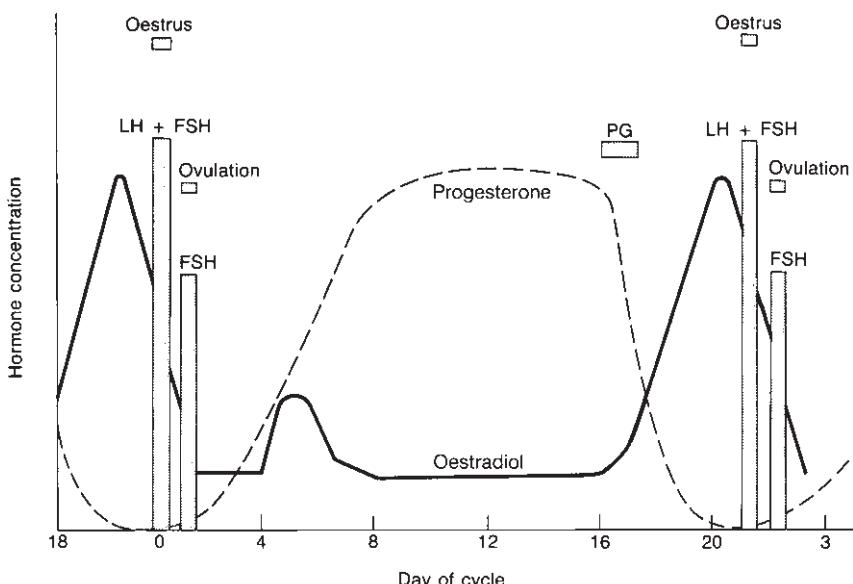

Fig. 42.1 Changes in blood plasma concentrations during the bovine oestrous cycle (schematic): — oestradiol; --- progesterone.

Table 42.1 Examples of prostaglandin analogues available in the UK and elsewhere (2003).

| Trade name | Active component | Distributor | Route of injection | Dose rate (mg) | Insemination timing recommendations (hours) | |
|------------|----------------------------|--------------------|--------------------|----------------|---|-------------------|
| | | | | | Double | Single |
| Estrumate | Cloprostenol | Schering-Plough | im | 0.5 | 72, 96 | 72–84 |

days 8 and 11, i.e. in the mid luteal phase, and therefore responsive to prostaglandin.

(3) The two injections plus two inseminations method. The so-called 'two plus two' technique was designed to synchronize groups of animals cycling at random without prior knowledge of their precise ovarian status. All cattle are injected on day 1 of treatment and the injection is repeated 10 or 11 days later. Artificial insemination (AI) is then carried out usually three and four days later (72 and 96 hours after the second prostaglandin injection).

The principle of this regimen is illustrated in Fig. 42.2. At the time of the first injection some animals will be responsive to the prostaglandin, i.e. between days 5 and 17 of the cycle. These will undergo luteoly-

sis in response to the injection and will ovulate some four days or so later. At the time of the second injection (10 or 11 days later) these cows will be on about days 8 and 15 of the next cycle (Fig. 42.2). The cows that were not responsive to the first injection, i.e. those between days 18 and 4 of the cycle, would now be between days 8 and 15 at the time of the second injection. Therefore all animals are theoretically in the responsive mid luteal phase at the time of the second injection. The technique is popular and quite successful in synchronizing cycles in heifers (Cooper, 1974) and has resulted in pregnancy rates equivalent to control animals. However, pregnancy rates achieved with this technique in adult cows have not always been consistent and some of the reasons for this are discussed later.

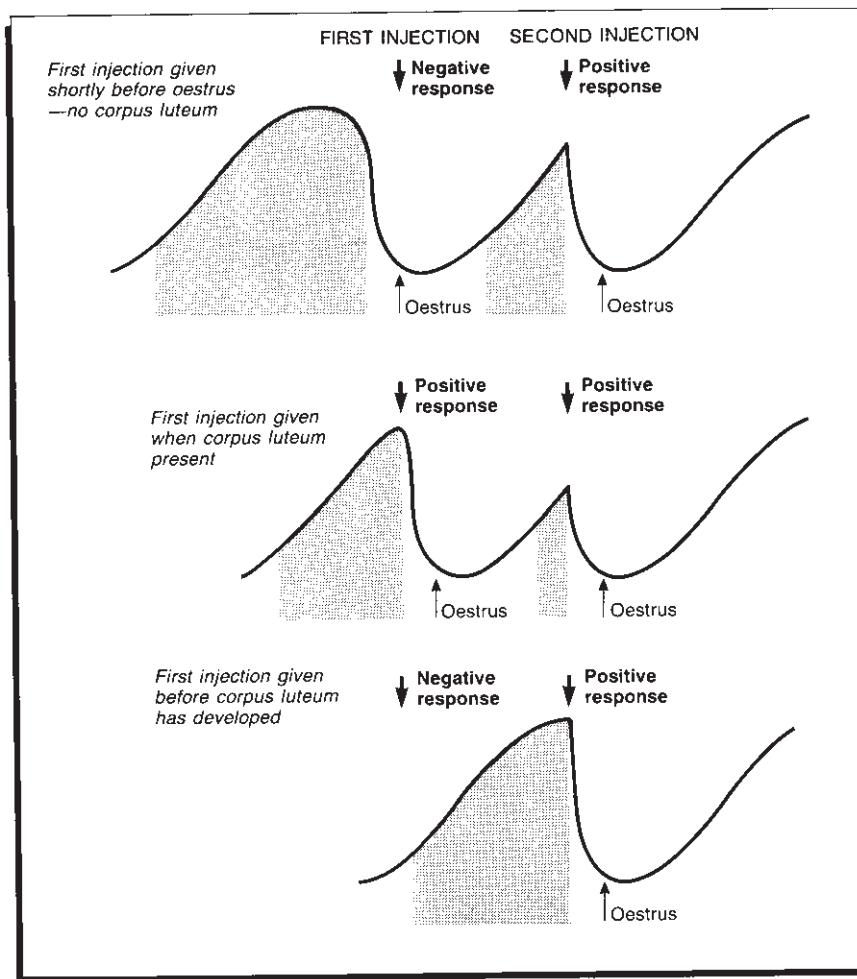

Fig. 42.2 The effect on progesterone concentrations of giving two injections of prostaglandin 11 days apart. (MAFF, 1984).

(4) A further method of using prostaglandins that has been quite popular is the so-called '1½ method'. Cows are injected with prostaglandin and those that show oestrus are inseminated. Those that have not been seen in oestrus are injected again 11 days after the first injection and may be inseminated either at a fixed time(s) or at observed oestrus. Although requiring further effort in terms of oestrous detection, this method tends to give better results than the 'two plus two' regimen and is the current method of choice. Its main advantage, however, is the reduction in cost by the reduction of both the number of treatments used and the number of inseminations per cow.

Trophic hormone and prostaglandin combinations

Gonadotrophin releasing hormone (GnRH) or its analogues can be used to reprogram the developing waves of ovarian follicles to maximize the possibility of

a dominant follicle being present at the time of induction of luteolysis seven days after the administration of the GnRH. Regimes involving this approach to 'priming' of the oestrous cycle have been tested in the UK (Mawhinney *et al.*, 1996). In most cases a second administration of GnRH has been used in an attempt to further synchronize the timing of ovulation after luteolysis. The second GnRH is administered 48 to 56 hours after prostaglandin administration, with insemination being carried out 18 to 24 hours after the post luteolytic GnRH (Roche, 1999).

Use of progestagens

The third method of controlling the cycle is to simulate the function of the corpus luteum by the administration of progesterone or one of its derivatives. In this method, gonadotrophin release, and hence ovarian follicular maturation, is suppressed until progesterone withdrawal. If progesterone is used to treat a group of cows and then it is withdrawn from all cows simultaneously,

this will theoretically synchronize ovulation in the whole group.

In order to synchronize a group of randomly cycling cows effectively, it is necessary to treat them with progesterone for a period at least equivalent to the length of the natural luteal phase, i.e. 16 days. This is because exogenous progesterone has little or no effect on the life span of the natural corpus luteum and therefore, in a small proportion of cases, the natural corpus luteum might outlive a short-term progesterone treatment, resulting in a failure of synchrony. However, it has been shown that longer-term progesterone treatments (18–21 days) result in poor pregnancy rates. It is thought that this is due to adverse changes in the intrauterine environment that may inhibit sperm transport.

Shorter-term progesterone treatments (7 to 12 days) generally result in more acceptable pregnancy rates. Unfortunately, short-term progesterone treatment does not control the cycle adequately since, if treatment is started early in the cycle, the natural corpus luteum may outlast the progesterone treatment. Therefore, it is often necessary to incorporate a luteolytic agent with short-term progesterone treatments in order to eliminate any existing corpus luteum.

Progestagens (progesterone-like compounds) can be administered in the feed, by injection or by implant. Administration in feed requires that the compound is 'orally active', i.e. it is absorbed into the systemic circulation unchanged. Progesterone itself is relatively inactive orally and thus synthetic analogues, for example medroxyprogesterone acetate (MPA) and melengestrol acetate (MGA), were developed for this purpose. However, this route of administration presents problems of controlled dosing and the possibility of tissue or milk residues, particularly in dairy cows. Therefore, such techniques are not favoured in the UK for oestrous control in cattle; however, they are used widely in the USA and other countries, particularly in heifers.

Progestagens can be given by injection, but as the half-life of progesterone and its analogues is short, repeated treatments may be necessary. The rate of absorption is often imprecise, so synchronized withdrawal of the compound can be unreliable. Implants appear to be the most suitable method of administration of progestagens since withdrawal can then be precisely controlled by implant removal.

Intravaginal progestagen-containing device (e.g. PRID or CIDR)

The PRID (CEVA Animal Health) or CIDR (InterAg/ART) are specialized forms of implant that are inserted into, and held within, the cow's vagina for a period of 7 to 12 days. The PRID consists of a stainless steel coil

Fig. 42.3 A progesterone-releasing intravaginal device (PRID).

covered by a layer of grey inert silastic (Fig. 42.3) in which 1.55 mg progesterone is impregnated. A gelatin capsule containing 10 mg oestradiol benzoate is attached to the inner surface of the coil. The oestradiol benzoate in the PRID is intended to act as a luteolytic agent. The CIDR is a Y-shaped device consisting of a nylon spine covered by a similar silicone elastomer impregnated with 1.9 g progesterone. These devices are inserted into the vagina by means of specialized applicators and are then left in place for up to 12 days.

The progesterone is continuously released from the elastomer until removal of the device. Removal is effected by pulling on the string (PRID) or plastic 'tail' (CIDR) which is left protruding from the vulva after insertion. Removal after 7 to 12 days causes peripheral plasma progesterone concentrations to fall, thus simulating natural luteolysis. Consequently, the cow should show oestrus 48–72 hours later and fixed-time AI may then be used.

There has been some interest in the use of low doses of oestrogens after the removal of the progesterone delivery device. Doses of 1 mg have been used in an attempt to further synchronize the onset of oestrus subsequent to the fall in plasma progesterone concentrations. Questions remain regarding the fertility consequences of this approach (Roche, 1999).

Norgestomet (Crestar)

Norgestomet, 17 α -acetoxy- β -methyl-19-nor-preg-4-ene, 20-dione (Crestar, Intervet), is marketed for planned breeding of beef cows and dairy and beef heifers. It is an example of a synthetic analogue of

progesterone and consists of an impregnated silastic subcutaneous implant. The implant is inserted subcutaneously behind the ear for a period of nine or ten days, during which time the progesterone is absorbed into the circulation. The implant is removed by making a small scalpel incision in the skin of the ear over the implant. At the time of the implantation an intramuscular injection of 5 mg oestradiol valerate is given as luteolysin, in combination with an initial injection of 3 mg norgestomet.

Factors affecting pregnancy rate after controlled ovulation

It cannot be overemphasized that in order to maximize results obtained with pharmacological control of the oestrous cycle, nutritional status and general management must be of a high standard. The efficacy of the pharmacological control of ovulation can be considered as two components:

- (1) The degree of synchrony obtained following treatment. This may be defined as the proportion of animals beginning to show oestrus or ovulating within a specified time period after the end of hormonal treatment. For the purposes of this discussion the target of synchrony is for the maximum number of animals to show oestrus within approximately 48 hours of progesterone withdrawal or 72 hours after prostaglandin injection (or to ovulate approximately 24 hours later in each case).
- (2) Reproductive performance, which may be expressed, for example, as the pregnancy rate achieved after treatment.

Obviously in some circumstances the pregnancy rate may be highly dependent on the degree of synchrony, particularly if fixed-time AI is used. For example, if there is a poor degree of synchrony there will be a wide variation in the timing of ovulation between cows or, more correctly, a proportion of cows will ovulate beyond the specific period anticipated. Therefore insemination would not be accurately timed and the pregnancy rates following fixed-time AI may be poor.

In view of the natural variation in timing of the behavioural and ovarian events around natural oestrus, it is perhaps not surprising that even after hormone treatments there is still considerable variation in the timing of responses between animals. Hence where fixed-time AI is used, two inseminations are usually recommended in order to maximize the probability of conception. In addition, other problems occur that appear to be specific to the particular compounds used and these are described below.

Synchrony after prostaglandins

Three major circumstances in which asynchrony can arise have been reported in the literature (Jackson *et al.*, 1979; Baishya *et al.*, 1980; Peters *et al.*, 1980).

Failure of complete luteolysis

This has occurred in 10 per cent or more of cows treated with prostaglandins. It takes the form either of complete lack of effect on progesterone concentrations or, for example, a fall to half of pre-injection levels, followed by luteal recovery, usually within 24–48 hours. Causes of luteolytic failure are not clear but may be related to several factors including the following:

- Non-responsiveness of some corpora lutea even in the appropriate phase of the cycle.
- Treatment too early in the luteal phase.
- Incorrect injection site or technique: in the case of intramuscular injections, occasionally the material may be injected accidentally into fat or ligamentous tissue.
- Short half-life of the chosen exogenous prostaglandin in the animal.

The extent of these various problems is not known and it must be admitted that all are to some extent speculative.

Long follicular phases after injection

In up to 20 per cent of cows injected with prostaglandin, although luteolysis appears to occur normally, progesterone concentrations remain low for an unusually long period. This may be associated with a delay in the timing of ovulation relative to oestrus. However, extended follicular phases (longer than eight days) also occur in about 17 per cent of untreated dairy cows. Thus it is likely that this phenomenon is related to a natural aberration in the adult cow's ovarian cycle. The problem has not been reported in heifers and certainly the cycles of adult cows would appear to be less uniform than those of heifers.

Acyclic cows

The ovary can only respond to prostaglandin if there is a functional corpus luteum. Therefore, cows with little ovarian activity at the time of injection do not respond. The proportion of cows in this state will vary from herd to herd and the average stage after calving, but it is generally regarded as a more serious problem in suckling beef cows. For this reason some advisors recommend

that prostaglandins are not used before day 42 after calving.

Synchrony after trophic hormone–prostaglandin combination techniques

It has been shown that more than 90 per cent of cattle treated with GnRH followed by prostaglandin and a second GnRH (the so-called 'GPG' system) can be induced into a low progesterone phase at the time of planned insemination. The proportion of cattle either failing to respond in this way or failing to show oestrus and ovulation as expected may be influenced by several factors:

- Some cows may fail to be in the luteal phase at the time of prostaglandin administration. This is thought to occur to a greater extent in heifer groups and may be a consequence of a difference in the frequency of follicular waves in immature cattle. The GPG system is usually less effective in heifer groups.
- Failure to respond to prostaglandins as previously discussed.
- Earlier than expected expression of oestrus. The normal recommendation is to serve on observed oestrus should cattle be available for service earlier than the time planned for insemination.
- Failure to exhibit behavioural oestrus due to slow or abnormal follicular development or true anoestrus

Synchrony after progestagens

There are two major circumstances in which synchrony may be incomplete following progestagen treatment.

Ineffectiveness of the luteolytic agent

As discussed above, oestradiol is often used as a luteolytic agent, along with progestagen treatments. If, for example, a nine-day progestagen treatment is started, without a luteolytic agent, at day 9 of one cycle and finishing before day 1 of the next, then these animals should synchronize adequately, since the end of treatment either coincides with, or occurs after, luteolysis (or the progesterone blocks ovulation). However, if treatment is started between days 2 and 8, then the corpus luteum can outlive the progestagen treatment. Hence, it is for cows in the early stages of the cycle that the luteolysis is required. If it is assumed that the group of cows is cycling at random, then one would expect about 30 per cent of them to be in this category and to respond poorly to oestrous synchronization using a progestagen

without a luteolytic agent. Synchronization rates of 70 per cent have been reported in practice (e.g. Drew *et al.*, 1979) Oestradiol is not always an effective luteolytic agent and, like prostaglandins, does not always prevent formation of the corpus luteum when administered early in the cycle (Peters, 1984).

Failure to maintain high blood concentration of progesterone

It has been shown that in some circumstances progesterone concentrations in the cow may fall before withdrawal of the progesterone source (Roche & Ireland, 1981). Obviously this could result in oestrus and ovulation occurring before removal of the device. This premature fall has occurred particularly with the intravaginal method of administration. It has been suggested that this is related to progesterone-induced changes in absorption across the vaginal wall rather than to exhaustion of progesterone in the device.

Possible methods of overcoming problems of asynchrony

Failure to undergo complete luteolysis

An alternative to the use of oestradiol as a luteolytic agent in combination with progestagens is to use a prostaglandin. Whilst problems of prostaglandin usage have been referred to above, they are clearly far more potent luteolytic agents than oestradiol. Prostaglandin is usually injected on the day before progestagen withdrawal. Various studies have shown that such combinations give well-synchronized oestrus and endocrine responses (Beal, 1983; Peters, 1984). However, there have been few reports where fixed-time AI has been used (Smith *et al.*, 1984). Unfortunately, such a treatment combination would obviously add further expense to a controlled breeding programme.

The use of low dose oestradiol

As detailed earlier, low (1 mg) doses of oestrogen have been used in the pro-oestrus period after removal of an intravaginal device. This is said to enhance the positive feedback that promotes the pre-ovulatory surge of the pituitary gonadotrophin, luteinizing hormone, which leads to ovulation. It is also said to enhance the behavioural expression of oestrus.

Prolonged follicular phases

This phenomenon has been associated with a delay in oestrus and ovulation. Therefore a logical approach

Table 42.2 Effect of cloprostrenol treatment of cyclic cows that had not been observed in oestrus by day 50 after calving (from Ball, 1982).

| Treatment | Time of insemination | No. of cows | Calving-to-conception interval (days) |
|----------------------------------|------------------------------|-------------|---------------------------------------|
| None until 90 days after calving | Observed oestrus | 166 | 107.4 |
| Cloprostrenol ^a | Observed oestrus | 61 | 98.1 |
| Cloprostrenol ^a | 2 and 3 days after injection | 75 | 104.0 |

^a 0.5 mg cloprostrenol (Estrumate, ICI) was injected intramuscularly 10–14 days after ovulation had occurred as judged from three times weekly milk progesterone measurements.

might be to attempt artificially to induce ovulation at a standard time after prostaglandin treatment. A single injection of gonadotrophin-releasing hormone (GnRH) administered approximately 60 hours after prostaglandin injection (Coulson *et al.*, 1980) has the effect of inducing a preovulatory-type LH surge normally associated with ovulation. This procedure has been used following synchronization of follicle development with GnRH as described earlier. There are also many reports on using GnRH after observed oestrus to produce a predictable ovulation in order to enhance conception success. This approach is discussed later.

Acyclic cows

This problem may be due to ineffective management in that either the cows are being treated too early after calving or that nutritional management is, and has been, inadequate (see Chapter 9). Assuming these problems are not present, then acyclicity may be overcome in a proportion of cows by the use of progestagens as opposed to prostaglandins.

Effect of the length of progestagen treatment on pregnancy rate

The deleterious effects of long-term progestagen treatment on fertility have already been discussed. However, there is some evidence that even short-term treatments can cause reduced fertility, particularly where the treatment is started during the late luteal phase of the cycle. It is possible that this occurs because the animal has been exposed to an uninterrupted long-term progestagen treatment, albeit a combination of endogenous and exogenous sources.

Field evaluation of oestrous synchronization techniques

Many field trials have been carried out to assess the effect of the various treatments on reproductive per-

formance. These will not be discussed in detail here but they may be summarized as follow:

- In adult cows the calving rate of control groups to single AI at observed oestrus is of the order of 50 per cent. Most studies report equivalent rates in treated cows.
- Fertility results are often up to 20 per cent better in heifers than in cows.
- In general, single fixed-time AI might be expected to result in 10–15 per cent lower pregnancy rates than two fixed-time AIs.
- It is clear that the best reproductive performance is achieved when oestrous cycle control is combined with insemination at observed oestrus. In that situation the reproductive performance of treated cows may often be higher than that of controls. This may happen particularly in a herd where the efficiency of oestrous detection is normally low. Following a synchronization treatment, it is to be expected that the vast majority of cows should show oestrus within 10 days after treatment. Therefore, the effect of treatment in this situation is to concentrate the occurrence of oestrous periods, so that detection efficiency can be increased over a relatively short time. Results of studies on the use of the prostaglandin analogue cloprostrenol with either fixed-time AI or observed oestrus are shown in Table 42.2 and help illustrate the advantage of insemination at observed oestrus. Following retrospective analysis of data from 17 published trials McIntosh *et al.* (1984) concluded that prostaglandin treatment combined with insemination at observed oestrus improved conception rates over controls by an average of 7 per cent.

Establishment of pregnancy

The ability to conceive is clearly vital in determining reproductive performance. A low pregnancy rate to first

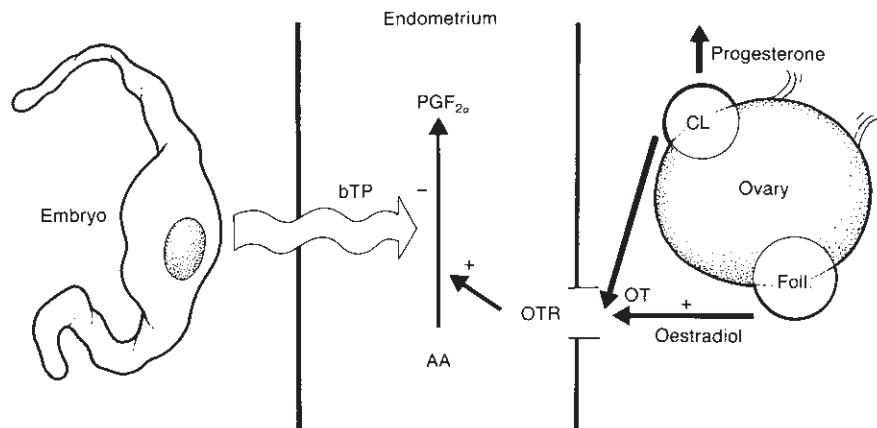

Fig. 42.4 Possible endocrine relationship between the early embryo, endometrium and ovary. bTP, bovine trophoblast protein; AA, arachidonic acid; OT, oxytocin; OTR, oxytocin receptor; CL, corpus luteum; Foll, follicle.

service is a major cause of poor reproductive performance. In the absence of specific infectious disease it has been shown that the major problem here, at least in cattle, is early embryonic death. Total embryonic and fetal mortality is estimated to be around 38 per cent and it is thought that 70 to 80 per cent of that loss occurs between days 8 and 16 after insemination (Sreenan & Diskin, 1986).

Pregnancy establishment involves active and passive communication between the embryo and the uterus. The exact cause(s) of embryonic death is unknown but it is circumstantially related to premature regression of the corpus luteum. In other words, the corpus luteum is normally maintained for the whole of gestation and early embryonic mortality is associated with its early loss. This results in a decrease in progesterone concentrations allowing the animal to return to oestrus, probably at the normal time.

Before examining methods of reducing embryo mortality it might be useful to provide a brief review of findings in relation to the establishment of pregnancy. This is illustrated in Fig. 42.4. In the non-pregnant animal PGF_{2α} secreted by the endometrium causes regression of the corpus luteum. There is evidence that oestradiol-17β from developing ovarian follicles stimulates the synthesis of receptors for oxytocin on endometrial cells. Oxytocin, produced by the corpus luteum (Wathes, 1984; Lamming & Mann, 1995), binds to these receptors, thereby stimulating the synthesis and secretion of PGF_{2α}. In early pregnancy a protein of molecular weight of approximately 18000 is secreted by the embryo. This protein appears to exert an anti-luteolytic effect and has been termed bovine or ovine trophoblast protein 1 (e.g. oTP-1). Stewart *et al.* (1989) showed that the amino acid sequence of oTP-1 has 70.3 per cent similarity, with bovine α2-interferon. Further studies have shown that oTP-1 and bTP-1 bind to receptors on the endometrium and intrauterine infusion of trophoblast proteins or recombinant interferon can extend the

length of the luteal phase in non-pregnant animals (Stewart *et al.*, 1989; Thatcher *et al.*, 1989). This work led to the conclusion that some embryo mortality may be related to a failure of some embryos to produce sufficient trophoblast protein.

A number of methods have been used in the field to improve pregnancy rates in cattle. Diskin and Sreenan (1986) reviewed the studies on comparisons of progesterone concentrations in pregnant and non-conceiving cows before and after insemination and concluded that the data were conflicting and inconclusive in all respects. Progesterone supplementation during early pregnancy has given equivocal results, but does seem to be effective where control pregnancy rates are particularly low, i.e. 40 per cent or below. In summarizing the results of progesterone supplementation during early pregnancy, Mann and Lamming (1999) conclude that while progesterone concentrations during the luteal phase are an important determinant of the outcome of pregnancy, they do not appear to be as important as the timing of the post ovulatory progesterone rise.

More recently attention has been paid to the use of gonadotrophin or GnRH in enhancing early luteal performance in support of the developing embryo. Peters (1996) found that 1500iu of human chorionic gonadotrophin on day 12 of the cycle resulted in a sustained increase in progesterone concentration and an increased diameter of the corpus luteum.

It has been common veterinary practice for many years to inject cows at the time of service with a 'holding' injection using either human chorionic gonadotrophin (HCG) (luteinizing hormone (LH)-like) or GnRH to stimulate endogenous LH release. The exact physiological rationale for this has not always been clear since such treatment could potentially have at least two effects. Firstly, there is a widely held belief that under some circumstances ovulation may be delayed relative to the timing of oestrus. Administration of GnRH will result in preovulatory

gonadotrophin release and subsequent ovulation. Secondly, LH is considered to be the major luteotrophic hormone, at least during the first few days of pregnancy. Therefore, GnRH-induced LH release may facilitate the development and maintenance of the corpus luteum in the post ovulatory period. Numerous trials have been carried out where either HCG (LH) or GnRH has been given on the day of service. In a meta-analysis of many studies Valks (1996) illustrated that a small effect was generally achievable (around 8 per cent) and that the magnitude of any effect was influenced by factors including body condition score. Study results varied, with some showing good responses and others showing no differences from control animals. This could be for one or more of the following reasons:

- (1) Poor design of trials, involving a few animals in each study group. This is a common problem where fertility rates are being studied. Due to the fact that pregnancy rate is discrete variable and that rates are very different between farms, very large numbers (several hundred per group) may be required to establish statistically significant differences between groups.
- (2) The actual cause of pregnancy failure may differ widely between farms and therefore one may be attempting to rectify many different primary problems by the use of such a treatment. The primary cause is often impossible to diagnose, at least at that time.
- (3) Thus it is probably a fair summary to state that the best results for the improvement of pregnancy rates have been achieved where the control or background fertility of the herd is poor, although there are some exceptions to this.

MacMillan *et al.* (1986), attempted to support the corpus luteum when it became susceptible to the luteolytic mechanism, i.e. approaching day 16 after oestrus in the cow. Treated cows (approximately 225) were given a single injection of 10 µg buserelin (a synthetic analogue of GnRH) on day 11, 12 or 13 after AI. Treated and control cows were palpated at six to nine weeks to determine pregnancy status, cows returning to service were re-inseminated. Pregnancy rates at six to nine weeks were 72.5 per cent and 60.9 per cent for the treated and control cows respectively (see Table 42.3). Of those cows returning to service the pregnancy rates to second service were 85.1 per cent and 69.5 per cent for treated and control cows, respectively (see Table 42.4).

In the UK a similar approach was adopted, with 1619 cows studied (Sheldon, 1993). When GnRH was used at 11 days after insemination first service pregnancy rates were enhanced by 9.4 per cent when compared with untreated controls. This benefit rose to 30 per cent in cows treated at third and subsequent services.

Table 42.3 Pregnancy rate (per cent) to first insemination with 10 µg buserelin injected between days 11 and 13 after insemination (from MacMillan *et al.*, 1986).

| Trial | Treated | Control |
|---------|-------------------|---------|
| A | 75.4 | 62.2 |
| B | 67.5 | 57.8 |
| Overall | 72.4 ^a | 60.9 |

^a P < 0.01.

Table 42.4 Pregnancy rates (per cent) to second insemination (from MacMillan *et al.*, 1986).

| Trial | Treated | Control |
|---------|-------------------|---------|
| A | 78.6 | 69.0 |
| B | 94.7 | 70.8 |
| Overall | 85.1 ^a | 69.5 |

^a P < 0.05.

Thatcher *et al.* (1989) suggested that buserelin acts in these situations by disrupting normal waves of ovarian follicular growth and oestradiol secretion, resulting in a failure of the luteolytic mechanism (see Fig. 42.4). Mann and Lamming (1995), however, maintain that GnRH causes a short-lived reduction in oestradiol secretion which reduces the stimulus to the development of the luteolytic mechanism.

Pharmacological induction of parturition

Many attempts have been made to induce parturition artificially in the final days of gestation. These methods have used exogenous hormones to simulate the mechanisms involved in the normal parturition process. These have included the use of corticosteroids, oestrogens and prostaglandins since these are all involved in the endocrine pathway (see Fig. 42.5).

These are several indications for the induction of parturition in cows. Firstly, in countries such as New Zealand, where a tight seasonal calving pattern is often required, this is considered to be an important aid to optimum management and utilization of feed resources. Secondly, cows can be induced to calve at a time when supervision is most readily available. Thirdly, if it is suspected that a high calf birth weight might result in dystokia, early induction may alleviate the problem.

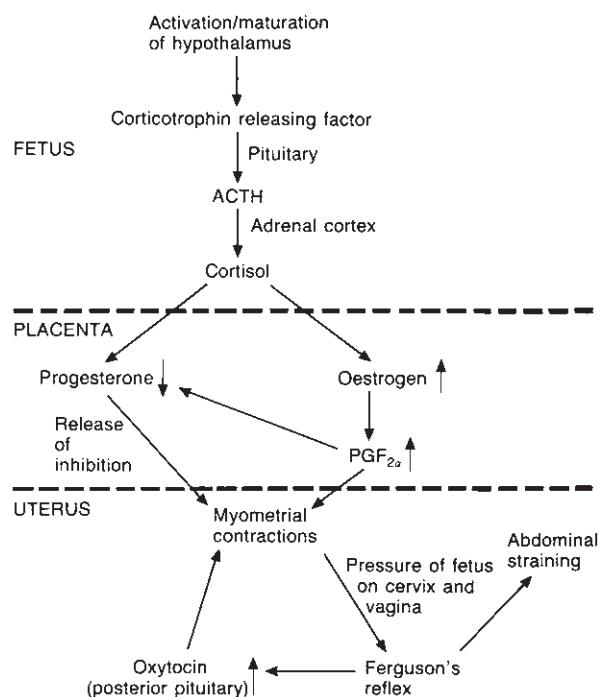

Fig. 42.5 The endocrine pathways controlling the induction of parturition.

Methods of induction of parturition

Corticosteroids

Parturition can be induced quite reliably from about day 255 of pregnancy onwards by a single injection of a synthetic glucocorticoid, such as dexamethasone, betamethasone or flumethasone. It is assumed that such therapy simulates the effect of the fetal adrenal cortex at term.

Induction of parturition using corticosteroids is an important part of management in many New Zealand dairy herds and considerable experience of the technique has been gained (Welch *et al.*, 1979; Verkerk *et al.* 1997). Both short- and long-acting formulations have been used.

Short-acting formulations, generally in the form of a soluble ester of the steroid, usually result in parturition two to three days later. Although the calves are usually viable, this method has been associated with a high rate of retention of the fetal membranes. Verkerk *et al.* (1997) used 21 mg dexamethasone isonicotinate followed by a short acting formulation of dexamethasone sodium phosphate 10 to 14 days later. Using this regime 35 per cent of cows calved before the second corticosteroid had been administered. This was more common if the cow was in the last 30 days of gestation. A 14 per cent incidence of retained fetal membranes was recorded.

Oestrogens

There is no clear evidence that exogenous oestrogen is effective in inducing parturition in cows, although in one trial cited by First (1979) treatment with oestradiol-17 β before corticosteroid treatment shortened the time to delivery and reduced the variation between cows.

Prostaglandins

Prostaglandins, both PGF_{2 α} and synthetic analogues, may be used to induce parturition in cows, although treatment before day 270 of gestation is not recommended. Parturition usually occurs between one and eight days after injection, but at an average of three days. A higher incidence of retained placenta compared to non-treated cows may be expected.

A study under UK conditions (Murray *et al.*, 1984) used a treatment regimen whereby cows were injected with 20 mg dexamethasone and those that had not calved 10 days later received an injection of 0.5 mg cloprostenol (an analogue of PGF_{2 α}). Although there was a high incidence of retained placenta, this did not affect subsequent reproductive performance. It was concluded that, provided management was organized adequately to supervise parturition and to take care of the newborn calves, then this procedure could be carried out to advantage.

A characteristic of early studies on the pharmacological induction of parturition was the high rate of calf mortality and post calving problems, particularly retained placenta. An important determinant of the incidence of retained placenta appears to be the oestrogen status of the cow at the time of induction. As discussed above, oestrogen concentrations rise during late pregnancy, hence the oestrogen status may simply be a reflection of the proximity of term or 'readiness to calve'. From an exhaustive review of the available literature, First (1979) concluded that if induction is carried out when oestrogen levels are elevated, both glucocorticoids and prostaglandins are effective. However, glucocorticoids were the most appropriate treatment if induction was to be attempted earlier. The earlier that interference is attempted, the higher the probability of calf mortality, retained placenta and other related problems.

Delay of parturition

It is also possible to delay parturition for several hours by pharmacological means. This is carried out so that supervision for calving can be more conveniently and readily available. Injection of the potent adrenergic drug clenbuterol inhibits myometrial contractions, thus slowing down the first stage of labour. However, if treat-

ment is started after second stage labour has already commenced, it would have little effect. Clenbuterol is not currently indicated for obstetric use.

(a) Bluetongue

R.P. Kitching

Bluetongue (BT) is an infectious, non-contagious disease of ruminants characterized by congestion, oedema and haemorrhage. The disease is caused by strains of orbivirus, within the family Reoviridae.

The genus orbivirus, Reoviridae also contains Ibaraki disease virus of cattle, epizootic haemorrhagic disease virus of deer (EHD), African horse sickness virus and Colorado tick fever virus. The outer shell of bluetongue virus (BTV) has a diameter of 65 nm, within which is an inner shell of 32 ring-shaped capsomers. The genome consists of ten segments of double-stranded RNA which code for the structural and non-structural viral proteins and which can be separated according to their relative sizes by polyacrylamide or agarose gel electrophoresis. Two of these segments (numbers two and five) code for the outer structural proteins (VP2 and VP5) which determine the serotype of the virus. Twenty-four immunologically distinct BTV serotypes have so far been identified by virus neutralization tests; however, it is probable that more types will be identified in the future. BTV is sensitive to low pH and storage at -20°C; it is partially resistant to lipid solvents.

Distribution

The distribution of BTV is approximately defined by the latitudes 40°N and 35°S, which includes most of Africa, the Middle and Far East, Northern Australia, United States of America, Central America and South America north from Southern Brazil, Paraguay and Bolivia.

Not all the BTV types are found throughout this enzootic region, and the distribution of the different types can vary between years. BTV types found within a region tend to have greater genome sequence homology, in genome segments other than those which encode the serotype-specific outer capsid proteins, than their designated serotype number would suggest. The type is defined by the outer capsid proteins alone, and while these are found to differ between different serotypes found in a particular region, the remaining genome segments show high levels of sequence homology. The BTV types have therefore been additionally grouped into Australian types and African types, with the North American types being more closely related to the African. The Australian BTV type 1 has more in common with other Australian types than with the African type 1, although sharing with the African type its antigenic determinants. This diversity may explain the marked difference in pathogenicity of the strains of BTV which does not appear to be related to a specific type designation; it also makes epidemiological studies based on serotype determinations of doubtful significance. Recombination can occur between different strains of BTV which adds further to the potential for diversity of BTV isolates.

The closely related EHD group of viruses has been isolated in the USA, Canada, Nigeria and Australia, whereas Ibaraki disease virus is restricted to South Korea, Japan, Philippines and Indonesia.

History

Bluetongue was first diagnosed in South Africa in sheep at the beginning of the twentieth century. It was first seen outside Africa in 1943 in Cyprus, although it had possibly been present in Cyprus as early as 1924. Subsequently BT was diagnosed in Israel in 1951, in Pakistan in 1959 and in India in 1963. A disease at first identified as sore muzzle of sheep in Texas in 1948 and California in 1952 was the following year diagnosed as BT. Between 1956 and 1960, BTV caused a major epizootic in sheep in Portugal and southern Spain, which reportedly resulted in the loss of 180 000 animals, but the virus then disappeared from the region.

Epidemiology and transmission

The distribution of BTV between 40°N and 35°S reflects the distribution of its main biological vectors, certain tropical and subtropical species of *Culicoides* midges, in particular *C. imicola* in Africa and the Middle East, *C. variipennis* in North America and *C. brevitarsis*, *C. fulvus* and *C. wadai* in North Australia.

The adult female *Culicoides* lays her eggs in damp muddy areas containing decaying vegetable material or in cattle dung, two to six days after a blood meal. Depending on the temperature these eggs may hatch in two to three days into larva. The larval stage lasts 12–16 days, followed by pupation and, two to three days later, the emergence of the adult *Culicoides*. In the subsequent 24 hours the adult females take a blood meal and mate, and they will continue to take a blood meal every three to four days until the end of their life, which may last for 70 days, but probably rarely exceeds 10. Optimum conditions are between 13°C and 35°C. Larvae of temperate species can remain dormant over winter and pupate the following spring. Seven to ten days after taking a BTV infected blood meal, vector species of *Culicoides* midge are able to transmit virus.

Culicoides usually feed at dusk, during the night or at dawn, and are subject to being transported, sometimes over considerable distances, by strong wind currents. The passive movement of infected *Culicoides* may be responsible for the introduction of BT into areas usually outside the enzootic region, such as Western Turkey and Cyprus. This introduction of BTV into an area may be associated with abnormal wind currents or may be a regular occurrence. The winds of the Intertropical Convergence Zone annually reintroduce BTV-infected *Culicoides* to South Africa from Central Africa. The movement of BTV into Sudan from Central Africa is also associated with a prevailing wind from the South. However, BTV may also become enzootic in new regions as climatic changes allow the main vectors to extend their breeding sites or, alternatively, virulent strains of new serotypes of BTV may be introduced into an area already infected with mild or avirulent strains.

Within BT enzootic regions the prevalence of seropositive animals may be very localized around areas particularly suitable for the breeding and survival of *Culicoides*, so called 'hot spots'. The possibility also exists for new species of *Culicoides* to take on the role of BTV vectors; it has recently been shown that some British species of *Culicoides* can biologically transmit BTV under experimental conditions.

Bulls may shed BTV in their semen intermittently during the viraemia following infection. Bowen *et al.* (1985) classified bulls into three categories, those from which virus could not be isolated from the semen (the majority), those from which only low titres of virus were

isolated on less than three occasions and those which shed virus over a two to three week period. BTV could only be isolated from the semen when there was a concurrent viraemia. Six out of nine susceptible heifers inseminated with the BTV-contaminated semen became pregnant and three of the nine became viraemic. None of the calves born at term showed any clinical abnormality. Considerable importance has been attached to reports of a bull which was persistently infected but seronegative from birth and intermittently shed virus in semen over an 11-year period (Luedke *et al.*, 1982). Attempts to duplicate the conditions which produce persistently BTV-infected, seronegative calves have been unsuccessful.

Host range

Sheep, goats, cattle, water buffalo, camels and many wild ruminants are susceptible to infection with BTV. BT is predominantly a disease of sheep and has only been reported as a disease of cattle in the USA, South Africa, Israel and Portugal.

Pathogenesis

Infection follows the bite of an infected *Culicoides* midge. The virus is carried to the local lymph node where primary replication occurs before dissemination of virus throughout the body. Viral replication then continues in the spleen, lungs, bone marrow and other lymph glands. In sheep, BTV also replicates in the endothelial cells of the blood vessels and, unlike in cattle, has been clearly shown to cross the placenta and can replicate in the developing fetus causing fetal resorption, abortion or developmental abnormalities. The peak viraemia occurs two to three weeks after infection, its duration and severity depending on the strain of BTV.

Clinical signs

BT in cattle is seen as a transient fever followed by hyperaemia and erosions of the buccal and lingual mucosa and nose and, rarely, the teats. Affected cattle salivate excessively and may walk with a stiff gait. The skin of the nose appears mottled and dark and has been described as 'burnt muzzle', and may completely slough. Fewer than 1 per cent of cattle in the USA infected with BTV show signs, and the lesions may be due to a delayed type hypersensitivity reaction. There is considerable controversy over whether BTV can cross the placenta of the pregnant cow. If the virus is able to cross the placenta it may only do so in association with other placental pathogens, or be restricted to only certain strains of BTV.

Diagnosis

It is not possible to make a diagnosis of BT on solely clinical signs. Cattle infected with BTV develop precipitating antibody detectable on an agar gel precipitation test (AGPT) which is not BTV serotype specific. Type-specific neutralizing antibodies can be titrated in a virus neutralization test using BHK21 cells in a microplate against each of the BTV types present or suspected present in the area. Some cross-reaction is seen on the AGPT with antibodies to EHD virus, however a group-specific competition ELISA using monoclonal antibody which does not cross-react with EHD antibody is now available. The viraemia associated with BTV infection can persist up to 120 days, in the presence of neutralizing antibodies. The virus is attached to the red blood cells and appears to be protected from the developing immune response. Intravenous inoculation of sonicated blood into eight to ten-day old embryonated chicken eggs is a very sensitive laboratory method of isolating virus from blood, whereas the inoculation of suspect material directly into sheep and the examination of sequential serum samples for evidence of seroconversion is the most sensitive test available. Virus can also be grown in the yolk sac of six-day old eggs kept between 33.5°C and 35°C, lamb kidney cells, hamster lung cells, BHK21 cells, some mosquito cell lines and following intracerebral inoculation of day old mice. Chick embryos which die from BTV infection have a characteristic haemorrhagic appearance.

Control

Bluetongue is a non-contagious disease and can only spread by the bite of infected *Culicoides* or the direct transfer of blood or semen from an infected to a susceptible animal. Bluetongue may be controlled by eliminating the vector or vaccinating susceptible animals against the serotypes prevalent in the area. Control of insects has usually been directed towards those insects which carry human disease, and experience gained in these programmes could undoubtedly be of value in BT control. However, there would be little economic justification for attempting to control *Culicoides* solely to prevent BT in cattle.

Cattle can be protected against BTV infection by vaccination (p. 1018) with live attenuated vaccine, although it would be extremely unlikely for it to be considered worthwhile. The practice of mixing together vaccines against each of the prevalent serotypes may result in the failure of one or more of the serotypes present in the vaccine to replicate (Jeggo, 1986). However, vaccination against one serotype, followed one month later with a second serotype can provide protection not only against the two serotypes in the vaccines, but can provide an heterologous protection against a third serotype (Jeggo, 1986). There would still be the difficulty of predicting the probable challenge BTV serotypes. The distribution of the serotypes of BTV tends to be dynamic, with some serotypes being present one year to be replaced the following year by other serotypes.

There is no evidence to indicate that BT can be transmitted during embryo transfer using standard techniques. BTV can be transmitted in the semen collected from viraemic bulls, but reports of a persistently infected, seronegative animal (Luedke *et al.*, 1982) have not been confirmed by further research.

Economic significance

The cost of BTV infection in a 1400 dairy cow herd in California, in terms of reduced fertility was \$23 000 over a 52-week study period (Osborn *et al.*, 1986). Of particular interest in this study was that the dairyman responsible for the herd was unaware of the passage of BTV through the herd and the associated increase in return to service of the affected animals. There is, therefore, the possibility that BT has a greater economic significance in cattle than previously thought and should not be considered solely in terms of isolated epizootics.

Animals and semen from BTV enzootic areas are subject to movement and export restriction, the costs of which are of greater significance than the direct effects of disease. Many of these restrictions have been formulated on unconfirmed experiments, but they reflect the cautious attitude of the veterinary authorities of importing countries.

(b) Enzootic bovine leukosis

C. Venables and M.H. Lucas

Two forms of bovine leukosis have been recognized, enzootic bovine leukosis (EBL), which occurs in adult cattle and is associated with bovine leukaemia virus (BLV) infection, and, less commonly worldwide, sporadic bovine leukosis (SBL), which affects calves and young cattle and is of unknown aetiology.

Enzootic bovine leukosis

Enzootic bovine leukosis was first described over 100 years ago in Europe. Clinical disease, in the form of multiple cases of lymphosarcoma, occurs most frequently in animals from three to eight years of age. Tumours may develop in peripheral lymph nodes, and are therefore easily detectable, or they may be confined

to internal organs, producing rather ill-defined signs. In some areas of the world appreciable economic losses occur through the tumorous form of the disease. Early workers recognized that the disease could spread slowly from known foci to adjoining regions, and because lymphosarcoma often occurred in familial aggregations it was interpreted as evidence that the disease was heritable. It has since been established that EBL is caused by bovine leukosis virus (BLV). This virus was first isolated from mitogen-stimulated, peripheral blood mononuclear cells by Miller *et al.* (1969) in the USA.

The virus

Bovine leukosis virus is an RNA virus belonging to the Retroviridae family. The family includes tumour and non-tumour inducing viruses of many species including man. The virus particle is spherical, 80–100 nm in diameter and enveloped with surface glycoprotein projections. The virus envelope glycoprotein, gp51, is believed to interact with a cell surface receptor, initiating receptor-mediated endocytosis, leading to entry into the host cell. Within the particle are three non-glycosylated protein structures, the matrix, the nucleocapsid and the core. Three enzymes, reverse transcriptase, integrase and a protease, are also packaged within the virion. The retrovirus genome is composed of two identical copies of positive sense, single-stranded RNA. During replication, viral RNA is converted to DNA by means of the enzyme reverse transcriptase. This enables retroviruses to integrate into the host DNA, establishing infection that persists for the life of the animal. Bovine leukosis virus is present in a subpopulation of circulating B-lymphocytes where its genetic information may be found integrated at multiple sites in the cellular DNA. Lymphocytes of BLV-induced tumours appear to be of the B-cell lineage. Tumour cells are monoclonal or oligoclonal for the site of BLV integration. No evidence has been observed so far for a common integration site for BLV provirus in different tumours.

BLV probably does not remain viable for long outside the host environment. It is readily inactivated by exposure to ultraviolet light, heating at 56°C for 30 minutes and pasteurization. The virus can, however, remain viable in blood stored at 4°C for at least two weeks.

Distribution

BLV is distributed worldwide, but with marked regional differences in prevalence. It is most common in North and South America, Australia and some regions of Africa. In Western Europe BLV has largely been eradicated in recent years, but it continues to be common in many areas of Eastern Europe. In addition to causing

significant animal health problems, EBL can also represent a major cause of economic loss.

Transmission

Virus is present in colostrum and milk, in tracheal and bronchial secretions and sometimes in nasal secretions and saliva of infected animals. Virus is also found in the cellular fraction of blood, but not in plasma or serum unless haemolysis has occurred. However, it has not been found in faeces or urine and is probably absent from the semen of most infected bulls. Very small numbers of infected blood cells are capable of transmitting BLV. As little as 0.1 µl of whole blood from an infected cow can be infectious when given intradermally to cattle.

Experimental transmission: Cattle can be infected by the intratracheal route, although not as reliably as by the subcutaneous route. Infection can be transmitted by instillation of infected lymphocytes into the nose and by aerosol exposure to cell-free BLV. A calf can be infected orally when newborn, but is probably resistant to infection by this route by three weeks of age. Adult cattle are not susceptible to infection by the oral route. Adult cows can be infected by the instillation of infected lymphocytes into the reproductive tract. Semen mixed with the inoculum may, however, have an inhibitory effect on transmission, and susceptibility of the genital tract of cows may decrease at the time of oestrus. The virus has been transmitted experimentally to sheep and cattle by rectal inoculation of whole blood from infected cattle.

Sheep can readily be infected experimentally by parenteral routes, but not consistently by the oral route. Between 10^3 and 10^6 lymphocytes from infected cattle, given intravenously, are sufficient to infect sheep. Tumours arise at a higher frequency and after a much shorter time than in cattle and may develop after 10 months to three years. As in cattle, various lymph nodes and visceral organs including heart, abomasum, uterus, kidney and urinary tract are commonly affected. Persistent lymphocytosis is not usual in sheep; once the number of circulating lymphocytes rises it invariably indicates the onset of tumour development. In contrast to cattle, contact transmission does not occur when infected sheep are kept in close contact with uninfected sheep. Goats inoculated with BLV orally and parenterally become infected and develop antibody but do not usually develop persistent lymphocytosis or lymphosarcoma. The incubation period in sheep and goats is variable, ranging from about two to 16 or more weeks. Experimental infection with BLV as indicated by persistent antibody production has been reported for chimpanzees, macaques, pigs, domestic rabbits, cats, dogs,

deer and rats. There is no evidence for the production of BLV antibodies following BLV inoculation in the mouse, chipmunk, ground squirrel, Japanese quail and chicken.

Natural transmission: Transmission of virus by contact is one of the most important means of spread of BLV in a herd. The rate of spread of virus is influenced by management and husbandry practices that determine the degree of contact between animals. Because the virus probably does not survive for long in the environment and because infectivity is associated with the cellular fraction of secretions it is therefore assumed that transmission takes place by direct exchange of infected lymphocytes in nasal, saliva and tracheobronchial fluids and possibly vaginal discharges. The role of milk in transmission under natural conditions does not appear to be very great. The presence of specific antibody in these secretions inhibits virus transmission, and also the susceptibility of the calf to oral infection decreases with age. Vertical transmission of the virus genome via the gametes does not occur. However, congenital transmission by the transplacental route occurs occasionally. Not all infected cows produce infected fetuses and individual cows may give birth to some infected and some uninfected calves. Fetuses infected *in utero* vary in their serological and virological status, and some may develop neoplastic lesions in the lymphatic tissue. Transmission by biting insects may be important in tropical and subtropical climates, but statistical evidence of seasonal trends is inconclusive.

Iatrogenic transmission is probably one of the main reasons for the high prevalence of infection in some herds. Infected blood transferred from one animal to another on a hypodermic needle can transmit bovine leukosis virus. The use of multidose syringes has been incriminated in virus spread, however there is no published evidence to associate intradermal tuberculin testing with an increased incidence of enzootic bovine leukosis. Dehorning and ear tattooing have been identified as possible methods of transmission. It has been suggested that the technique of rectal palpation to examine the reproductive tracts of cows could be a means of transmission if separate clean gloves were not used for each animal.

Transfer of embryos from BLV-infected cows into uninfected cows is not associated with transmission of virus. Virus has nevertheless been found in uterine flush fluid, but this may be due to contamination with blood cells. Virus has not been found in eggs or embryos from infected cattle. Ova, morulae and blastocysts have been exposed *in vitro* to BLV, but after washing no virus could be detected. Embryos similarly exposed to virus were washed and then transferred to uninfected cows, which did not subsequently develop antibodies to BLV.

It was concluded that it was safe to transfer embryos from infected cows providing that the embryos were washed before transfer. Virus transmission to dam or to progeny is not associated with the use of semen from infected bulls for artificial insemination (AI). Naturally occurring lymphosarcoma in sheep is rare. A retrovirus has been isolated from a diseased sheep and was found to be identical to BLV. Where BLV is found in sheep a bovine origin must be suspected. The virus has also been found in capybaras and water buffaloes. Human beings potentially exposed to BLV do not develop anti-BLV antibodies.

Signs

Following infection of an animal with BLV disease progression depends on genetic, environmental and unknown factors. Over 60 per cent of infected cattle are asymptomatic, however almost all develop detectable antibodies. Between 30 and 70 per cent of infected animals show persistent lymphocytosis, but less than 10 per cent develop lymphosarcoma. Persistent lymphocytosis is seen in 28–85 per cent of tumour cases. In BLV-infected cattle with leukaemia the increase in leukocyte count is due to an increase in B-lymphocytes. The percentage of B-lymphocytes in the blood can rise to 80 per cent, compared with normal values of 15–20 per cent. In clinically normal BLV-infected cattle without lymphocytosis there can still be an increase in B-lymphocytes to 40–50 per cent.

Clinical signs (Figs 43.1, 43.2) in animals that develop tumours depend on the particular organ or organs involved. One or more superficial lymph nodes may be enlarged and these can be felt as lumps beneath the skin, especially in the neck and hind flank areas. However, when the internal lymph nodes are the only ones affected diagnosis may be more difficult. Tumours can occur in the abomasum, right side of the heart, spine, uterus, lymph nodes, central nervous system (Fig. 43.3) and the retrobulbar aspect of the orbit. Clinical signs may include depression, indigestion, chronic bloat, displaced abomasum, lameness or paralysis. Abdominal tumours are sometimes detected by rectal palpation during pregnancy examination. Infection with BLV does not appear to be associated with lower milk production, impaired reproductive capacity in either sex, or with mastitis, lesser longevity or increased susceptibility to other diseases. Bovine leukosis virus does not appear to cause significant immunosuppression in the fetus or adult animal.

Diagnosis

Haematology: Herds with a high incidence of lymphosarcoma often contain many clinically normal cattle with persistent lymphocytosis. The development of

Fig. 43.1 A cow with enzootic bovine leukosis showing enlargement of the mammary lymph nodes. (Courtesy of Dr J. Miller, USDA National Animal Diseases Center, Ames, Iowa, USA and editors and publishers of *Modern Veterinary Production*.)

lymphosarcoma is often preceded by persistent lymphocytosis in the absence of any clinical signs. Haematological methods were the main diagnostic tools for a number of years and various 'keys' were developed relating lymphocyte counts and age, presenting maximal values above which an animal was declared to have persistent lymphocytosis. The percentage of B-lymphocytes in normal cattle varies from 18 to 28 per cent. In BLV-infected cattle with persistent lymphocytosis the percentage of B-lymphocytes can increase to as high as 70 per cent. In clinically normal BLV-infected cattle without lymphocytosis the B-lymphocytes are increased to 40–50 per cent.

Serology: The agar gel immunodiffusion test (AGIDT) can be used to detect specific antibody to viral antigens p15, p24 and gp51. The test for gp51 antibody is more

Fig. 43.2 Adult cow with enzootic bovine leukosis showing loss of condition, with wasting of lumbar muscle, brisket and submandibular swelling. (Courtesy of J. Miller, USA.)

Fig. 43.3 Brain from a cow with neoplasm between cerebellum and medulla. (Courtesy of J. Miller, USA.)

sensitive than the p15 and p24 tests or haematology for the detection of infected animals. The test is simple and practical and has been very widely used. The glycoprotein antigen employed in the test is prepared from the supernatant fluid of a cell line persistently infected with BLV.

Using BLV-infected cell monolayers, sera can also be tested for specific antibodies by indirect immunofluorescence or immunoperoxidase techniques. Various

neutralization tests have also been described, based on the ability of antibodies to inhibit the effects of BLV in cell cultures. These include a virus neutralization and syncytia inhibition tests. The complement fixation test using viral antigens from a cell line infected with BLV has been used, but seems to be less sensitive than the agar gel immunodiffusion test for antibodies to the gp antigen. A reverse transcriptase inhibition test, based on the fact that serum of some leukaemic cattle inhibits the activity of the reverse transcriptase of BLV, has been described. Radioimmunoassay is very sensitive but has the disadvantage that radiolabelled reagents and special equipment are required.

Enzyme-linked immunosorbent assay (ELISA) is the currently preferred method for the detection of BLV antibodies. The test can be used with milk or tissue fluids as well as serum samples. ELISA is rapid, sensitive and suited to the testing of large numbers of samples. Commercially available ELISA kits, sufficiently sensitive to permit the examination of pooled sera and milk for screening and surveillance, have formed the basis of successful EBL eradication programmes in several European countries.

Isolation and detection of virus: Bovine leukaemia virus particles can be demonstrated by electron microscopy in short-term cultures of lymphocytes from BLV-infected animals. Virus can also be recovered from infected cattle by cocultivation of peripheral blood mononuclear cells with a susceptible indicator cell, e.g. fetal lamb kidney cells. Several passages of the cultures may be required before syncytia can be observed in Giemsa-stained monolayers. Infected cells may be specifically visualized, often in advance of syncytium formation, using immunofluorescence or immunoperoxidase techniques. However, as with other retroviruses, neither electron microscopy nor virus isolation is a particularly sensitive method for demonstrating infection.

Nowadays, techniques including assaying for reverse transcriptase activity or demonstrating the presence of specific BLV nucleic acid sequences are frequently used. Polymerase chain reaction (PCR) assays, generally developed to detect BLV proviral DNA and offering exquisite sensitivity and specificity, are rapidly gaining the advantage over cultural methods in the research, diagnostic and surveillance fields.

Control

Control measures appropriate to any particular situation are largely dictated by local factors. Prevalence of infection is probably the primary consideration, but economics, husbandry practices, cattle movements

and politics may all be significant. Increasingly, driven by trade advantages, EU Member States and other European countries have set in place surveillance and eradication strategies. Many of these have been successful and the countries are now officially EBL-free. The types of actions used, linked with serological monitoring, to produce BLV-free herds are detailed below:

- BLV-positive animals are kept physically separated from BLV-negative animals. Check testing of negative animals is carried out at regular intervals.
- Calves born to negative cows are kept apart from infected animals.
- Calves born from infected cows are reared only on colostrum and milk from negative cows and are kept isolated. If serologically negative at seven months of age these calves join the negative herd.
- Replacement animals should be introduced from sources known to be virus-free, and should be serologically screened. Any originating from herds of unknown status should demonstrate two clear tests at six-month intervals before joining the main herd.
- Embryo transfer and AI are sometimes used as part of a control programme so that new genetic stock can be introduced with minimal risk of introducing BLV.

Where the prevalence of infected cattle has been low, as has been the case in most Western European countries now free of EBL, serological screening followed by slaughter of reactors has been successfully used. However, increased prevalence of infection rapidly makes this approach uneconomic.

Vaccination

Preliminary experiments using inactivated BLV, persistently infected cell lines or purified gp51 indicated that high antibody titres to gp51 could produce some short-term protection to BLV infection. However, no successful vaccine is currently available.

Public health

The structural similarities between BLV and the human T-cell leukaemia viruses, HTLV I and II, have led to speculation about the zoonotic potential of BLV. Serological reactions to BLV p24 in two small studies of people with these diseases and multiple sclerosis have also been reported, but current opinion indicates serological cross-reactions with HTLV proteins to be the cause. This is supported by repeated failure to demonstrate BLV proviral DNA in other studies on human

leukaemia patients and the failure of epidemiological studies to demonstrate a link between BLV and human disease.

Sporadic bovine leukosis

Lymphosarcoma may be found in young animals in the absence of BLV. Three distinct forms are recognized that are collectively classified as sporadic bovine leukosis (SBL):

- The *juvenile* form in calves under six months of age involves lymph nodes, liver, spleen and bone

marrow (Figs 43.4–43.7). During the early stages of disease, marked enlargement of superficial lymph nodes may be the only clinical sign. But as the disease progresses internal organs such as the heart and liver may also become affected, leading to the death of the animal.

- The *thymic* form is seen in animals 6–30-months old. There is massive tumour formation in the thymus and tumorous changes are also seen in the lymph nodes of the neck and thorax (Fig. 43.8). The condition is fatal.
- The *cutaneous* form is a rare condition occurring in animals 18 months to three years of age, in

Fig. 43.6 Same calf as in Fig. 43.5 showing gross distension of the head lymph nodes and the prefemoral lymph nodes. (Courtesy of J. Miller, USA.)

Fig. 43.7 Liver from a calf with sporadic bovine leukosis showing the surface and cut surface with focal neoplastic areas. (Courtesy of J. Miller, USA.)

which nodular lymphocytic neoplasia is seen in the skin. The first signs are urticaria-like nodules (1–2 cm in diameter) in the skin, especially round the neck, back and thighs (Fig. 43.9). These become encrusted with thick scabs, and alopecia and hyperkeratosis follow. Apparent recovery may take place over several weeks (Fig. 43.10). However, the remission is temporary, and lesions reappear together with general lymph node involvement, leading to the death of the animal.

The cause or causes of all forms of sporadic bovine leukosis remains unknown.

(c) Foot-and-mouth disease

R.P. Kitching

Foot-and-mouth disease (FMD) is a highly contagious disease of domesticated and wild ungulates characterized by vesicles in the mouth and on the feet. Hedgehogs and very rarely man may also become infected.

Aetiology

Foot-and-mouth disease is caused by infection with a virus of the genus *aphthovirus*, in the family *Picor-*

naviridae. There are seven antigenically distinct types of FMD virus, identified as types A, O, C, SAT (South African Territories) 1, SAT 2, SAT 3 and Asia 1. Within each of these seven types there are a large number of strains which form an antigenic spectrum, from closely related strains to strains so antigenically different as to almost justify the establishment of additional types. Attempts to classify the strains into subtypes within the types foundered on the ever increasing number of strains which fulfilled the criteria for creating a new subtype. New isolates of FMD virus are now referred to by the World Reference Laboratory for FMD by their type, country of origin, a sequential number relating to the number of isolates received in that year from

the same country and the final two numbers of the year in which they were received, e.g. O India 53/79, Asia 1 India 8/79. The cause of recent infections in Europe, South Africa, Asia, the Far East and the Middle East (Pan Asia strain) was first isolated from an outbreak of FMD in northern India in 1990 (Knowles *et al.*, 2001). Classical subtyping is now only of historical interest.

Aphthovirus has an icosahedral symmetry and a diameter of 24 nm. The outer capsid consists of 32 capsomeres and surrounds a single-stranded molecule of RNA of approximately 8000 bases and molecular weight 2.8×10^6 daltons. This RNA codes for a single large polyprotein which is cleaved into eight non-structural proteins (L, 2A, 2B, 2C, 3A, 3B, 3C and 3D) and the four structural proteins (VP1, VP2, VP3 and VP4), 60 copies of which make up the outer capsid. The RNA base sequence is extremely variable, which is reflected in variations in the amino acid sequence of the proteins for which it codes. The structural characteristics of the outer capsid proteins of the virus stimulate an immune response in the infected host animal. Thus mutations in the genome which change the structure of these proteins can reduce the ability of a vaccinated or previously infected animal to resist challenge with mutated virus.

Distribution

Foot-and-mouth disease is endemic throughout sub-Saharan Africa as far south as Tanzania, and also Ecuador, Bolivia, Peru, part of Brazil, Columbia and Venezuela in South America and most of the Middle and Far East. Canada, Central and North America, Australia, New Zealand, Japan, Argentina, Chile and South Korea are free of FMD. Most of Europe is also free of FMD, but suffers occasional outbreaks of disease in spite of strict import regulations. When disease occurs, however, it can be severe, as in the European and in particular the British outbreak commencing February 2001. From 1992 routine vaccination against FMD ceased in all countries of the European Union and has since also stopped in Eastern Europe, other than parts of Russia. In Southern Africa FMD virus is usually restricted to wildlife in the game parks, although it rarely escapes into cattle areas bordering the parks.

Types O and A of FMD virus are the most widespread, especially in S. America, the Middle East and Asia; types SAT 1, SAT 2 and SAT 3 are generally restricted to Africa, although they have periodically spread into the Middle East; Asia 1 occurs in the Far East and India, although it also has spread into the Middle East. Type C only rarely causes outbreaks in Asia and has all but disappeared (Kitching, 1998).

Epidemiology

Foot-and-mouth disease is an extremely contagious disease, with as few as ten infectious units being able to initiate disease in a bovine by the respiratory route. The virus can survive in dry faecal material for 14 days in summer, in slurry up to six months in winter, in urine for 39 days and on the soil between three days in summer and 28 days in winter. FMD virus is, however, very susceptible to inactivation by extremes of pH, i.e. below pH 6.0 and above pH 10.0. It is most stable between pH 7.2 and 7.6. Within this range at 4°C the virus can survive in suitable media up to a year but, as the temperature is increased, its survival time is reduced to eight to ten weeks at 22°C, ten days at 37°C and to less than 30 minutes at 56°C. The survival of airborne virus is optimal when the relative humidity is above 60 per cent. Natural ultraviolet light in sunlight has little direct effect on the FMD virus.

Like many diseases, FMD is most commonly spread by the movement of infected animals; of particular significance are sheep, goats and wild ungulates, because disease in them can be mild, and pigs because of the amounts of virus they can excrete. An infected pig excretes up to 400 million infectious units per day, 3000 times more than an infected bovine, sheep or goat. In infected cattle, milk products and semen may contain FMD virus up to four days before the appearance of clinical signs and can also be responsible for the spread of disease. Pigs can carry virus for ten days before disease is manifested. Lorries, fomites and stockmen may also be contaminated with virus from infected carcasses, although the reduced pH of the carcase following *rigor mortis* is sufficient to inactivate the virus in the meat.

The possibility of windborne spread of FMD virus has been given considerable significance, particularly in temperate countries where the climate is conducive to the survival of the virus. There is evidence to indicate that FMD virus has been carried up to 250 km over the sea and up to 60 km over land. The spread of disease by the wind is dependent on the amount of virus generated by infected animals, the weather conditions, the topography over which it is carried and the susceptibility of the animals contacting the airborne virus. A plume of virus will be subjected to vertical and horizontal dispersion, which is related to wind speed and turbulence, the vertical air temperature gradient and ground topography; the survival of the airborne virus will depend on relative humidity. Cattle have a large respiratory tidal volume compared with other FMD susceptible stock and can be infected following inhalation of relatively low quantities of virus and thus are most at danger to infection from the airborne virus. Windborne spread of FMD virus is believed to have occurred in 1981 when

Fig. 43.11 A recently ruptured vesicle in the mouth of a cow with foot-and-mouth disease, showing epithelial separation.

infected pigs in Brittany, France, spread disease to cattle in the Isle of Wight, England, over a distance of 250 km, predominantly over sea. Computer models now exist which can predict the likely windborne spread of virus from an infected herd. The maximum daily excretion of virus can be calculated by establishing the number of clinically infected animals and the species infected, and estimating the duration and quantity of airborne virus excreted. The local meteorological office provides information about wind speed and direction, relative humidity and precipitation. When combined with local topographical information and local distribution of livestock holdings, the computer model can give an indication of which herds are most at risk from secondary windborne spread of FMD. Manpower resources for surveillance activity can then be concentrated on the herds adjudged to be at greatest risk.

In tracing the movement of FMD between countries, and identifying specific strains of FMD virus, molecular epidemiology has proved very valuable (Samuel *et al.*, 1997). By precisely characterizing the RNA of an outbreak strain by its nucleotide sequence, it is possible to show its relationship to strains previously isolated in other countries or in use in vaccines. For instance, in Europe between 1970 and 1990 there were a number of FMD outbreaks attributed to the use of improperly inactivated vaccines and escape of virus from establishments producing vaccine. In several instances biochemical analysis of the outbreak strains showed a clear identity with a vaccine strain in contemporary use.

Monoclonal antibodies, which specifically identify some of the individual antigenic determinants on the FMD virus, are becoming important in FMD virus strain characterization. These determinants may change as the virus mutates through the course of an outbreak.

Cattle recovered from FMD and vaccinated cattle in contact with FMD virus may retain virus in their pharyngeal region for many months. This is the carrier state. Vaccinated cattle which have had contact with disease may also develop a pharyngeal infection without showing any clinical signs. The significance of these carrier animals is not clear but, although it has proven difficult to show transmission from a carrier to a susceptible animal under experimental conditions, there is considerable circumstantial evidence supported by sequencing of carrier and outbreak strains suggesting that carriers may have initiated outbreaks.

Transmission and pathogenesis (Figs 43.11–43.13)

Cattle are most susceptible to FMD by inoculation of the virus intradermally into the tongue and this is a

Fig. 43.13 Vesicular lesions of the interdigital skin of the foot in foot-and-mouth disease. (Courtesy of A.I. Donaldson.)

commonly used method of challenging cattle during vaccine trials. However, natural infection is most frequently by inhalation of droplets containing FMD virus or by ingestion of FMD virus contaminated material. One infectious unit of FMD virus is sufficient to infect a bovine by intradermolingual inoculation, while between 10 and 100 infectious units can initiate disease in a bovine following inhalation. Many thousand infectious units may be required to infect an adult bovine by ingestion, although less will be required by a calf following insufflation of infected milk.

The primary site of replication of inhaled virus is in the pharynx and lymphoid tissue of the upper respiratory tract. FMD virus then enters the blood stream, is distributed around the body and following secondary replication in other glandular tissues appears in the body fluids such as milk, urine, respiratory secretions and semen, before the appearance of frank clinical signs of FMD. However, it is during the early vesicular stage of the disease that the majority of virus is excreted into the environment. Milk may contain $\log_{10}6.7$ infectious doses_{50/ml}, semen $\log_{10}6.2$ infectious doses_{50/ml}, urine $\log_{10}4.9$ infectious doses_{50/ml} and faeces $\log_{10}5.0$ infectious doses_{50/g}.

An infected bovine can excrete up to $\log_{10}5.1$ infectious doses_{50/day} by the respiratory route and can provide a potent source of FMD virus to the remaining uninfected cattle in the herd. This may be sufficient to overcome a waning vaccinal immunity.

The incubation period for FMD can be up to 14 days with low infecting doses and with strains of virus of low virulence. However, as the quantity of virus in the environment of an FMD outbreak increases, the incubation period in cattle decreases. For susceptible cattle in contact with an infected animal it is frequently between two and four days.

Clinical signs

The incubation period is between two and 14 days, depending on the route of infection, the dose, the strain of virus and the susceptibility of the host. Following an initial pyrexia in the region of 40°C (104°F), lasting one or two days, a variable number of vesicles develop on the tongue, hard palate, dental pad, lips, muzzle, coronary band and interdigital space. Vesicles may also be seen on the teats, particularly of lactating cows. Young calves may die before the development of vesicles because of a predilection by the virus to invade and destroy the cells of the developing heart muscle.

The vesicles in the mouth quickly rupture, usually within one to two days of their formation, leaving a shallow ulcer surrounded by shreds of epithelium. The vesicles on the tongue frequently coalesce and a large proportion of the dorsal epithelium of the tongue may be displaced. The vesicles on the feet may remain for two to three days before rupturing, depending on the terrain or floor surface of the cattle accommodation. Healing of the mouth lesions is usually rapid; the ulcers fill with fibrin and by day 10 after vesicle formation they appear as areas of pink fibrous tissue, still, however, without normal tongue papillae. Healing of the lesions on the feet is more protracted and the ulcers are susceptible to secondary bacterial infection. The horn of the heels may become under-run, as a consequence of both the initial vesicle and secondary bacterial infection.

Acutely infected cattle salivate profusely and develop a nasal discharge, at first mucoid and then mucopurulent, which covers the muzzle. They stamp their feet as they try to relieve the pressure on first one foot and then another. They may prefer to lie down and resist attempts to raise them. Lactating cattle with teat lesions are difficult to milk and the lesions frequently become infected, predisposing to secondary mastitis. Affected cattle quickly lose condition; the drop in milk yield can be dramatic and will not be recovered during the remaining lactation. Some animals fail ever to completely regain their previous condition, due to the

development of lesions in the thyroid gland – ‘hairy panthers’.

An outbreak of FMD can be economically devastating in an intensively farmed region. However, in the extensive husbandry systems of South America and Africa, where expectations of cattle productivity are low, FMD may seem insignificant compared with the prevalent clostridial, haemoparasitic and deficiency diseases. This attitude frustrates programmes to completely control FMD and attempts to introduce intensive farming or a dairy industry.

Pathology

The epithelial cells of the stratum spinosum of the skin undergo ballooning degeneration. As the cells disrupt and oedema fluid accumulates, vesicles develop which coalesce to form the aphthae and bullae that characterize FMD. The cells of the squamous epithelium of the rumen, reticulum and omasum may also become involved. In young animals the virus invades the cells of the myocardium and macroscopic grey lesions may be seen particularly in the wall of the left ventricle, giving it a striped appearance (tiger heart). Cells of the skeletal muscles may also undergo hyaline degeneration.

Diagnosis

Initial diagnosis is usually on the basis of clinical signs, with or without a history of contact between the herd and an infected animal or reports of FMD in the vicinity. In a fully susceptible herd the clinical signs are frequently severe and pathognomonic. However, in endemic regions in herds which have a partial natural or vaccinal immunity, clinical signs may be mild and may be missed. All vesicular lesions in cattle should be investigated as potential FMD (OIE, 1996).

The success of the laboratory confirmation of a presumptive diagnosis of vesicular virus infection depends on the submission of adequate material, sent under suitable conditions. A minimum of 2 square cm of epithelium from a ruptured vesicle in a 50/50 mixture of glycerine and 0.04 molar buffered phosphate (pH 7.4–7.6) should be sent to a laboratory designated for handling FMD virus and equipped with the reagents required to type a positive sample.

Diagnosis of FMD is usually controlled by a government department. Where laboratory diagnosis cannot be adequately carried out within a country, samples should be sent by the relevant government department to the regional FMD laboratory or to the World Reference Laboratory (WRL) for Foot-and-Mouth Disease, Institute for Animal Health, Pirbright Laboratory, Ash Road, Pirbright, Woking, Surrey, GU24 ONF, UK. Even

when diagnosis is performed within a country, it is recommended that duplicate samples also be sent to the WRL or regional laboratory for confirmation of diagnosis and strain identification. Details of the method of submission of samples are described by Kitching and Donaldson (1987), although new regulations now also apply to sending pathological specimens by air.

Foot-and-mouth disease virus is very sensitive to pH values away from neutrality and is, for example, quickly inactivated below pH 6. Virus can also be isolated with heparin from vesicular fluid or from whole blood collected from the viraemic animal (up to four days after the initial appearance of vesicles). Although high titres of virus can be recovered from milk and internal body organs such as lymph nodes and muscle, these specimens should only be sent in addition to, and not instead of, epithelium samples. Negative tests on these tissues could be misleading and cause a false sense of security.

On receipt at the WRL, epithelial samples are prepared as 10 per cent suspensions for the enzyme linked immuno-sorbent assay (ELISA). This test identifies virus antigen within the sample and can distinguish between the seven FMD virus types; it has now replaced the classical complement fixation test for FMD diagnosis. Results from this test are available within three hours of arrival. At the same time as the ELISA test is being prepared, samples of the epithelial suspension are inoculated onto primary bovine thyroid cells and pig kidney cells (IB-RS-2 cells). If a clear positive is not obtained from the ELISA test, virus growth on either or both of these two cell systems would provide sufficient antigen after 24 or 48 hours for a second ELISA test. In the absence of virus growth on thyroid or pig kidney cells after 48 hours (first passage) the cells are inoculated onto fresh thyroid and pig kidney cells (second passage). Samples are considered negative following negative ELISA and failure of virus growth after 48 hours on second tissue culture passage, i.e. after a minimum of 96 hours following arrival at the WRL. The polymerase chain reaction (PCR) is also available for detection of FMD virus genome in diagnostic samples.

In countries which use vaccination to control FMD, there is a requirement to relate the outbreak strain to existing vaccine strains. This can be shown using a two-way microneutralization test. Mixtures of field virus and antisera to a vaccine virus, usually prepared in guinea pigs, are incubated at 37°C for one hour and then inoculated with BHK-21 cells into the wells of a microtitre plate. The plates are placed in a 37°C incubator and examined daily for evidence of a virus-induced cytopathic effect in the cells. The titre of serum which neutralizes 100 tissue culture infective dose (TCID)₅₀ of virus is calculated and compared with the

titre of the same serum which neutralizes 100 TCID₅₀ of the vaccine virus. The ratio of titre of serum against field virus to titre of serum against vaccine virus is the r_1 value, and gives an indication of the antigenic relationship between the field and vaccine strains and therefore the probable usefulness of that vaccine in controlling the outbreak of FMD.

A similar r_1 value can be derived using the ELISA (Kitching *et al.*, 1988).

The serum antibody titre against FMD virus of cattle vaccinated against FMD can also be measured using the virus neutralization (VN) or ELISA test. Immunity in cattle to FMD can be correlated with the level of serum antibody at 30 days after primary vaccination, although the relationship is not absolute, being dependent on the challenge dose of virus and the closeness of its antigenic relatedness to the vaccine strain. The VN and ELISA are FMD virus type-specific, so that when used to determine whether an animal has had contact with FMD the tests must be performed separately against each of the FMD serotypes with which the animal may have had contact. In some parts of the world, e.g. Africa, this could be any one of up to six different FMD serotypes. Such testing can be time-consuming, expensive and present results difficult to interpret. A non-type-specific screening test has been developed which estimates the presence of antibody to the non-structural proteins of FMD virus; these are formed in an infected animal as the virus replicates and the non-structural proteins are expressed.

The antigenic characteristics of these proteins are conserved between serotypes. Traditionally the 3D non-structural protein or virus infection associated antigen (VIA antigen or polymerase) was used, but better results, particularly in distinguishing between vaccinated and recovered animals, have been obtained by detecting antibody to the polyprotein 3ABC (Mackay *et al.*, 1998) together with antibody to the 2C protein (Lubroth & Brown, 1995). Both can be produced as pure reagents for an ELISA test by expression in a plasmid vector system. Because animals vaccinated with the dead FMD vaccine produce relatively little antibody to the non-structural proteins (some may be produced against the 3D protein), the tests will also distinguish animals which have been vaccinated – these are positives only for the antibodies to the major structural proteins (see above) – from recovered animals which have antibodies to both structural and non-structural proteins. This would therefore also identify potential virus carrier animals. The problem still remains of how to detect the vaccinated animal which has had contact with live virus and thus become a carrier, but because of its protected status therefore remains negative for antibodies to the non-structural proteins.

Control

The control of FMD depends on prevention of the introduction of virus, prevention of infection of stock and the prevention of spread of virus from infected animals. How this is achieved by individual countries depends on a variety of economic and practical considerations.

Exotic FMD virus may enter an area or country in infected animals and this can include certain zoo animals. Acutely infected animals are usually recognized, but sheep and goats frequently only develop very mild clinical signs. Vaccinated cattle can also develop only local lesions of FMD, particularly in the mouth, and may carry infection if imported to FMD-free areas. The importance of cattle and buffalo that are carrying FMD virus in the pharynx is not proven, although there is ample field evidence of FMD having been introduced with such carrier animals. In order to prevent the introduction of FMD in this manner, FMD-free countries may refuse entry of any ungulate from FMD endemic areas or may insist that any ungulate entering the country has no serum antibody to FMD virus and that oesophageal-pharyngeal scrapings taken by probang are negative for the presence of FMD virus. Any animal vaccinated against FMD is, therefore, prohibited.

FMD virus could also enter in the carcase or products of an animal infected before slaughter. In skeletal muscle the virus is inactivated as the pH of the meat falls as the carcase ‘sets’, but virus in the bone and lymph glands is not subject to this increased acidity and will escape inactivation. Regulations in FMD-free countries require that meat imported from endemic areas has had the bones and lymph glands removed and may also impose additional requirements such as regular vaccination and certification of the absence of FMD from the farm of origin of the meat, the slaughter house and the surrounding areas. If infected meat should still enter in spite of these restrictions, an additional safeguard is the prohibition of feeding uncooked meat or other swill to pigs. There are many examples of pigs being the first animals to be infected in an FMD outbreak. The Office International des Epizooties (OIE) provides guidelines for trade between countries of different FMD status (OIE, 2001).

The early detection of an FMD outbreak requires the existence of an efficient veterinary service and a rapid diagnostic capability. The World Reference Laboratory, Pirbright, offers a worldwide diagnostic service, although by the time samples are received from abroad an FMD outbreak could be well established. Nevertheless, the service can provide valuable additional support and identify the most suitable vaccine for use to control an outbreak.

Following suspicion of an FMD outbreak the movement of all infected animals must be prevented and local markets and abattoirs closed. The slaughter of all cattle, sheep, goats and pigs on infected premises is practised by countries that do not routinely vaccinate against FMD, and by many countries that do vaccinate, as this will eliminate the source of virus emission and prevent the establishment of a nucleus of potential carrier animals. Cattle, sheep and goats on surrounding farms that have already been vaccinated should be revaccinated with a vaccine antigenically related to the outbreak strain. Pigs are generally also included in emergency vaccination programmes. All previous movement of animals, animal products and other potentially infected material up to 21 days prior to the estimated appearance of the first clinically infected animals must be investigated. This will not only indicate which other farms may develop secondary outbreaks of FMD, but may also identify the source of the infection. Subsequent movement on and off the infected premises must then be kept to a minimum and adequate facilities for cleaning and disinfection provided. Such controllable precautions will identify and considerably reduce the chance of secondary spread. Windborne spread of FMD virus prior to the slaughter of the infected animals is, however, uncontrollable. Numerical models developed to predict this windborne spread can be used to indicate those farms most at risk and have proved their value in helping to control outbreaks of FMD in Europe.

Vaccination against FMD is an effective method for protecting livestock against disease (p. 1016). Only inactivated vaccines are used and they are assessed by their antigen content and the results of potency trials, ideally carried out in fully susceptible cattle (OIE, 2000). An FMD vaccine is most effective against infection with the homologous strain from which the vaccine was prepared. However, a good vaccine must also protect against closely related strains of FMD virus, although its effectiveness will be reduced the more the antigenic characteristics of the outbreak strain differ from the vaccine strain. It is therefore necessary to identify the types and strains of FMD virus that pose the most significant threat. Nowhere has it been necessary to use more than a quadrivalent vaccine, although there are frequent situations when it is necessary to include more than one strain of the same serotype. In addition, the characteristic variability of FMD virus has rendered some vaccine strains no longer effective, and new ones must be introduced.

Maternal antibody can interfere with the development of active immunity in young animals. It is therefore recommended that if calves of immune dams are vaccinated in their first three months of life they should be vaccinated twice more at four and five and possibly

again at six months of age. Subsequently cattle should be vaccinated twice yearly, or even three times yearly in areas where FMD is prevalent.

The method used by different countries to control FMD is dependent on a number of factors. Countries free of FMD and protected on their borders by natural barriers such as desert, sea or mountain ranges can maintain their status by strict import controls and can avoid the recurring cost of vaccination or the possibility of initiating an outbreak through the use of improperly inactivated vaccine or escape of FMD virus from a vaccine production plant. In addition, should FMD virus enter a non-vaccinating country it can usually be immediately identified clinically because of the complete susceptibility of the livestock, whereas FMD virus has been known to circulate in countries that do vaccinate without the knowledge of the veterinary authorities. Finally, countries free of FMD which do not vaccinate have a privileged international trading status. However, should FMD virus enter, there is always the possibility of rapid uncontrollable spread, with severe consequences.

Many countries have no choice but to control FMD by mass vaccination. The movement of nomadic people with their animals, and of wild animals across international borders in Africa, the Middle and Far East, makes disease regulations impossible to enforce. The airborne spread of FMD virus cannot be controlled by legislation. Barrier vaccination can reduce the danger of FMD entering a country or area and has been successful in preventing exotic strains of FMD entering Europe through Turkey and Greece, and in allowing South Africa and Zimbabwe to restrict vaccination to their borders and around game reserves. Countries which do not vaccinate or vaccinate against two or three strains may use emergency vaccination to control an outbreak due to a new strain of FMD by slaughtering affected animals and ring vaccinating around the infected area with a monovalent vaccine specifically against the exotic strain.

Economic importance

The economic importance of FMD is hard to quantify accurately. The direct costs of vaccination, slaughter of infected animals, movement restrictions and closure of markets can be measured. The indirect local and national costs, e.g. loss of potential export markets, may be the most significant and yet most uncertain cost.

Assuming that a country wishes to prevent FMD remaining or becoming endemic, two options are available. Either all cattle (and possibly sheep, goats and pigs) are routinely vaccinated or no vaccination is carried out and outbreaks are controlled by slaughter as they occur. Which policy is the most economic can

be assessed by critical point analysis or by estimating the critical point at which the cost of one policy equals the cost of the other policy. Costs that must be considered are the cost of vaccine and its administration or its storage as a strategic reserve. If it is also assumed that neither policy will eliminate the possibility of FMD outbreaks, the cost of controlling an outbreak must be assessed and multiplied by the estimated total number of outbreaks.

The cost of an FMD outbreak must include the cost of controlling the outbreak, including ring vaccination, the cost of slaughtered animals, the loss of production and the interruption of domestic and international trade. The international trading status of a country that vaccinates already will be considerably less affected than that of a country that does not vaccinate. Similarly, the status of a country that does not use routine FMD vaccine but vaccinates in order to control an FMD outbreak may be affected by lengthy trade restrictions with other non-vaccinating countries following the cessation of vaccination (OIE, 2001).

The difficulty in assessing these uncertain costs may be illustrated by an analysis of the cost of annual vaccination (policy A) and the cost of a stamping out with ring vaccination (policy B) carried out in the Federal Republic of Germany (Lorenz, 1987). The average annual cost of policy A was estimated to be between 52 and 286 million DM, while the average annual cost of policy B was between 2.5 and 321 or more million DM. The wide range reflected the number of assumed FMD outbreaks that could occur under each regime. The estimates considered most likely, however, were between 183 and 227 million DM for policy A and between 47 and 61 million DM for policy B.

Any scenario for assessing the cost of FMD control must ultimately assume the existence of an efficient veterinary service, capable of diagnosing the disease and with facilities available to control it. Without this infrastructure any, even approximate, estimate of the economic significance of FMD becomes academic.

(d) Rinderpest

by E.C. Anderson

The State Veterinary Service in the UK was brought into being specifically to deal with rinderpest or cattle plague. In the eighteenth and nineteenth century devastating outbreaks of rinderpest were responsible for millions of deaths in cattle in Europe. By 1930, with the exception of parts of Turkey, Europe was free of the disease and since that time only small outbreaks have

occurred. Rinderpest has however continued to persist in Asia and the Indian subcontinent and is still present in Pakistan, India, Bangladesh and Nepal. Occasional outbreaks occur in the Near and Middle East. Rinderpest was introduced into Africa in the early 1800s and was responsible for a massive pandemic between 1889 and 1897. Africa has not been free of rinderpest since, although it has largely been confined to countries north of the Tropic of Capricorn. An international vaccination programme carried out between 1962 and 1975 almost eradicated the disease (Scott, 1985). A second international vaccination programme, commencing in the mid-1980s, has reduced the incidence in West Africa to a level where eradication may be achieved (Rossiter, 1996). Extensive outbreaks have, however, continued in eastern Africa where vaccination coverage has been hampered by civil unrest. The disease is still endemic in the horn of Africa and southern Sudan.

Aetiology

The causal agent of rinderpest is a paramyxovirus of the genus morbillivirus. The other members of the morbillivirus genus are measles, canine distemper, phocine distemper (Osterhaus & Vedder 1988; Mahy *et al.*, 1988; Kennedy *et al.*, 1988) and peste des petit ruminants (PPR) to which rinderpest virus is antigenically related. Recently morbilliviruses have been isolated from diseased marine mammals (Barrett *et al.*, 1993) and a morbillivirus-like agent caused fatal respiratory disease in man and horses in Australia. The morbilliviruses are pleomorphic, enveloped, helical particles of between 150–300 nm diameter and contain a non-segmented negative-strand RNA genome. This codes for six structural proteins and possibly one non-structural protein. The virus structural proteins comprise the nucleocapsid protein (N), which surrounds the genomic RNA, a large polymerase protein (L) and a small polymerase-associated protein (P), a matrix protein (M) associated with the virus envelope and two envelope glycoproteins, the haemagglutinin (H) and fusion protein (F). The P gene shows significant homology between members of the morbillivirus group (Barrett & Underwood, 1985).

There is only one serotype of rinderpest virus and rinderpest virus can be distinguished from PPR virus in reciprocal cross-neutralization tests. Alternatively, the two viruses may be distinguished by comparing their protein patterns in polyacrylamide gels as the N proteins have been shown to have markedly different molecular weights (Diallo *et al.*, 1987). They can also be distinguished by nucleic acid hybridization using cDNA probes to the H gene (Diallo *et al.*, 1989) and by the reverse transcription-polymerase chain reaction (RT-PCR) (Forsyth & Barrett, 1995). It is now also possible to distinguish the two diseases in recovered animals by

means of a competitive enzyme-linked immunosorbent assay (ELISA) based on the use of monoclonal antibodies (Mabs) to the haemagglutinin of each virus (Anderson *et al.*, 1991).

The virus is sensitive to lipid solvents, is relatively heat sensitive and is unstable at low pH. It is also labile when exposed to light and survives best at low or high relative humidities but is rapidly destroyed when the relative humidity is between 40–60 per cent. Infectivity is lost when it is suspended in glycerol or water but it is stable in 0.86 per cent sodium chloride at low temperatures with the loss in infectivity rising exponentially with temperature. The use of molar concentrations of magnesium sulphate improves the thermostability of the virus.

Species susceptible

Rinderpest is potentially infective for all members of the order Artiodactyla (Scott, 1964) but in particular infects members of the families Bovidae, Suidae and Cervidae (Plowright, 1968). Of these cattle, water buffalo, Cape buffalo (*Syncerus caffer*) and yak are most susceptible. The disease occurs in sheep and goats and, in India, also in pigs. It also affects camels. It has been recorded in a large number of wildlife species in Africa including eland (*Taurotragus oryx*), lesser kudu (*Tragelaphus imberis*), giraffe (*Giraffa camelopardalis*) and warthog (*Phacochoerus aethiopicus*). In 1994 the disease caused significant mortality in buffalo, lesser kudu and eland in the Tsavo National Park in Kenya (Barrett *et al.*, 1998).

Transmission

Rinderpest is spread by direct contact between infected and susceptible animals, by the inhalation of virus-containing aerosols or by ingestion of infected secretions and excretions. On rare occasions it has spread through indirect contact with contaminated fodder and water. Pigs have been infected through eating meat from contaminated carcasses. Different strains of virus vary in their invasiveness and infectivity for different species.

Pathogenesis

Infection is through the upper respiratory tract with primary replication of the virus in the tonsils and local lymph nodes (Plowright, 1968). The virus is disseminated in the blood, where it is closely associated with the mononuclear leucocytes, to all lymphoid tissue and the mucosae of the alimentary and respiratory tracts. The incubation period lasts from two to nine days and viraemia can be detected one to two days before the onset of pyrexia. The prodromal phase usually lasts

from two to five days. The virus is shed in all secretions and excretions, the peak of virus production being during the prodromal fever but continuing after the appearance of erosive lesions. Virus levels fall as antibody begins to be produced with viraemia ceasing before the disappearance of the virus from the tissues, about 14 days after the onset of fever. Viraemia lasts on the average about six days but there is considerable variation between strains of virus. Viraemia can occur following exposure to some strains that lasts four to six days without the development of lesions.

Clinical signs

The clinical signs of rinderpest in cattle and other natural hosts are essentially the same but show wide variations in severity depending on the strain involved, and the resistance of the animal, natural or acquired.

The disease may be hyperacute, acute, subacute or chronic (Plowright, 1968). The typical acute disease can be divided into four phases: incubation, prodromal, mucosal and convalescent.

Incubation phase

Prodromal phase: This is characterized by a sudden onset in fever reaching a peak on the second or third day after onset. It is accompanied by depression or restlessness, loss in appetite and a fall in milk yield in cows. The visible mucous membranes are congested, the muzzle is dry and there may be the beginning of a serous discharge from the eyes and nostrils. There is tachycardia and accelerated respirations, ruminal stasis and constipation. This phase lasts about three days with lesions appearing between two to five days following the onset of pyrexia.

Mucosal phase: The first lesions comprise small foci of necrosis, superficial erosion and capillary haemorrhage in the mucosae of the mouth cavity, which are particularly noticeable on the lower gum and tips of the buccal papillae. They extend to involve the lips, upper gum, hard palate and ventral surface of the tongue. Similar lesions occur in the nasal, vulval and preputial mucosae where they may occur earlier than in the oral cavity. The lesions extend and fuse to produce extensive areas of necrotic erosion with a characteristic fetid smell. There may be excessive salivation and at this stage the lacrimal and nasal secretions become profuse and purulent.

Animals at this stage of the disease are very depressed and respirations are laboured, but pneumonia is rare. Diarrhoea appears usually between four and seven days of pyrexia and one to two days after the

appearance of lesions. It is at first watery but later dysentery develops and it may contain pieces of intestinal mucosa. Dehydration is rapid resulting in weakness, prostration and death between six and twelve days after the onset of pyrexia. The mortality rate is over 90 per cent when susceptible animals are infected with virulent strains.

Mild forms of the disease in partially immune animals or following infection with less virulent strains give rise to reduced general signs and less extensive mucosal lesions. However, these may be completely absent with the only sign a transient diarrhoea. Even this may be absent, and some strains of virus result in a complete spectrum of signs from the classical acute febrile disease with extensive lesions and eventual death to a form in which there is fever but no lesions although antigen can be detected in lacrimal secretions (Anderson *et al.*, 1990; Forsyth *et al.*, 2003).

Convalescent phase: Visible mouth lesions may heal within as little as two to three days beginning from the third to the fifth day after their appearance. Diarrhoea may persist for longer. Complete recovery from the acute form takes about four weeks depending on the environment and plane of nutrition.

Pathology

The gross pathology has been described by Maurer *et al.* (1956). The mucosae of the upper alimentary and respiratory tract are eroded and necrotic often being coated with a mucopurulent exudate. Erosions, ulcers and oedema occur in the abomasum, which may also be congested. Peyer's patches in the small intestine are haemorrhagic, oedematous and necrotic. The mucosal surface of the caecum, colon and rectum frequently has characteristic haemorrhagic stripes due to the congestion of the capillaries. Erosion and ulcers also occur in the urogenital tract. The virus has a predilection for lymphoid tissues in which there is extensive necrosis of the lymphocytes of the germinal centres, and the appearance of multinucleated giant cells about eight days after infection. The appearance of cytoplasmic and intranuclear inclusions has been described (Plowright, 1968). The stratified squamous epithelium, particularly of the upper part of the alimentary tract shows syncytium formation and degenerative changes, which are followed by necrosis and detachment to form erosions and ulcers.

Diagnosis

Laboratory confirmation of rinderpest is based on the detection of specific antigens and the isolation of the

virus. Retrospective diagnosis is obtained by the detection of specific antibody (Scott *et al.*, 1986).

Antigen detection: Virus is present in the secretions and excretions within two days of the onset of fever. Specific antigen can be detected from this time particularly in the lacrimal secretions but also later in swabs or material from lesions in the mouth, vagina or prepuce. Lymph node biopsies may also be taken.

Early diagnosis is desirable and a rapid chromatographic strip test based on Mab-labelled latex particles is now available for pen-side diagnosis (Buning *et al.*, 1999). The most sensitive method is, however, RT-PCR and this can also be used with lacrimal secretions as well as material from mouth lesions and lymph node biopsies. This method also has the advantage of generating DNA fragments whose sequence may help in defining the origin of the outbreak or differentiating the disease from PPR (Forsyth & Barrett, 1995). Specific antigen can also be detected by the less sensitive immunodiffusion or counterimmunoelectrophoresis (CIEOP) tests in field laboratories. The ELISA is a very sensitive test used in suitably equipped laboratories and is preferable to the complement fixation test (Libeau *et al.*, 1994). Histochemical methods using fluorescein or enzyme-conjugated antiserum may be used on smears, biopsy material or tissue sections (Scott *et al.*, 1986; Saliki *et al.*, 1994).

Virus isolation: Virus may be isolated in tissue cultures of primary or secondary calf or sheep kidney cells or Vero cells. It may be isolated from swabs of lesions or secretions, from the leucocyte fraction of blood collected in EDTA or from lymphoid tissue collected at post mortem. Specimens should be transported on ice but glycerol should not be used as a transport medium, as it inactivates the virus.

Antibody detection: The detection of a rising antibody titre in paired serum samples or in disease surveys may be done using the virus neutralization test. This is suitable for small numbers of diagnostic samples but for disease surveillance requiring the screening of large numbers of samples the ELISA is the test of choice. Other tests that are used include indirect immunodiffusion and CIEOP.

Differential diagnosis

In cattle the one disease that cannot be distinguished from rinderpest without laboratory tests is bovine virus diarrhoea. In sheep and goats peste des petits ruminants is identical to rinderpest. Otherwise there are few conditions that should be confused with the acute form of rinderpest. The mild forms in particular, where

diarrhoea is the only clinical sign, are indistinguishable from other enteric conditions.

Control

Rinderpest spreads slowly in endemic countries where it affects mainly immature animals. In these countries control is by vaccination annually of all immatures. In such countries attempting eradication, vaccination of the entire cattle population, as well as sheep and goats in those countries where the disease occurs in these species, for three to five years is practised.

In high risk countries adjacent to endemic regions or those importing livestock from endemic countries quarantine and vaccination are combined (see p. 1013).

All rinderpest vaccines in use are live attenuated vaccines. Most countries use a tissue culture vaccine (Plowright, 1968). New lyophilization techniques have improved the thermostability of these vaccines (House & Mariner, 1995). Goat adapted vaccine and lapinized vaccine are still used in some countries.

(e) Vesicular stomatitis

R.P. Kitching

Vesicular stomatitis (VS) is a vesicular disease of cattle, horses and pigs which can also infect a large range of wild animal species (see p. 366). The virus belongs to the genus vesiculovirus, within the family Rhabdoviridae.

There are two serologically distinct types of VS virus (VSV): New Jersey (NJ) and Indiana (IND). The IND type can be further subdivided into Indiana 1 (Indiana strain), Indiana 2 (Cocal and Argentina strains) and Indiana 3 (Alagoas and Brazil strains). In common with all other rhabdoviruses VSV is a single-stranded RNA virus, the RNA being arranged in an enveloped helical nucleocapsid. The intact virus is bullet shaped, measuring 180 nm by 75 nm, and is covered with 10 nm spikes.

Vesicular stomatitis virus will grow in a wide range of primary cells and continuous cell lines, and laboratory animals such as mice, rats, ferrets, guinea pigs, hamsters and chick embryos. Humans are susceptible to VS, the disease being characterized by fever, myalgia, nausea, vomiting, headaches and occasionally vesicles on the mucosa of the mouth and throat. No deaths have been reported, and the disease rarely lasts more than a week.

Epidemiology

The behaviour of VS in the field has been well documented but in spite of detailed observations there are many aspects of its epidemiology which are still unclear.

Enzootic VS has a limited geographical location, within which the appearance of disease is cyclical, apparently related to season or rainfall. The majority of infections are inapparent and can occur in animals isolated in cages or otherwise separated from other susceptible species. Epizootic spread of VS is associated with simultaneous outbreaks over a wide area, although some herds within this area may remain unaffected. Of the domesticated species, cattle are the most commonly affected, followed by horses and then pigs; sheep and goats never show clinical signs of VS. Few cases are reported in young cattle, most cases appearing in milking cows. Mouth lesions are most frequently reported, although in some outbreaks only teat lesions are seen. Insects have been strongly implicated in the transmission of VS, but this has not yet been conclusively demonstrated. The cyclical appearance of VS suggests the existence of interepizootic reservoir hosts, but these have also resisted identification.

A number of theories have been put forward to explain these observations. It has been suggested that VSV circulates in feral pigs, elk, mule deer and antelope and possibly also in water birds and rodents such as wood rats and deer mice. In support of this theory antibody against VSV has been found in all these species and, in some areas, prior to the onset of a VS epizootic in domesticated animals. It has also been suggested, without much supporting evidence, that VSV could persist in the soil and be circulated by arthropods or even that VSV is primarily a plant virus.

Studies using T_1 oligonucleotide mapping of VSV-NJ (Nicol, 1987) and nucleotide sequencing of VSV-NJ and VSV-IND (Rodriguez, 1999) have helped to identify the origin of VS epizootics in the USA. By precisely characterizing the outbreak strains it has been shown that a VS epizootic is not caused by the simultaneous eruption of many strains of VSV within the United States but the rapid spread of a single strain north from the enzootic region of Mexico. A correlation has been shown between outbreaks of VS in North America and wind direction from VS infected areas, indicating a possible involvement of insect vectors carried by the prevailing wind.

VSV-IND appears to have different epidemiological characteristics from VSV-NJ, and its spread is less associated with clinical disease and has consequently attracted less attention. It is also apparent that the behaviour of VSV need not remain consistent; its mode of transmission, for instance, can vary even during epizootics.

Distribution

VSV is restricted to North, Central and South America and the Caribbean islands. The disease was transported

with horses from America to South Africa in 1884 and 1887, and to France in 1915, but did not persist in either country. The first report of VS in N. America was in horses during the American Civil War, and there were further reports in 1889, 1904 and 1907. In South America VS was first diagnosed in Argentina in 1939, in Venezuela in 1941 and in Colombia in 1943.

Indiana 1 and New Jersey strains of VSV are enzootic in southern Mexico and Central America, but a characteristic of both is their periodic movement out of the enzootic areas to cause epizootics in the southern United States and northern South America. VSV-IND has spread as far north as the United States–Canadian border. These seasonal epizootics occur typically at the end of the summer, or in the tropics at the end of the rainy season, and usually finish in the temperate regions at the onset of the frosts. The 1982 VSV-NJ epizootic did not, however, follow this cycle and persisted through the winter. Epizootics which spread into the mid-western and western states of North America tend to occur at intervals of approximately five to ten years, while major epizootics have been occurring every 30 years. The predominant serotype causing vesicular disease in the United States is VSV-NJ, and it is endemic in at least one site in the USA – Ossabaw Island, Georgia. Vesicular stomatitis has not been reported in the New England area, eastern Canada or Alaska.

Transmission

The epidemiological characteristics of VS suggest that the disease is predominantly spread by insects. *Culex* and *Aedes* species of mosquitoes, *Phlebotomine* sandflies, *Culicoides*, *Simulium* blackflies, *Musca* species, *Hippelates* eye gnats and *Anthomyidae* have all been implicated in the transmission of VS. Transovarial transmission of VSV has been shown in the sandfly *Lutzomyia trapidoi* and biological transmission of VSV-NJ by *Simulium* sp. (Mead & Maré, 1999). However, the very low or possibly absent viraemia associated with VS rules out traditional concepts of vector transmission. The vesicular lesions of clinical VS are rich in virus and could provide a potent source for insect infection, but this fails to explain the transmission of VS between subclinically infected animals. Nevertheless, the climatic conditions which predispose to the spread of VS and the more frequent appearance of VS in animals at pasture strongly implicate the involvement of insects. In addition, the characteristic termination of a VS epizootic with the onset of subzero night time temperatures is typical of many vectorborne diseases. Experimentally inoculated sandflies and *Aedes aegypti* have been shown to transmit VSV to vertebrate hosts (Letchworth *et al.*, 1999). The virus does not appear to be totally dependent on insect transmission, as evidenced by the con-

tinuation of the North American 1982/83 epizootic through the winter.

Transmission of VS can also occur by direct contact between infected and susceptible cattle, this being frequently associated with subclinical infections. An association has been made between the feeding of abrasive feeds, which compromise the integrity of the buccal mucous membranes, and the spread of VS.

Clinical signs

Vesicular stomatitis in cattle may be an inapparent, mild or severe disease, animals over nine months of age being most commonly affected. Following an incubation period of two to three days, a usually mild fever develops accompanied by depression, lameness and excessive salivation. The fever reduces as vesicles develop on the coronary bands of the feet, or in the mouth or on the teats; rarely are vesicles seen on more than one of these sites. In severe cases over 50 per cent of the tongue epithelium may be affected and the resultant difficulty in eating can cause dramatic weight loss. Milk yield is depressed. True vesicles may fail to develop, lesions appearing as crusts or ulcers. Recovery is usually rapid, although milk yield frequently fails to recover during the remaining lactation and secondary mastitis may be a problem. Some animals fail to recover fully and remain in poor condition. The lesions produced by vesicular stomatitis virus in cattle are clinically indistinguishable from lesions of foot-and-mouth disease.

Pathogenesis

Vesicular stomatitis virus enters the animal through a skin or mucosal abrasion or it may be inoculated by an infected insect bite. Aerosol infection has been reported in humans and may also occur in cattle. A low titre viraemia has been detected in some experimentally infected animals between 11 and 56 hours after infection, but even this must be considered a rare event. Replication of virus occurs at the site of infection in the prickle cells of the Malpighian layer, but there is no information on subsequent sites of virus replication. As the cells degenerate and transudate from the blood stream accumulates, vesicles develop and the animal becomes febrile. It is not clear why lesions are rarely generalized, but are usually restricted to the teats, mouth or feet. Immunosuppressed or overcrowded animals are more likely to develop lesions. VSV does not cross the placenta and there are no reports of calves from infected dams being viraemic or having precolostral antibodies to VSV. However, VSV-NJ has once been recovered from an aborted fetus.

Diagnosis

Diagnosis of VS is by clinical examination of affected animals and the demonstration of the presence of VSV or of a rising antibody titre to VSV. Laboratory confirmation of VS is essential in order to distinguish the disease from foot-and-mouth disease.

VSV has a characteristic appearance under the electron microscope. The virus will also grow on a wide range of primary and continuous cell lines, on the chorioallantoic membrane or in the allantoic cavity of fertile eggs and in many laboratory mammals. The Vero-M (green monkey) cell line is used extensively for the growth of VSV for assay of VS antibodies in the virus neutralization test. The complement fixation test and fluorescent antibody test are also used in the diagnosis of VS, although indirect sandwich ELISA is now considered the most economic and rapid (OIE, 2000). Details given for the submission of samples for FMD diagnosis (see p. 704) apply also to the submission of samples for VS diagnosis, although VSV is much less susceptible to pH outside the range of 7.2 to 8.0. As a differential diagnosis is usually required between FMD and VS, the more stringent requirements of FMD virus should be followed.

Virus neutralization and liquid phase blocking ELISA antibodies may be detected 96 hours after experimental inoculation, and they reach a peak by day 12. These antibodies persist for many years and are valuable in showing evidence of previous infection. Their persistence has led to the suggestion that the virus itself may persist in an animal long after recovery from the disease, although it may remain in a defective, non-infectious form. Complement fixing antibodies recede three to six months after infection. A four-fold or greater increase in VSV neutralizing antibodies between early infection and convalescent serum is diagnostic of infection. The presence of neutralizing antibodies does not appear always to prevent reinfection or the development of clinical signs.

Prior to the establishment of suitable laboratory tests, VS was diagnosed by scarifying infective material into the snout of swine and the tongues of cattle and horses, and by intramuscular inoculation of cattle. VSV produced lesions on pigs, cattle and horses, but not in cattle when given by intramuscular injection. FMD virus produced disease in swine and cattle, but not horses, and vesicular exanthema virus affected only swine, although occasionally lesions were also produced on the tongues of horses.

Control

Measures designed to control VS reflect the poor understanding of its epidemiology, notably the possibil-

ity that animals can remain carriers of VSV. It has been observed that recovered cattle have appeared to spread VSV to susceptible animals, and that some of these recovered cattle have again developed vesicles, usually, but not invariably, on a site different from the original area of infection. These recurrent lesions have usually occurred within 48 hours of moving the recovered cattle, and this has led to the suggestion that the recrudescence of clinical disease was brought on by stress. Although it has not been possible to isolate virus from clinically normal animals recovered from VS, the persistence of high levels of neutralizing antibodies in these animals does suggest the presence of a continuous antigenic stimulation.

An additional problem is the high proportion of sub-clinical cases during epizootics and the possibility that VS could circulate in an area unobserved.

Measures designed to eliminate virus shed in the saliva of infected cattle do reduce transmission; 10 per cent household bleach used on utensils and dairy equipment, and for washing hands, has proved useful. In addition, replacement of hard or abrasive feed with a softer alternative reduces mouth lesions and thereby introduction of the virus.

Within the USA, animals infected with VSV are quarantined for at least 30 days after all signs of VS have disappeared. Countries free of VS are usually considerably more stringent and will not import any animal with virus neutralizing antibodies to VS. This precaution is intended to exclude the possibility of importing a persistently infected animal.

Living and formalin-inactivated vaccines have been prepared against VSV-NJ (see p. 1018). The dead vaccine reduces the incidence of overt disease, while the live vaccine, given by intramuscular inoculation, gives a better protection and does not spread to in-contact susceptible animals. A recombinant vaccine has also been developed by inserting the gene for the VSV glycoprotein into the genome of vaccinia virus. This vector vaccine against VS is reported to be highly effective, but has not been used in the field due to its potential danger to humans (Letchworth *et al.*, 1999).

Economic importance

It is difficult to assess the full economic importance of VS because of the effect the presence of disease has on export markets. Direct losses due to disease can be severe, particularly in high yielding dairy herds, and have been calculated to have been between \$97 and \$253 per clinical case during the 1982 epizootic in the United States (quoted by Monath *et al.*, 1986). Losses due to reduced growth rates in beef cattle in South America are also reported to be significant. Consequent movement restrictions and the closure of local

markets can also cause considerable loss. Nevertheless, it is the exclusion of animals in VS enzootic or previous epizootic areas from countries free of VS that causes the most significant economic losses.

(f) Bovine immunodeficiency virus (BIV)

A.H. Andrews

The virus

The bovine immunodeficiency virus (BIV) is a lentivirus first isolated as strain R29 in the USA from a cow with lymphoproliferative lesions. The organism has also been known as bovine immunodeficiency-like virus, bovine visna virus and bovine lentivirus. The virus is difficult to isolate, thus there have only been two subsequent isolates in the USA and also two in Japan. The virus has a similar morphology to other lentiviruses with a viral envelope of structural gene products and a core of viral nucleic acid, p26 capsid, p16 nucleocapsid, reverse transcriptase and integrase proteins. The RNA genome is 1842 nucleotides in length. While the BIV contains the same non-structural accessory genes as HIV, it lacks the addition gene *nef* found in primate lentiviruses. A genetically related virus to BIV, Jembrana disease virus, has been isolated but is restricted to Indonesia (see p. 766) and causes a severe disease in Banteng cattle (*Bos javanicus*) but a milder problem in *Bos taurus*.

Distribution

Although the virus has been rarely isolated there is serological evidence to suggest that it is distributed worldwide. While it is said to be more prevalent in the southern states of the USA, it is also present in the United Kingdom, Portugal, Switzerland, Croatia, France, The Netherlands, Italy and Germany in Europe. It is also reported to be present serologically in New Zealand, Australia, Canada, China, Korea and Pakistan. It probably is found in other countries but testing is difficult. Serological data suggest the highest prevalence of infection is in the USA and Canada, ranging from 20 to 60 per cent. A recent seroprevalence study in Great Britain suggested a level of 5.9 per cent for dairy cattle and 5.0 per cent in beef cattle (Scobie *et al.*, 2001). While sheep, goats and rabbits have all been infected experimentally, there is no evidence to suggest that this happens naturally. There is nothing to suggest that BIV is of any significant risk to man. It would appear that

natural infection is probably confined to cattle. Laboratory workers exposed to infection have not seroconverted. The virus is heat labile and is killed by milk pasteurization.

The disease appears to be expressed in few clinical signs, although in some herds in the USA and possibly in Europe disease can be infrequently expressed. This lack of ability to identify the organism or detect it consistently serologically means that its economic importance cannot be properly assessed. In many instances infection appear to be concomitant with another viral disease, such as enzootic bovine leukosis (EBL) (see p. 693).

In infected animals the infection follows a progression similar to that seen with HIV. Thus the animals have a persistent and chronic lifelong infection. The period of development for natural infection is not known, although following experimental infection cattle become seropositive in two to four weeks. Transmission is thought to be horizontal, although proviral DNA has been detected in the blood and semen of bulls experimentally infected (Gradil *et al.*, 1999). However, transplacental BIV infection has been demonstrated between seropositive dams and their calves (Scholl *et al.*, 2000).

Clinical signs

There is much debate as to the severity of the disease in cattle. It does appear that in many instances the virus causes no detectable signs, although in a few herds it does appear to cause major problems. It has been difficult to define whether the virus caused problems on its own or whether infection predisposes animals to opportunistic infections by other cattle disease pathogens. There is still argument as to whether or not BIV causes true immunodeficiency and this is why it is often referred to as bovine immunodeficiency-like virus.

The main signs in severely affected animals include loss of weight and poor condition, unthriftiness leading to emaciation in some animals. There is a variable degree of lymphadenopathy, which may be localized or generalized. Lameness or stiffness may be generalized or result in one or more legs showing lameness. There are nervous signs including changes in behaviour, nervousness, hyperesthesia and also aggression in some animals, but other cases exhibit depression, dullness and lethargy. Some animals become ataxic and will on occasion fall over. Milk yield is depressed or even absent. A few animals may show prolapse of the third eyelid.

In some infected herds, outbreaks of common disease problems in calves and older animals such as diarrhoea, pneumonia and abortion will result in particularly severe disease in some individuals and not in others.

Pathology

The pathological changes are very variable in extent and severity. In some animals there is lymph node hyperplasia and mild perivascular cuffing in the brain. The most common finding at post mortem examination has involved body lymph nodes which become or contain large spheroidal haemal nodes, black in colour. These haemal nodes vary considerably between infected animals in size, distribution and number (Munro *et al.*, 1998).

Diagnosis

Diagnosis is difficult because the virus is not easily isolated. Thus virus isolation in tissue culture is of limited use as it is of low sensitivity and is also usually complicated by the presence of other viral agents. However, polymerase chain reaction (PCR) techniques have been successfully used to detect the presence of proviral DNA. Very variable results have also been obtained by serological methods. The unreliability of some assay methods has meant that there may have been false positive results during testing in the past. At present, most diagnostic methods involving serology use indirect immunofluorescent antibody (IFA), enzyme linked immunosorbent assay (ELISA) or western blot. The tests most likely to be of use in screening large numbers of cattle would appear to be based on ELISA and one currently in use is based on the TM region of BIV.

Treatment and control

There is no available treatment for BIV infection. The best that can be done at present is to ensure full and adequate treatment of all secondary infections. In some herds where clinical signs have been present it has been the result of management deficiencies such as poor nutrition or poor housing. In some herds where those deficiencies have been improved, the clinical signs have been reduced or become latent.

Anthrax

Bacillus anthracis infection in cattle causes a peracute or acute disease, which is characterized by a septicaemia and sudden or rapid death. The disease is a zoonosis and is subject to official control measures in a number of countries. Infection in man usually results in the cutaneous form of the disease. Inhalation producing 'woolsorter's disease' is very severe but uncommon.

Aetiology

Bacillus anthracis is a Gram-positive capsulated bacillus and its morphology, together with the staining reaction of the capsula, is of diagnostic importance. When stained by Giemsa's, Wright's or similar stains, the capsule stains a reddish mauve colour, is square ended and its outline is rather ragged or 'shaggy' (Plate 44.1). A similar reaction is produced by methylene blue, but because of the variability in the content of its oxidized products, azur A and B, which have an affinity for the capsule, the staining reaction is less consistent and the staining of the capsule is a less intense mauve colour. The organism produces a lethal toxin that causes death through shock and acute renal failure.

The organism is a spore-forming bacillus, but mature spores are not formed in the animal before death. The

vegetative bacilli are not very resistant to environmental conditions or to physical and chemical agents, and are rapidly destroyed by putrefactive processes in unopened carcasses (Sterne, 1959). However, sporulation occurs when carcasses are opened or when discharges containing bacilli are exposed to air. Mature spores are extremely resistant to environmental conditions and certain disinfectants, and in soil they remain viable for many years.

Anthrax has been reported from most if not all cattle rearing countries of the world, but the incidence of disease is dependent on a number of factors, including climate, soil, animal husbandry and disease control methods. Serious outbreaks of disease are more commonly encountered in tropical and subtropical countries. In such areas, infection persists in the soil – spores can survive for decades – and is a major source of infection. The disposal of animal carcasses also presents a serious problem unless whole carcasses are removed. Otherwise cattle and other animals readily come into contact with the tissues, particularly bones, of animals that die from anthrax. This method of infection is very important in phosphorus deficient areas where cattle develop pica and chew bones in an attempt to remedy the deficiency.

In temperate countries sporadic outbreaks occur involving single or a small number of animals, arising from the ingestion of contaminated feedingstuffs. Campbell (1969) reported that the vast majority of anthrax outbreaks in cattle in England and Wales were associated with compound feedingstuffs containing meat and bone meal derived from imported materials from Asia and South America, but he also emphasized that often vegetable protein became contaminated with anthrax organisms in the holds of ships that were being or had been used for the transport of meat and bone meal. Hugh-Jones & Hussaini (1975) confirmed that in Great Britain, contaminated feedingstuffs were the major source of infection, although infection was sometimes derived from tannery effluent and soil at sites where the carcasses of animals had been buried some years previously.

Infection is acquired through the ingestion of soil or effluent-contaminated fodder or contaminated com-

pound feedingstuffs. Schlingham *et al.* (1956) have demonstrated that clinical disease in cattle can be regularly produced by the oral administration of organisms in feed pellets. The spores penetrate the intact mucosa, or through small abrasions in the mucosa of the mouth and pharynx, and are then transported to the local lymph nodes where germination and multiplication occurs, followed by passage via the lymphatics into the bloodstream, leading to a septicaemia with an explosive invasion of all body tissues.

Signs

All ages of cattle are susceptible to infection. The incubation period is thought to be one to two weeks, although in some incidents it would appear to be three to five days.

At the beginning of an outbreak, the peracute form of the disease is more common, animals usually being found dead within a few hours of being seen in normal health. On the rare occasions that animals are seen ailing, fever, muscle tremors, dyspnoea, collapse and terminal convulsions are the predominant signs, with death occurring in 1–4 hours. In the acute form, which runs a course of 24–48 hours, fever, depression, rapid and laboured respirations, diarrhoea or dysentery, haemorrhagic congestion of the visible mucous membranes and in dairy cattle a sudden drop in milk yield are the main signs. Pregnant animals may abort.

Atypical signs have been recorded in calves receiving prophylactic levels of oxytetracycline or chlortetracycline for the control of salmonellosis. In such animals, a mild fever, bleeding from the nose and eyes and melaena were the only signs observed before death, which occurred 48–72 hours after onset (B.M. Williams, unpublished data).

Pathology

Because of the peracute/acute nature of the disease in cattle, there is little opportunity for ante-mortem laboratory examinations. It may be possible to detect organisms in appropriately stained smears of peripheral blood, but sufficient numbers of organisms are only likely to be present during the later stages of the disease. A haematological examination may reveal a leucocytosis and a shift to the left, but because of the relatively short course of the disease, these changes are not marked.

Before a necropsy is carried out on an animal that has died suddenly or after a very short illness, it is essential that anthrax be eliminated, to prevent contamination of the environment and ensure proper disposal of the carcass. Thus a careful evaluation of the circumstances and a thorough preliminary examination of the

carcass must be carried out. If anthrax cannot be eliminated, then a blood sample should be taken from a superficial blood vessel and a stained smear examined microscopically. It is more difficult to identify anthrax bacilli if animals have been treated with antibiotics. The procedures for dealing with suspected anthrax cases vary from country to country and those currently in force in Great Britain are discussed below.

Rapid decomposition of the carcass sets in soon after death and in most instances rigor mortis is absent and dark tarry blood exudes from all the body orifices. There is bloodstained fluid in all body cavities and there are widespread haemorrhages throughout the carcass, particularly on the parietal pleura and peritoneum. Unclotted or poorly clotted blood oozes from the cut blood vessels and there is an intense inflammation of the mucosa of the abomasum and both small and large intestine. The spleen is almost invariably greatly enlarged with sometimes a rupture of the capsule, and a dark semifluid pulp. The lesions in animals that have been treated with antibiotics before death are similar but much less spectacular.

Diagnosis

The diagnosis of anthrax is based on the demonstration of capsulated bacilli in peripheral blood and subsequent confirmation by laboratory isolation and identification. In Great Britain and many other countries, anthrax is a notifiable disease and the State Veterinary Service is responsible for confirmation.

There are numerous causes of sudden death in cattle, including clostridial infections, hypomagnesaemia, lead poisoning and lightning strike, all of which can be confirmed by a post-mortem examination and appropriate laboratory examinations. As emphasized earlier, such procedures should not be undertaken until anthrax has been eliminated.

Treatment and prevention

Bacillus anthracis is sensitive to a number of antibiotics and treatment of animals during the early stages of the disease is likely to be successful, although severely ailing animals are unlikely to recover. Greenough (1965) successfully treated animals with 5 megaunits of penicillin alone or with streptomycin. The recommended dosage of penicillin is 10000 units/kg body weight administered twice daily for at least three to five days. Streptomycin, in 4–5 g doses, should also be administered twice daily for the same period. Lincoln *et al.* (1964) consider that septicaemic anthrax is best treated with a combination of large doses of penicillin and streptomycin twice daily, although oxytetracycline and chlortetracycline are the next antibiotics of choice.

Bailey (1953) also recommends tetracycline for the treatment of anthrax. Anthrax antiserum administered intravenously is effective but the high cost and large volumes required makes its routine use impractical.

When anthrax has been confirmed in a herd, all animals should be carefully observed at frequent intervals and any that are showing signs of ill health isolated, their temperatures taken and, if elevated, immediately treated with antibiotic.

In Great Britain and elsewhere, anthrax is a notifiable disease under the provisions of the Anthrax Order of 1938 for the protection of both animal and human health. An owner or veterinary surgeon must report any suspicion of disease to a police constable, who informs the Local Authority, which then immediately imposes restrictions on the movement of animals onto and off the premises. The carcass(es) of the suspected animal(s) must be detained and the skin must not be incised other than for the removal of a blood sample for diagnostic purposes by the owner's veterinary surgeon or a veterinary officer appointed by the Minister, usually the Divisional Veterinary Manager or a veterinarian acting on his/her behalf.

This State Veterinary Service is responsible for the disease investigation and a stained smear is made from a superficial blood vessel and examined microscopically. If the Veterinary Inspector is satisfied that disease does not exist, the Local Authority is informed and the movement restrictions are withdrawn. If the inspector is not satisfied, an unfixed blood smear and a sample of blood is submitted to the Central Veterinary Laboratory for cultural and biological examination and the Local Authority informed accordingly: On receipt of this information the Local Authority is responsible for disposal of the carcass, usually by burning, and carrying out disinfection of the premises as prescribed in the Order. The disinfectants of choice are 5 per cent lysol, 5 per cent formalin or 5–10 per cent caustic soda. When these procedures have been completed, movement restrictions are withdrawn.

Confirmation of the disease is dependent on the results of the examinations at the Central Veterinary Laboratory, which may take seven or more days. On rare occasions disease is not confirmed; even so the existing procedures are considered effective in view of the serious nature of the disease and the human health implications.

Where enzootic disease exists, then an avirulent spore vaccine is available, and all cattle should be vaccinated on an annual basis. Vaccination is seldom necessary in Great Britain (see p. 1005).

The number of confirmed incidents in Great Britain is now very low. This is largely due to the efforts of feedingstuffs compounders, who no longer use meal and bonemeal (MBM) in their feeds. In other countries,

where MBM can be legally used, it is essential to use sterilized meal and minerals in their finished feeds.

Bacillary haemoglobinuria

Bacillary haemoglobinuria or infectious ictero-haemoglobinuria of cattle was described by Roberts (1959) as a rapidly fatal infectious disease, manifested clinically by a high fever and haemoglobinuria, and pathologically by the presence of an infarct in the liver.

Aetiology

The causal organism is *Clostridium novyi* type D, previously designated *Cl. haemolyticum*. Like other clostridia it is a soil-borne anaerobe, the spores of which are resistant to environmental factors and may survive in soil for weeks if not months. The disease is considered to be one essentially of poorly irrigated or wet swampy land, which favours survival of the organism and is likely to harbour *Lymnaea* spp., the host snail of the liver fluke. The principal toxin produced by the organism is beta, which is haemolytic, necrotizing and lethal.

After ingestion the organism is transported from the alimentary tract to various organs. Smith (1957) recovered the organism from the liver, kidneys and bone marrow of normal cattle, where it remains as a latent infection. It is thought that, as in infectious necrotic hepatitis, the latent spore infection is activated by liver damage, especially by migrating immature liver fluke. The disease has been produced experimentally by infecting calves orally with the spores of *Cl. novyi* type D and carrying out a liver biopsy, and by implanting the organism in the liver suspended in calcium chloride solution (Blood *et al.*, 1983). It has also been postulated that telangiectasis may also be a precipitating factor.

When conditions are favourable for the activation of the latent infection, the damaged liver tissue provides a focus for initial multiplication of the bacteria. An organized thrombus develops in a subterminal branch of the portal vein resulting in a large anaemic infarct in which further rapid bacterial multiplication and toxin production occurs. The toxin produces a haemolytic anaemia, and later a bacteraemia develops. The duration of illness may vary from about 18 hours to four days. Bacillary haemoglobinuria has been observed in North and South America, Australia and New Zealand. Few incidents have been reported in Great Britain.

Signs

Cattle at pasture that are inspected at infrequent intervals may be found dead. The onset of disease is usually

Fig. 44.1 Bacillary haemoglobinuria: a large infarct in the bovine liver caused by *Clostridium novyi* type D.

sudden, with cessation of feeding, rumination and defecation. Cows in lactation suffer a sudden and dramatic drop in milk yield. Animals are disinclined to move and the temperature is elevated to 39–41°C (102–106°F). The mucous membranes are jaundiced and there may be oedema of the brisket, submaxillary region and conjunctiva. Small amounts of bloodstained faeces may be passed in the early stages, but later there may be a frank dysentery. Not all these signs may be seen in individual cases and the variation may be due, in part, to different strains of organisms.

Pathology

One of the obvious features of the disease is the profound anaemia that develops before death. Blood samples from ailing animals show a depressed erythrocyte count, which may be as low as $10^6/\text{mm}^3$ and haemoglobin values are in the range of 40–80 g/l. Leucocyte counts are normally elevated to around $20000/\text{mm}^3$. The organism may be recovered from blood cultures taken during the acute phase. There is a very obvious haemoglobinuria in a proportion of cases, but there are no free red cells in the urine.

In the typical case, the necropsy picture is considered to be pathognomonic, the main features being generalized jaundice often with anaemia; subcutaneous oedema especially over the brisket; accumulation of slightly bloodstained fluid in the pericardial sac, pleural and peritoneal cavities; widespread haemorrhages in the subcutaneous tissues, over the pleural and peritoneal serosa, and endocardium; haemorrhagic abomasitis and enteritis. The liver is usually mahogany

coloured with a characteristic yellow infarct, up to 20 cm (8 inches) in diameter, surrounded by a zone of hyperaemia (Fig. 44.1). The kidney cortex is petechiated and deep-red coloured urine may be present in the kidney pelvis and bladder. Evidence of liver fluke damage is not a constant feature.

Diagnosis

Bacillary haemoglobinuria must be differentiated from other conditions in which haemoglobinuria is one of the clinical signs. Acute leptospirosis, due to *Leptospira interrogans* serovar *pomona* (p. 734), is one of these and to confirm a diagnosis in the live animal serological tests and cultural examination of the urine is necessary, although there should be little difficulty in differentiating the two diseases at necropsy. Babesiosis (p. 748) and anaplasmosis (p. 761) can be differentiated by the demonstration of the organisms in blood smears. Post-parturient haemoglobinuria is accompanied by a hypophosphataemia (see p. 792), whilst blood and liver copper levels are elevated in chronic copper poisoning (p. 948). Both these conditions and haemoglobinuria due to the consumption of cruciferous plants (p. 941), such as rape and kale, are afebrile.

Confirmation of diagnosis of bacillary haemoglobinuria is based on the clinical signs, necropsy findings and demonstration of the causal organism in the liver lesion and other sites by fluorescent antibody techniques. It may also be possible to culture the organism from tissue and demonstrate toxins in the liver infarct, but both procedures are time-consuming and laborious.

Treatment and prevention

Bacillary haemoglobinuria can be successfully treated by the administration of wide-spectrum antibiotics in the early stages (Smith & Holdeman, 1968). Early treatment with large doses of penicillin is also effective (Williams, 1964). Supportive treatment by the administration of electrolyte solutions orally and parenterally and the provision of mineral supplements containing iron, copper and cobalt is also necessary, as well as careful nursing.

The disease can be successfully prevented by vaccination with an aluminium hydroxide adsorbed, formalinized whole culture and it is also claimed that infectious necrotic hepatitis vaccines also confer immunity. Annual vaccination is necessary in enzootic areas (see p. 1005).

Botulism

Botulism may be defined as a lethal type of food poisoning in man and several species of animals, caused by the ingestion of *Clostridium botulinum* toxins, which have been produced by the organism in decaying plant or animal tissue.

Aetiology

Smith (1977) defines *Cl. botulinum* 'not as a single species, but as a conglomerate of several distinct culture groups, alike in that they are clostridia and produce toxins with a similar pharmacological action'. There are a number of distinct serological types (A, B, C, D, E, F and G) and although the toxins are similarly designated, the serological specificity of the toxin produced by any strain may not be entirely related to its serological classification.

Like other clostridia, *Cl. botulinum* is a spore-forming organism, which under certain conditions thrives in putrefying animal tissue or decaying plant material. The organism has a world-wide occurrence and is found in the intestinal tracts of herbivores and in soil. It would appear that different soil types favour different types of the organism. Smith (1997) reported that in the USA, type A strains were prevalent in the alkaline soils of the south-west, types B and E in the damp soils of most areas, type C in the acid soils of the Gulf Coast and type D in the alkaline soils of the west.

The toxins of *Cl. botulinum* are neurotoxins, causing motor paralysis without the development of any gross or histological lesions in the nervous system. Although the mode of action is still debated, it appears that the site of action of the toxins is at the synapses of efferent parasympathetic and somatic motor nerves, by inter-

ference with the secretion of acetylcholine, which is the chemical mediator of nerve impulse transmission.

Two forms or types of botulism are recognized in cattle. The first is the form that develops after the consumption of, or contact with, carcasses or skeletons of dead animals containing botulinum toxins. The second form of the disease follows the consumption of conserved fodder that is contaminated by the toxins.

The first type of botulism has been widely reported in South Africa (Iamsieket), Australia (bulbar paralysis) and in the USA (loin disease). In these countries it has been associated with low phosphorus levels in soil, poor pastures and drought. Under such circumstances animals including the local fauna, which carry *Cl. botulinum* in their intestines, die and the organisms invade the carcass tissues and produce large amounts of toxin. Muller (1961) has demonstrated that the levels of toxin may reach 10^5 – 10^6 mouse lethal units/g of tissue. Animals that consume tissue from such carcasses, because of a phosphorus deficiency and a subsequent pica, or feed shortage, ingest both toxin and *Cl. botulinum* spores and will subsequently become a source of toxin and spores for other animals. In Europe, similar circumstances may arise after the spreading of litter from poultry houses on to cattle pastures. Investigations into such outbreaks reveal the presence of poultry carcasses in the litter, which are the source of the toxins (Appleyard & Mollison, 1985; Clegg *et al.*, 1985).

The second type of botulism, forage poisoning, occurs in those countries where conserved forage, especially baled hay and silage, is fed to cattle. The source of toxin has usually been identified as the carcasses of small animals (mice, rats, rabbits and birds) accidentally killed and subsequently baled in the hay or ensiled with the grass or cereal crop. Prevot & Silliac (1955) recorded that more than half of the cattle botulism in France was associated with the presence of cat carcasses in the feed. Fjolstad & Kluna (1969) also reported an outbreak in which the source of toxin was a cat carcass and demonstrated 500000 mouse lethal doses/g of the carcass. A hedgehog, discovered in a hay rack, was the source of toxin in an outbreak in cattle with 20000 mouse lethal doses in its subcutaneous tissue (Ektvedt & Hanssen, 1974). Recently, however, it has been demonstrated that proteolytic strains of *Cl. botulinum* may produce toxin in silage under certain conditions and without the presence of animal tissue (Notermans *et al.*, 1979a, b). It would appear that a low pH prevents toxin formation in silage. The incorporation of poultry manure and poultry waste in cattle feed can also lead to outbreaks of botulism (Egyed *et al.*, 1978) and brewers grains contaminated with *Cl. botulinum* has also been incriminated (Breukink *et al.*, 1978).

Botulism in any species of animal tends to be associated with certain types of the organism. Ruminants are

susceptible to types C and D, although in The Netherlands disease has been associated with type B (Haagsma & Laak, 1977).

Signs

Clinical signs usually appear within two to fourteen days of ingestion of the toxin, although in peracute cases the incubation period may be only a few hours. Illness is afebrile.

In peracute cases the onset of disease is sudden, characterized by a rapid paralysis and death within 12–18 hours. In less acute cases the onset is more gradual, affected animals showing a progressive muscular paralysis of the head, neck and limbs, leading to recumbency, often with the head and neck outstretched or deviated towards the flank.

The majority of cases, however, appear to be of the subacute type. The first signs are periodic periods of restlessness, incoordination especially of the hindlimbs, and an apparent difficulty in chewing and swallowing. These signs progress to ataxia, difficulty or inability to rise, recumbency and in some an obvious paralysis of the tongue, which protrudes from the mouth. There is usually partial or complete anorexia and adypsia. Animals may survive for up to seven days after becoming recumbent, but during the terminal stages respiration becomes laboured and of the abdominal type due to paralysis of the thoracic muscles. An animal often appears to rest its chin on the ground and will lift it when stimulated. A foreleg may be extended. As the condition progresses nominal movements reduce. Later stages often involve lateral recumbency with extended legs which can be flexed. The animal is conscious.

Some animals may recover after showing relatively mild clinical signs over a period of three to four weeks (Clegg & Evans, 1974; Davies *et al.*, 1974). Clegg & Evans reported that surviving animals developed a pronounced respiratory roaring sound, which persisted for three months after recovery.

Pathology

A number of authors have reported on the value of certain biochemical tests on blood and urine from affected animals as aids to diagnosis, but in cattle such tests are of little help in the live animal. However, it is possible in some cases to demonstrate circulating toxins in the serum of clinically affected animals by mouse inoculation tests (Clegg *et al.*, 1985), but such cases are of the peracute or acute type.

As already indicated, the toxins of *Cl. botulinum* do not produce any specific or detectable lesions in the central nervous system, nor do they produce specific changes in the carcass. Those changes that are observed

are non-specific and include haemorrhages on the endocardium and epicardium and congestion of the parenchymatous organs and intestinal mucosa. However, it may be possible to demonstrate toxin in the intestinal contents or liver by mouse inoculation tests. Whilst the presence of the organism in the intestine is of little diagnostic value, its isolation from the liver is of significance. In many cases investigation of outbreaks is unrewarding.

Diagnosis

It must be emphasized that in many instances it is not possible to confirm all suspected cases of botulism by detection of toxin either in the sera of affected animals or in the intestinal contents or liver at necropsy. As *Cl. botulinum* is not normally found in the liver of cattle, isolation from the liver is regarded as significant.

Attempts may be made to demonstrate toxin in suspected feed, but such an approach has its limitations. Suspected feed may be fed to experimental animals of the same species, or an infusion of the feed may be administered to experimental animals. However, toxins in feedingstuffs are not distributed evenly, rather in pockets, and samples of feed for testing must therefore be carefully selected, e.g. from near carcasses or areas of contamination. It is also possible that all the botulinum-contaminated feed will have been consumed before the onset of clinical signs.

Postparturient paresis/hypocalcaemia (p. 781) can be differentiated from the disease by the examination of blood samples and the response to calcium therapy. In some cases of listeriosis (p. 904) there is a paralysis of the tongue, but it is accompanied by fever and other clinical signs such as unilateral facial paralysis and panophthalmia. Bovine spongiform encephalopathy (p. 911) in its later stages might be confused but there is no paralysis and the animal will still eat.

Treatment and prevention

There is little value in the administration of antitoxin, except possibly in the very early stages, and there are conflicting views on the merits of purgatives to remove the toxins from the intestine. However, Breuknik *et al.* (1978) reported that symptomatic treatment for dehydration and acidosis seemed to assist recovery. As a general rule, treatment of subacute cases only should be undertaken, as these are the ones most likely to recover.

Vaccination with toxoid is only necessary in enzootic areas and should be given every two years (p. 1005). Where botulism is associated with the disposal of poultry litter on to pasture, every effort should be made to remove any poultry carcasses in it before application.

All poultry waste should ideally be heat treated before incorporation into compound feeds for direct feeding to livestock.

Clostridial myositis: blackleg and malignant oedema

Two forms of clostridial myositis are recognized in cattle: blackleg, which is caused by *Clostridium chauvoeui*, and malignant oedema, which is caused by a number of clostridial species and is nearly always associated with wound infection. It is often difficult or impossible to differentiate between the two conditions at a clinical or post-mortem examination (Williams, 1977).

Blackleg

Blackleg or blackquarter is defined as a gangrenous myositis caused by the activation of a latent *Cl. chauvoeui* spore infection (Jubb *et al.*, 1983). These authors also refer to a 'false or pseudo-blackleg' caused by the activation of *Cl. novyi* and *Cl. septicum* spore infection, but this condition is more appropriately designated malignant oedema.

Aetiology

Clostridium chauvoeui is a Gram-positive, spore-bearing anaerobic bacillus, the spores of which are highly resistant to environmental conditions and therefore remain viable for many years. It is, like other clostridia, regarded as a soil organism and following ingestion by cattle, sheep and other animals, the spores localize in the spleen, liver and muscles (Kerry, 1964). The vegetative form of the organism produces a number of toxins, which are capable of inducing local muscle necrosis and toxæmia. The trigger mechanisms responsible for the activation of the endogenous latent spore infection are unknown, but it is assumed that a lowered oxygen tension and a degree of muscle damage are necessary. After activation, rapid bacterial multiplication and toxin formation produce the typical muscle gangrenous lesion and systemic toxæmia.

Most cases occur in animals between six months and two years of age at pasture, although incidents may occur in housed animals.

Signs

Often when stock are infrequently inspected animals may be found dead without signs of illness having been observed. The clinical signs that are seen in ailing

animals are related to the site of lesion. Limb involvement is manifested as a lameness with a swelling of the upper part which, at first, is hot and painful, but later becomes cold and emphysematous. A lesion of the tongue results in a tongue and throat swelling, with the tongue protruding from the mouth and marked respiratory distress. Stiffness and a reluctance to move is apparent when the sublumbar muscles are involved. In addition to these clinical signs, there is a marked depression, anorexia, rapid pulse rate and high temperature, usually in excess of 40°C (104°F). Later there is dyspnoea, recumbency and coma leading to death within 12–24 hours.

Pathology

The disease usually runs an acute course so that there is little opportunity for collecting specimens for laboratory examination before death. After death the carcass becomes bloated and putrefaction occurs rapidly. Bloodstained froth exudes from the body orifices. It may be possible to palpate the lesion, if it is in a superficial muscle group, but this is usually difficult because of the rapid onset of putrefaction.

Animals dying from blackleg are in good body condition. The body cavities contain bloodstained fluid and the parenchymatous organs show evidence of degeneration and post-mortem decomposition. All the skeletal muscles must be carefully examined by palpation and incision for lesions, which may not be extensive. The lesion produced by *Cl. chauvoeui* has a characteristic appearance (Williams, 1977) (Plate 44.2). The muscle is blackened, dry and crepitant with a spongy appearance and a rancid odour. Pale yellow serous fluid surrounds the affected muscle, but this becomes progressively more bloodstained as post-mortem decomposition proceeds.

Diagnosis

A diagnosis can be reached on the basis of clinical signs and necropsy findings, but it is essential that when no clinical signs have been observed, anthrax (p. 717) is eliminated before a necropsy is carried out. *Clostridium chauvoeui* can be identified by the staining of lesion impression smears by the specific fluorescent antiglobulins that are now commercially available. Cultural examination is likely to be unrewarding unless fresh tissue is available and special techniques used.

Blackleg may be confused with other conditions especially when death is sudden. Lead (p. 944) and other chemical poisonings (pp. 941–3) require laboratory examination for confirmation, but the typical lesions of blackleg are absent. Black disease (p. 729) and bacillary haemoglobinuria (p. 719) may also have to be considered in a differential diagnosis, but the

characteristic liver infarcts are a diagnostic feature of these two diseases.

Treatment and prevention

Antibiotic treatment of affected animals is likely to be effective only if commenced early. Large doses of penicillin (10000 units/kg body weight) should be administered intravenously, followed by longer acting preparations, some of which should be given into the affected tissue (Radostits *et al.*, 2000). However, because of the extensive tissue involvement, even if the infection is eliminated, the subsequent muscle loss is so great that recovered animals are of little economic value. Treatment of animals with tongue infection should not be attempted, because even if successful the whole tongue or most of it will be subsequently lost and early slaughter on humane grounds should be considered. Carcasses should be burned or undergo deep burial.

Blackleg can be successfully prevented by the use of commercially available *Cl. chauveoi* vaccines and all animals over six months of age should be vaccinated prior to being turned out in the spring. There are, however, considerable advantages in the use of multi-valent vaccines containing the antigens of *Cl. chauveoi*, *Cl. novyi* and *Cl. septicum*, which offer maximum protection to cattle against blackleg, malignant oedema and black disease (p. 1005).

Malignant oedema

Malignant oedema is considered to be an acute wound infection caused by organisms of the genus *Clostridium* (Radostits *et al.*, 2000). However, if blackleg is restricted to cover endogenous *Cl. chauveoi* infection then malignant oedema must also include those incidents, albeit relatively few in number, arising from activation of latent *Cl. novyi* and *Cl. septicum*, which undoubtedly occur.

Aetiology

Clostridium chauveoi, *Cl. novyi*, *Cl. perfringens*, *Cl. septicum*, *Cl. sordelli* and other clostridia have been isolated from, or demonstrated in lesions of clostridial myositis in cattle. Williams (1977) in a survey of 173 cases in Wales demonstrated *Cl. chauveoi* in 75 (43 per cent), *Cl. chauveoi* and *Cl. septicum* in 22 (13 per cent), *Cl. novyi* in 53 (31 per cent), *Cl. novyi* and *Cl. septicum* in nine (5 per cent), *Cl. septicum* in 11 (6 per cent) and *Cl. sordelli* in three (1.7 per cent). In this series *Cl. perfringens* was isolated from about 50 per cent of the lesions, but its presence was not considered to be of significance.

There is still some uncertainty about the role of *Cl. septicum* in bovine malignant oedema.

Deep puncture wounds, accidentally inflicted, provide ideal conditions for the multiplication of anaerobes and development of malignant oedema. It may also develop after surgical operations, parturition, intramuscular administration of non-antibiotic preparations such as prostaglandins (Harwood, 1994), anthelminthic and vitamin preparations, and vaccination. The clostridia are soil organisms that persist in the animal environment and therefore readily gain entry to wounds. The tissue damage and low oxygen tension allow rapid multiplication and toxin production so that clinical signs usually develop within 48 hours. Occasionally, malignant oedema may affect a group of animals that had previously been housed or penned for a short period of time and the absence of any form of wound suggests that some factor, perhaps trauma from bruising, may have activated a latent spore infection.

Signs

The disease is usually sporadic involving single or small numbers of animals. All ages of cattle are affected and clinical signs appear within 48 hours of infection. The clinical signs will vary with the site of infection, but in all cases, anorexia, depression and fever are very marked. A local lesion develops at the site of infection consisting of a swelling, which becomes tense and depending on the type of infection may become emphysematous. Lameness, stiffness and muscle tremors may be evident. Animals usually die within 48 hours.

When infection is associated with parturition, the vulva and perineum swell and there is a bloodstained discharge from the vulva. Death is rapid, usually within 24–36 hours after the onset of signs.

Pathology

In malignant oedema there is little opportunity for the laboratory examination of specimens taken from affected animals. As in blackleg, it is necessary for a post-mortem examination to be carried out as soon after death as possible, because of the bacterial invasion of the carcass and rapid onset of putrefactive changes.

The site of infection is surrounded by an extensive oedema of the subcutaneous tissues and intramuscular fascia. It may be possible to identify the initial wound, but tissue damage is usually so extensive that the only trace is a small wound in the skin. The oedema fluid may be clear and gelatinous in *Cl. novyi* infections with very little muscle damage. Infection with *Cl. septicum* produces an extensive bloodstained frothy oedema, with the underlying muscle a dark red colour permeated

with gas. *Clostridium sordelli* produces changes similar to those produced by *Cl. novyi* except that the oedema is more bloodstained and has a foul odour. The lesion produced by *Cl. chauveoi* is similar to that described under blackleg.

All body cavities contain bloodstained fluid and the parenchymatous organs show degenerative changes and post-mortem decomposition. If the infection involves the reproductive tract, the uterus will contain a large volume of foul-smelling bloodstained fluid and the uterine and vaginal walls will be greatly thickened, permeated with bloodstained fluid and gas.

Diagnosis

The clinical signs and necropsy findings are so characteristic that diagnosis can be readily reached. It will, however, be necessary to resort to laboratory examination of lesions for the identification of the organisms by fluorescent antibody tests or culture.

Treatment and prevention

Affected animals should be treated with high doses of antibiotics, preferably parenteral penicillin or broad spectrum. In addition, wounds should be drained and irrigated with antiseptic solutions, and packed with a suitable antibiotic preparation.

Trivalent vaccines, containing the antigens of *Cl. chauveoi*, *Cl. novyi* and *Cl. septicum* are available and are effective in preventing malignant oedema (p. 1005).

Harwood (1984) highlights the dangers from intramuscular injections administered to cattle, particularly if infection is introduced and if large volumes are used, and under such circumstances routine vaccination is recommended.

Contagious bovine pyelonephritis

This disease is a specific infection of the urinary tract of cattle, which results in a chronic purulent inflammation of the kidneys, ureters and bladder.

Aetiology

Corynebacterium renale is considered to be the specific causal agent, although other organisms, especially streptococci, staphylococci, *Arcanobacterium* (*Actinomyces*, *Corynebacterium*) *pyogenes* and *Escherichia coli*, as well as *C. renale* are present in the urine of some animals with pyelonephritis and may also be implicated. *Corynebacterium renale* is an obligate parasite of

cattle and occasionally sheep, and can be readily cultured from the urine of affected and carrier animals.

Goudswaard and Budhai (1975) identified four serotypes, of which type 1 is the most pathogenic.

It has been demonstrated that the pathogenicity of *C. renale* is dependent to a large extent on the presence of pili on the organism, which assist its adhesion to the urinary epithelium. This process is pH dependent and Takai *et al.* (1980) showed that the proportion of pilated organisms adhering to bladder cells is high at a pH above 7.6, but significantly lower at a pH below 6.8, a factor that is important in the pathogenesis of pyelonephritis.

The disease is considered to be the result of an ascending infection, involving successively the bladder, ureters and kidneys. Hiramune *et al.* (1972) established infection in cattle after the introduction of organisms into the bladder and the characteristic lesions developed. Females are far more susceptible than males to infection and the short length of the urethra in the female is thought to be a major factor in the establishment of infection. Stasis of urine is an important predisposing factor in the pathogenesis of pyelonephritis and cystitis and such circumstances may occur when a permanent or temporary obstruction of the urinary tract occurs through the presence of calculi or pressure exerted by a gravid uterus.

The disease is widely recognized in Europe and North America, but the prevalence of infection is largely unknown. Morse (1950) found that *C. renale* could be recovered from the urine of 22.7 per cent of cattle in herds in which pyelonephritis had been confirmed, whereas only 10.7 per cent of cattle in other herds were infected. Clinically infected or carrier cows are the principal source of infection, the disease being mainly transmitted by direct contact, although Morse (1950) reported that infection was transmitted by indirect contact from affected and carrier cows tethered in stalls to those in adjacent stalls. In some herds there is circumstantial evidence to support the existence of venereal spread and the organism has been readily isolated from the prepuce of normal bulls (Hiramune *et al.*, 1975).

Signs

In affected herds, clinical cases appear sporadically with animals under three years of age rarely affected. Most cases occur in dairy herds with the peak incidence usually in winter.

There is considerable variation in the clinical signs observed from case to case, particularly during the early stages. Bloodstained urine may be passed intermittently by an apparently healthy animal over a period of weeks,

before other signs appear. In other animals, one, two or more attacks of acute colic lasting up to 6 hours or more may be the first sign. More frequently, however, the onset is insidious. The most common signs are a gradual loss of condition, a slowly declining milk yield, fluctuating or capricious appetite, intermittent fever, and the intermittent passage of bloodstained urine. As the disease progresses, urination becomes more frequent and painful with the passage of small volumes of urine containing blood and tissue debris. During the later stages it may be possible to detect, by rectal examination, enlargement of one or both kidneys, a thickened bladder and enlargement of one or both ureters, particularly the terminal portions where they cross the neck of the bladder. Frequently, palpation of the kidneys induces a pain response. The course of the disease may run from a period of weeks to two or more months, death resulting from a combination of kidney failure and blood loss with an extensive loss of condition.

Pathology

The urine of clinically affected animals is turbid and in the early stages intermittently bloodstained, but in the later stages the urine is almost constantly bloodstained. Microscopic examination of the centrifuged deposit of the urine reveals the presence of erythrocytes, leucocytes and epithelial tissue debris. *Corynebacterium renale* can be readily demonstrated in Gram-stained smears and Ado & Cook (1979) have reported on the value of fluorescent antibody tests for the identification of the organism. It can be readily isolated on blood agar and other media in common use. The clinical signs are so characteristic that haematological examination and blood chemistry estimations are seldom considered necessary. In any case, such examinations are unlikely to reveal any abnormalities until the disease is well developed when anaemia and uraemia are the most prominent findings.

Animals dying from pyelonephritis are usually in poor condition and the carcass pale and anaemic. Specific lesions are confined to the urinary tract. One or both kidneys are enlarged with less well marked lobulation than normal and a markedly thickened capsule. The surface is mottled by greyish white necrotic areas. On section the renal pelvis is greatly dilated and contains varying amounts of blood, pus and mucoid fluid. Greyish white streaks of necrotic tissue radiate from the pelvis towards the cortex and there may be numerous abscesses in the cortex and medulla of each lobule. The ureters are grossly enlarged and distended by blood, pus and mucus. The bladder wall and the urethra are thickened and the mucosa oedematous, haemorrhagic and necrotic.

Diagnosis

The diagnosis of pyelonephritis is based on the clinical signs, the changes in the urine and the presence of *C. renale* in the urine together with the detectable abnormalities in the urinary tract. Enzootic haematuria (p. 947) has some clinical features in common with pyelonephritis, but it is afebrile, lesions are confined to the bladder and the urine from such cases is sterile or negative for *C. renale*. Similarly, non-specific cystitis may also resemble pyelonephritis, but the bladder only is affected and the urine is sterile or negative for *C. renale*.

Treatment and prevention

Corynebacterium renale is sensitive to a range of antibiotics but penicillin remains the antibiotic of choice for the treatment of pyelonephritis in the bovine. A complete recovery can be achieved if treatment is commenced during the early stages, when little tissue damage has occurred. In advanced cases, however, when there is considerable tissue destruction, only a temporary recovery can be achieved through antibiotic therapy, although this may enable an animal to be fattened and subsequently sent for slaughter. Large doses of procaine penicillin G should be administered, e.g. 10000–15000iu/kg daily for at least 10 days. The acidification of the urine by the administration of monobasic sodium phosphate is still considered by some as useful supportive therapy and 100g daily for a period of five days during antibiotic treatment is recommended.

There are no specific control measures other than isolation of affected animals and thorough cleansing and disinfection of the contaminated environment. In affected herds where natural breeding is practised, the introduction of artificial insemination may achieve a reduction in the number of clinical cases.

Endocarditis

Endocarditis may be defined as inflammation of the endothelial lining of the heart. The inflammatory processes usually result in valvular insufficiency or stenosis that interfere with the flow of blood into and out of the heart, leading to congestive heart failure.

Aetiology

Most cases of bovine endocarditis appear to be caused by bacterial infection. Several species of bacteria have been incriminated, but streptococci especially enterococci of Lancefield's group D, *A. pyogenes*, staphylo-

cocci, *Mannheimia* and *Pasteurella* species are the commonest (Evans, 1957; Larsen, 1963).

It would appear that a persistent bacteraemia is necessary for the development of endocardial lesions and it is significant that in most, if not all, confirmed cases, a primary focus of infection in the form of mastitis, metritis, reticulitis, limb abscesses, etc. can be identified at post-mortem examination (Evans, 1957; Andersen, 1963; Larsen, 1963).

Although it is generally accepted that the causal organisms are transported to the heart via the blood-stream, the method by which they reach the endocardial lesion is still uncertain. It is possible that some bacteria may be able to adhere to the intact endothelium. However, it is more likely that they adhere to damaged endothelium and it is assumed that trauma and debility are the main factors in producing sufficient damage for the bacteria to localize in the endothelium. This hypothesis is based on the fact that the usual sites of the lesions are on the free edges of the valves exposed to the blood flow and that they are in apposition to others. The heart valves of the bovine have their own blood supply and it is thus possible for the bacteria to produce emboli in the capillaries, which form a focus of infection.

The early lesions of endocarditis are seldom seen except in experimental infections. Initially, the leaflet of the valve becomes swollen and an irregular ulcer develops on its surface, in which the bacteria localize. From this ulcerated area the characteristic vegetative structures develop. These have a similar composition to thrombi, except that they contain few platelets. Several layers of thrombus-like material are deposited on the affected valve in response to the bacterial activity, so that vegetations assume a cauliflower or wartlike appearance and the valves become distorted and shrunken and functionally incompetent. Fragments of the vegetation may become detached to form emboli, which lodge in other organs.

Signs

All ages of cattle are affected although Larsen (1963) found that nearly half of the 53 bovine cases he encountered were in animals between two and three years of age. Both Evans (1957) and Biering-Sørensen (1963) found that 3.9 per cent of cattle examined in abattoir surveys had either died from, or been slaughtered because of, endocarditis.

The published descriptions of the clinical signs of bovine endocarditis are varied and reflect the stage to which the endocarditis had progressed and also the extent to which the clinical signs were attributable to the primary focus of infection (Evans, 1957; Power & Rebhun, 1983). Thus the initial signs may not indicate

heart involvement and the onset of the clinical signs of endocarditis may be insidious.

A recurrent or persistent fever of 40–41°C (104–106°F), anorexia, depression and a reluctance to move are the usual early signs. Pinching of the withers and ballottement of the sternum ventral to the heart elicit a pain response. The heart rate is accelerated to 100–120 beats/minute and in due course the jugular vein becomes engorged, which is followed by oedema of the brisket and submandibular areas. The detection of a heart murmur on auscultation is an important clinical feature, but this is not easily detected when the right atrioventricular valves are involved. Lacuta *et al.* (1980) have reported on the value of electrocardiography and echocardiography in the diagnosis of endocarditis. Whilst echocardiography is of value in that it will demonstrate reflected echoes from the vegetative lesions and detect abnormal valve movements, electrocardiography is less so because the abnormalities shown are not diagnostic of endocarditis.

As the disease progresses, secondary involvement of other organs and systems occurs, leading to pneumonia, nephritis, arthritis, etc. Progressive weight loss, anaemia and weakness inevitably is followed by recumbency and death. The course of the disease may extend from one or two weeks to two or three months.

Pathology

Blood samples from affected animals show a leucocytosis and a shift to the left, although in the more chronic cases these changes are less well marked. Plasma fibrinogen levels are elevated (Wuijckhuise-Sjouke, 1984) but this is a feature of inflammation of serous membranes as well as endocarditis. The causal organism can be isolated on blood culture during periods of fever but at least 20ml of blood are necessary and the cultures may have to be repeated on a number of occasions.

The heart lesions found at necropsy are fairly constant (Plate 44.3). The pericardial sac is distended with varying amounts of oedematous fluid and the heart is enlarged and distorted, due to hypertrophy of the myocardium and dilatation of one or more chambers, because of the incompetence/stenosis of the affected atrioventricular valves. In the majority of cases the right atrioventricular valves are affected. The affected valves are shrunken and thickened, particularly in the later stages, and attached to them there are wart-like or cauliflower vegetations.

The parenchymatous organs may show pathological changes. The lungs are passively congested with frequently a number of embolic infarcts, and the liver is usually enlarged due to passive venous congestion and may show evidence of cirrhosis. Numerous small haemorrhagic foci are scattered over the surface of the

kidneys and within the cortex and there may be a number of infarcts or abscesses in the cortex.

Diagnosis

The clinical diagnosis of endocarditis is dependent upon the detection of heart murmurs, which may be extremely difficult when the lesions involve the right atrioventricular valves. Thus it may be difficult or impossible to differentiate between endocarditis and pericarditis (p. 731) (John, 1947) or other causes of congestive heart failure. Cardiac lesions of enzootic bovine leukosis (EBL) (p. 695) may also produce signs of congestive heart failure, but affected animals show a persistent lymphocytosis and are positive to the agar gel immunodiffusion and ELISA tests for EBL.

Treatment

The organisms associated with bovine endocarditis are sensitive to a range of antibiotics. However, the nature of the heart lesions is such that therapeutic concentrations of antibiotic may not penetrate through to the bacteria. Furthermore, the permanent damage inflicted on the heart valves and the embolic lesions in other organs cannot be effectively repaired. Thus treatment of ailing animals is unlikely to lead to complete recovery. Although temporary improvement may occur after intensive antibiotic treatment for seven to ten days, a relapse within seven days is the usual outcome. However, Power and Rebhun (1983) reported that nine cows, in which an early diagnosis had been made, responded to long-term penicillin therapy.

Haemorrhagic septicaemia

Haemorrhagic septicaemia, or more appropriately septicaemic pasteurellosis of cattle, is a peracute disease, which is characterized by a septicaemia and a very high mortality rate.

Aetiology

Carter and Bain (1960) and Carter (1982) highlighted the confusion and conflict in the terminology of diseases attributed to *Pasteurella* infection in bovines. Thus it is difficult to assess the accuracy of many of the early reports on haemorrhagic septicaemia. It is now considered to be a primary pasteurellosis caused by *Pasteurella multocida* capsular serotypes B and E, which appears now to be confined largely to the tropical countries of Asia. Shirlaw (1938) reported on the occurrence of septicaemic pasteurellosis in the Northumbrian area

of Great Britain in 1926. The lesions in the affected animals were those of a bronchopneumonia and although *Pasteurella* was isolated from the lungs it was not fully typed but likely to have been type B. Since then there have been no further reports of haemorrhagic septicaemia in Great Britain. In the USA only four outbreaks, three in bison and one in cattle, have been confirmed and Carter (1982) speculated on its disappearance from that country.

Pasteurella multocida is not a very resistant organism and it is unlikely to survive for long periods outside the animal body. In soil and mud, for example, where competition from other organisms is strong it does not survive for more than 24 hours (Bain, 1963). Toxins have been demonstrated in culture filtrates, but all the evidence suggests that the most significant of these are endotoxins, which are important in producing the clinical disease and rapid death.

The main source of infection is the carrier animal, the organism localizing in the nasopharyngeal mucosa and tonsils. In herds that experienced haemorrhagic septicaemia 44.4 per cent of healthy cattle were carriers, whereas the carrier rates in three herds in which the disease had not been confirmed were 3.89 per cent, 5.5 per cent and nil (Mustafa *et al.*, 1978). Furthermore, the carrier rate was higher in cattle under two years of age than in adult cattle. It is estimated that approximately 10 per cent of carrier animals become immune.

Spread of infection is through the ingestion of feed contaminated by carrier or clinically affected animals. The role of biting and blood-sucking ectoparasites in the spread of infection is still unclear, although Macadam (1962) suggested on the basis of experimental work in rabbits that ticks could transmit the disease.

It is generally accepted that environmental stress is an important factor in precipitating outbreaks of disease. Outbreaks occur when animals are exposed to cold and wet weather, housed under poor conditions or exhausted by prolonged periods of work. Under such circumstances the immunity of carrier animals wanes, allowing a rapid multiplication of the organism and spread within the carrier animal and its subsequent dissemination to susceptible contact animals.

Signs

The disease may be peracute with death frequently occurring so rapidly that few, if any, clinical signs are observed. In the acute form, there is a sudden onset of fever (41–42°C, 106–108°F), severe depression, oedema of the throat, profuse salivation and rapid death, usually in less than 24 hours. The oedematous form of the disease is also acute with the development of hot painful swellings of the head, throat, brisket, perineum and limb(s). Severe oedema of the head and throat may

result in dyspnoea and eventually death through asphyxiation rather than death from a septicaemia.

Pathology

Large numbers of *Pasteurella* organisms can be demonstrated in the nasal discharges and saliva of clinically affected animals. The course of the disease is usually less than 14 hours, which limits the opportunities for carrying out laboratory examination on specimens from ailing animals.

On post-mortem examination the most prominent features are widespread petechial haemorrhages on the serous membranes and in various organs, especially the lungs and muscles, and a subcutaneous oedema of the throat region. The lungs are oedematous, may also show an early interstitial pneumonia and often there is a haemorrhagic gastroenteritis. In the oedematous form of the disease, there is widespread oedema of the head, tongue, brisket and/or one or more limbs as well as widespread petechiation. The spleen is not greatly enlarged.

Diagnosis

The regional occurrence of the disease is of some aid in diagnosis, but the clinical signs, rapid course and necropsy findings are similar to those of other diseases, e.g. anthrax (p. 717), clostridial myositis (p. 723), acute leptospirosis (p. 735), so that confirmation can only be achieved by isolation and identification of the causal organism. *Pasteurella multocida* can be readily isolated from heart blood, spleen, liver and other sites, but identification of the specific serotypes may require submission to specialist laboratories.

Treatment and prevention

Pasteurella multocida is sensitive *in vitro* to a range of antimicrobial substances, including oxytetracycline, florfenicol and penicillin/dihydrostreptomycin and, in theory, therefore treatment of clinically affected animals should be feasible. However, the sudden onset and rapid course of the disease are such that treatment during the very early stages only is likely to be successful. Even if all the organisms are eliminated, death from *Pasteurella* endotoxaemia may still occur (Jubb *et al.*, 1985).

The only effective method of control is vaccination of all herds at risk. A dead vaccine in an adjuvant base containing paraffin and lanolin has proved highly effective when used prophylactically and is also of value in reducing losses if used during an outbreak, immunity persisting for at least 12 months. Persistent subcuta-

neous swellings may develop in some animals and after the administration of some batches of vaccine, anaphylactic shock has occasionally been recorded. A live streptomycin-dependent mutant of *P. multocida* vaccine has been developed (Wei & Carter, 1978) and successfully tested in field trials (De Alwis & Carter, 1980), but does not appear to be commercially available as yet.

The observations of Sawada *et al.* (1985) on naturally acquired immunity to *P. multocida*, capsular types B and E, are of considerable interest. They found, on the basis of serological and passive immunity tests in mice, that 81 per cent of feeder calves were immune to type B and 91 per cent to type E. The immunity appeared to develop in the absence of either of these serotypes in the microbial flora of the calves.

Infectious necrotic hepatitis (black disease)

Infectious necrotic hepatitis is a highly fatal acute or peracute infectious disease of sheep and cattle, characterized by the presence of one or more necrotic areas in the liver, in which *Cl. novyi* type B has multiplied and produced lethal toxins.

Aetiology

The causal organism is *Cl. novyi*, which like other clostridia is a Gram-positive spore-bearing bacillus, widely distributed in the environment, particularly in soil. The more pathogenic types, however, are more prevalent in those areas where infectious necrotic hepatitis occurs. After ingestion, spores are transported to the liver and other locations, where they remain as a latent infection. On the basis of toxin production a number of types are recognized, but infectious necrotic hepatitis in cattle is caused by type B, which produces large amounts of the lethal alpha toxin.

The disease occurs in cattle and sheep in those areas where liver fluke infection also occurs (p. 276), and it has been demonstrated experimentally in sheep that migrating immature liver fluke produce liver damage and through this an environment suitable for the activation of the latent infection. It is assumed that the same sequence of events occurs in cattle, although Williams (1964) noted the absence of liver fluke damage in some confirmed cases. It has been demonstrated that the survival of *Cl. novyi* and *Fasciola hepatica* is favoured by the same type of soil environment (Bagadi & Sewell, 1973). Other migrating parasites, e.g. the intermediate stages of certain canine cestodes, may also activate latent *Cl. novyi* infection.

Fig. 44.2 A typical black disease lesion in the vertical lobe of a bovine liver. Note the central necrotic area surrounded by a zone of congestion.

The organism multiplies rapidly in the damaged liver and large amounts of the lethal and necrotizing toxin are formed, which leads to the production of the characteristic lesion. The toxin is rapidly absorbed, leading to a systemic toxæmic and it is only rarely that the organism can be recovered from other organs in the fresh carcass.

The disease has been confirmed in most countries where fascioliosis occurs. Cattle of all ages may be affected; Williams (1964) found that in a series of 46 cases, one was in a six-month-old calf, two were in cows over seven years old and the remainder in bullocks and heifers between one and two years old. There is little information on morbidity rates in cattle, but experience in the UK indicates that in most herds only single animals succumb. It is likely, however, that the disease is becoming more common in some areas.

Signs

Most cattle with infectious necrotic hepatitis are found dead but, in some, illness may last for one to two days (Herbert & Hughes, 1956). Affected animals develop severe depression, are disinclined to move, with a normal or slightly elevated temperature. Signs of discomfort are exhibited on palpation of the liver region.

Pathology

Because of the acute nature of the disease it is not possible to carry out ante-mortem laboratory examinations.

Animals dying from the disease are usually in good condition. The subcutaneous vessels are engorged and

clear gelatinous fluid in variable amounts is present in the axillary and inguinal regions, and over the brisket. Fluid, sometimes bloodstained and containing fibrin strands, is present in the pleural and peritoneal cavities and in the pericardial sac. Haemorrhages are scattered over the endocardium and sometimes over the epicardium, parietal pleura and peritoneum. The mucosa of the abomasum is usually congested and often the abomasal wall is distended by a gelatinous oedema. The duodenum and jejunum may show a patchy mucosal congestion.

The pathological changes in the liver are characteristic. The organ is a dark brown colour due to venous congestion and the gall-bladder is usually distended. One, two or more sharply demarcated yellowish necrotic areas up to 8 cm (3 inches) (Fig. 44.2) or more in diameter may be identified, most frequently on the surface but also in the depths of the parenchyma, where they may be missed unless the liver is carefully palpated and sectioned with a knife. The necrotic area is surrounded by an obvious zone of deep congestion. Lesions may be found anywhere in the liver, but the majority tend to be located in the ventral lobe. Evidence of liver fluke migration in the form of subcapsular haemorrhages and greenish yellow scars (accumulations of eosinophils) may be evident near the lesion.

Microscopical examination of sections prepared from the liver lesions show a central core of necrotic tissue demarcated from the congested parenchyma by a leucocytic barrier (Fig. 44.3). Within the barrier and at the periphery of the necrotic tissue, large numbers of vegetative clostridia are evident. The hepatic cells immediately adjacent to the leucocytic barrier show degenerative changes.

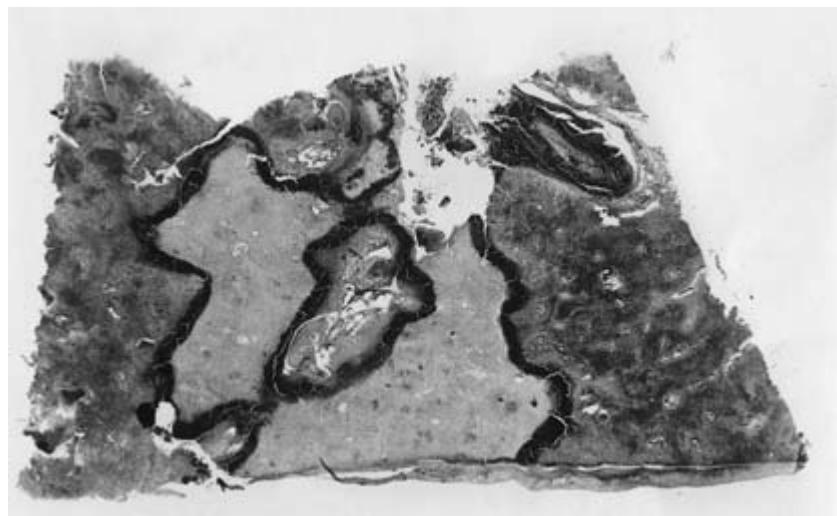

Fig. 44.3 A section through a black disease lesion demonstrating the central necrotic area and the clearly stained leucocyte barrier. (Haematoxylin and eosin, $\times 5$.)

Diagnosis

The post-mortem findings of the characteristic lesions provide a firm basis for arriving at a diagnosis. Fluorescent antibody techniques can be used for the rapid identification of *Cl. novyi* in impression smears made from the periphery of the liver lesion as described by Batty *et al.* (1964). Toxins may also be demonstrated in the liver lesions and peritoneal fluid (Williams, 1964), although the laboratory tests for these are laborious and time-consuming. If the post-mortem findings are inconclusive and the carcass shows evidence of decomposition then the fluorescent antibody and toxin tests cannot be reliably used, since *Cl. novyi* may have multiplied in the liver and other locations after death (Bagadi & Sewell, 1974), and some of the strains found in livers are of low pathogenicity (Williams, 1964) but are detected by fluorescent antibody techniques.

Other cases of sudden or rapid death have to be considered in differential diagnosis and these include anthrax (p. 717), other clostridial infections such as clostridial myositis (p. 723), lead poisoning (pp. 906, 944) and metabolic disorders (Chapter 46). It is vital that blood smears for anthrax diagnosis be examined before post-mortem examination is carried out and thereby prevent environmental contamination with anthrax spores.

Treatment and prevention

There is little opportunity for effective treatment, although in those cattle that are ailing for one to two days, the administration of broad-spectrum antibiotics or penicillin and *Cl. novyi* antiserum may be of value.

Effective vaccines have been developed and in areas where liver fluke occurs their use should be advocated.

Two doses of vaccine at an interval of not less than one month are required to produce a satisfactory immunity (see p. 1005). Because of the association with liver fluke infection, control measures should also be adopted for this parasite. (see p. 278).

Pericarditis

Infection of the pericardial sac by micro-organisms results in a purulent or non-purulent pericarditis with the accumulation of varying amounts of fluid and consequential masking or muffling of heart sounds, and may lead to congestive heart failure.

Aetiology

A wide range of micro-organisms are associated with bovine pericarditis and they include *A. pyogenes*, *Haemophilus somnus*, *Mycobacterium bovis*, *Mannheimia* and *Pasteurella* species, staphylococci, streptococci and *Mycoplasma* species.

Infection with pyogenic bacteria is nearly always primary and frequently associated with traumatic reticulitis. The organisms are introduced during penetration of the pericardial sac by a foreign body originating from the reticulum, or infection may be the result of direct spread from a traumatic mediastinitis. In some instances a purulent infection may be superimposed on an original non-purulent fibrinous pericarditis. Infection of the pericardial sac also occurs through the localization of a blood-borne infection or through the direct extension of a myocarditis or pleurisy.

During the early stages of a purulent pericarditis there is a marked hyperaemia and deposition of a fib-

rinous exudate on the epicardium. Varying amounts of fluid accumulate within the pericardial sac and, as the volume significantly increases, both atria and the right ventricle are compressed to such an extent that their function is impaired and congestive heart failure results. A severe toxæmia may also develop. In some instances, however, the volume of exudate is small and adhesions develop between the epicardium and pericardium, which become organized, resulting in complete attachment of the epicardium and pericardium, impaired cardiac function and congestive heart failure.

In non-purulent or fibrinous pericarditis, there is seldom a significant exudation of fluid and therefore no marked distension of the pericardial sac. The epicardium is hyperaemic and fibrinous deposits appear at the base of the heart, which subsequently spread over the whole of the epicardium and internal surface of the pericardium. Adhesions develop between the epicardium and pericardium, but these are not sufficiently dense or strong to impair cardiac movement.

Signs

The early clinical signs of pericarditis are often difficult to identify because they are obscured or dominated by those of the primary disease, e.g. pleurisy, traumatic reticulitis, and the onset of pericarditis may therefore be insidious. Arching of the back, reluctance to move, shallow and rapid abdominal respirations and elevation of body temperature to 40–41°C (104–106°F) are the initial signs. The pulse rate is increased, and percussion and palpation over the cardiac area of the thoracic wall elicits a pain response. It may be possible to detect a rough pericardial friction sound by auscultation during the early stages, but this is by no means easy and may be missed.

As the condition progresses, fluid accumulates in the pericardial sac and the heart sounds become muffled, although sometimes a splashing sound may be detected. The signs of congestive heart failure, engorged jugular veins, a jugular pulse and subcutaneous oedema of the submandibular space, brisket and inguinal region, develop and most animals die within one or two weeks.

Some animals survive the acute phase with antibiotic treatment, and the signs of congestive heart failure abate slowly. However, complete recovery seldom if ever occurs and recovered animals should be sent for slaughter at the earliest opportunity.

Pathology

Blood samples from animals affected with a purulent pericarditis, especially traumatic pericarditis, show a marked leucocytosis and a shift to the left. However,

the overall haematological picture depends to some extent on the causal agent and other lesions that may be present, so that the total white cell count may vary from only marginally above the normal range to more than 30000/ μ l.

The cardiac lesions found at post-mortem examination depend on the type of infection and the duration of illness. In acute purulent pericarditis the pericardium and epicardium are thickened and covered by a fibrinous deposit, and the pericardial sac distended with fluid, which varies from a dirty grey to a yellowish green colour with a foul odour. The atria and the right ventricle are compressed. When the condition is associated with traumatic injury it may be possible to identify a foreign body, but should this be wire it may have disintegrated. Occasionally, a rupture of one of the coronary vessels, an atrium, or ventricle may occur in traumatic pericarditis and under such circumstances the pericardial sac contains a mixture of blood and purulent fluid. In more chronic cases, the grossly thickened pericardium and epicardium are closely adherent except for loculi containing inspissated or thick creamy pus giving a ‘bread and butter’ appearance. Signs indicative of congestive heart failure are also identifiable and these include congested liver and lungs, engorged jugular veins and subcutaneous oedema of the submandibular space, brisket and inguinal region. If the pericarditis is associated with other conditions, e.g. traumatic reticulitis, pneumonia or pleurisy, then lesions attributable to them will also be present.

Evidence of a non-purulent or fibrinous pericarditis is sometimes seen in apparently healthy animals dying from other causes. In such animals there is a patchy or diffuse thickening of the pericardium with similarly distributed adhesions to the epicardium, which can be easily broken down. There is no evidence of interference with the cardiac function and the lesions are of no pathological significance.

Diagnosis

The clinical diagnosis of pericarditis is not easy because the signs may be dominated or obscured by those of the primary disease and it may be difficult to recognize the pericardial sounds. The characteristic friction sounds in the early stages may be confused with those of pleurisy, although the latter is synchronized with the respiratory movements. Similarly, the pericardial sounds may resemble the murmurs (p. 727) produced by valvular lesions, but unlike the murmurs, they persist for the whole of the cardiac cycle. The heart sounds may also be muffled by effusion associated with pleurisy but under such circumstances there are signs of respiratory involvement.

Treatment

Although long-term therapy with antimicrobial agents is indicated, it seldom results in complete recovery, especially when the pericarditis is traumatic in origin. Thus Blood and Hutchins (1955) report that only about 50 per cent of cattle with traumatic pericarditis treated with sulphamezathine and/or penicillin responded and were sufficiently recovered for salvage. Surgical drainage of the pericardial sac either by pericardiocentesis or pericardiotomy as described by Horney (1960) may also have to be considered. However, it must be emphasized that pericardiocentesis offers only temporary relief of less than 24 hours duration in most cases. There are a number of reports on the successful treatment of fibrinous and traumatic pericarditis by pericardiectomy (Jennings & McIntyre, 1957; Krishnamurthy *et al.*, 1979; Mason, 1979).

Tetanus

Tetanus has long been recognized as a highly fatal disease of all species of farm livestock. The disease is produced by the toxin of *Clostridium tetani* and is characterized by hyperesthesia, tetany and convulsions.

Aetiology

Clostridium tetani is a spore-bearing organism and is considered to be one of the least fastidious clostridia as far as growth requirements are concerned. The spores are extremely resistant to environmental conditions. The organism has two main habitats, namely the soil and gastrointestinal tracts of animals and humans. It has been suggested that the main reservoir of infection for animals is soil. The organism produces a number of toxins, but the neurotoxin is the one of principal importance.

The portal of entry is usually through a deep puncture, although in cattle introduction into the genital tract at the time of parturition is also important. The organism may also gain entry into surgical wounds, e.g. after castration, and may be introduced into muscle during vaccination and other injections. There are however outbreaks of disease in cattle in which the organism has not localized in any tissue site but remained within the gastrointestinal tract, and such outbreaks are designated as idiopathic tetanus (Wallis, 1963).

After gaining entry into the tissue, the organism remains localized. Multiplication will only occur if optimal conditions develop at the site of infection. If at the time of initial injury there is sufficient tissue damage

and a lowered oxygen tension, immediate growth and toxin production will occur. However, such conditions may only be attained after healing at the surface has occurred, so that multiplication and toxin production may be delayed. Thus the incubation period may vary from a few days to four weeks or more. In idiopathic tetanus it would appear that the neurotoxin is produced in the rumen (Smith & Holdeman, 1968).

From the site of production the neurotoxin reaches the central nervous system via the peripheral nerve trunks. The exact mechanisms of transport are not known, nor are the means by which the toxin exerts its influence on the nervous system. Smith & Holdeman (1968) state that the neurotoxin can also reach the central nervous system via lymph and blood.

Individual or small numbers of animals are usually affected in a herd, but in outbreaks of idiopathic tetanus many animals may be affected.

Signs

As the incubation period may vary quite considerably it is not always possible to relate the onset of clinical disease to specific incidents of injury or surgical interference. The first signs are those of apparent stiffness and reluctance to move, accompanied by muscle tremors that become more pronounced. Another early sign in some cattle is prolapse of the third eyelid, which becomes more prominent with handling of the head. These signs are progressively followed by the appearance of a slight but persistent ruminal tympany, elevation of the tail, unsteady gait of the hindlimbs, especially when turning, and trismus with saliva drooling from the mouth. Because of inability to adopt the normal urinating posture, urine is retained. Further progression leads to generalized muscular tetany with the adoption of a 'rocking horse'-like posture. Attempts at walking lead to lateral recumbency and an inability to rise. Tetanic convulsions and opisthotonus soon develop. Initially, the convulsions are triggered by external stimuli, but later these occur spontaneously. The duration of fatal disease in young cattle is four to five days, but older cattle may survive for up to 10 days. Non-fatal cases do occur, but generally these do not progress to the convulsive stage and recovery is slow over a period of weeks or sometimes months.

Pathology

There are no tests available for the diagnosis of tetanus in the live animal and any tests undertaken would be for the purpose of eliminating those conditions that produce similar clinical signs. Nor are there any gross or microscopic pathological findings that would confirm

tetanus, although attempts should be made to identify the site of infection and culture the organism.

Diagnosis

Because of the distinctive clinical signs, classical tetanus is seldom confused with other diseases. Clinical hypomagnesaemia (p. 255) in calves and cattle (p. 787) is accompanied by tetany and convulsions, but there is no prolapse of the third eyelid or ruminal tympany, and low blood calcium and magnesium levels are diagnostic. Cerebrocortical necrosis (CCN) (polioencephalomalacia) (p. 261, 903) may produce a similar clinical picture, except that again there is no prolapse of the third eyelid and no ruminal tympany. Also, in CCN the erythrocyte transketolase activity is decreased and blood pyruvate and lactate levels are increased, and classical lesions are obvious at necropsy. Some cases of lead poisoning (pp. 906, 944) may also show similar clinical signs, but elevated blood and kidney/liver lead values are diagnostic. Strychnine poisoning is extremely rare in cattle in Great Britain and is usually associated with the ingestion of earthworms treated with strychnine. Strychnine is used for the destruction of moles, and can be identified in the abomasal contents. It is used in other counties, often illegally, to kill wildlife. Bovine spongiform encephalopathy (p. 909) may also need to be differentiated but the signs usually develop over a longer period than tetanus.

Treatment and prevention

Cattle appear to respond better to treatment than horses and sheep, although it is unlikely that fully developed tetanus will respond and therefore under such circumstances euthanasia should be considered.

When treatment is undertaken it should have three objectives: elimination of *Cl. tetani*, neutralization of unfixed neurotoxin and the induction and maintenance of muscle relaxation until all the neurotoxin has been destroyed or eliminated.

Large doses of penicillin administered parenterally is the recommended treatment for *Cl. tetani* infection and this should be supplemented by treatment of the infected site (if located) by irrigation and topical application of antibiotics. Thus treatment should continue for at least seven days.

The administration of antitoxin for the neutralization of unfixed neurotoxin is considered to be of little value unless administered during the very early stages of the disease. If the site of infection has been identified then local injection of the antitoxin may be of value.

A number of drugs have been used to relieve muscle tetany, but because of the need for long-term relaxation some are not suitable because their activity is of short

duration. The recommended drugs (Radostits *et al.*, 2000) are chlorpromazine (0.4 mg/kg body weight intravenously, 1.0 mg/kg body weight intramuscularly) three to four times daily and acetyl promazine (0.05 mg/kg body weight), administered twice daily for eight to ten days or until the severe clinical signs have disappeared.

Animals that are treated should be kept in dark quiet surroundings with ample bedding and sufficient space to avoid injuring themselves if convulsions occur.

On farms where tetanus is a problem, vaccinations should be routinely undertaken (see p. 1005).

Leptospirosis (other than *Leptospira hardjo* infection)

Aetiology

There are many different serotypes of *Leptospira interrogans* present in cattle.

Aetiology

Many serotypes do occur but probably the most important are *L. interrogans* serovar *icterohaemorrhagiae* and serovar *canicola*. *Leptospira interrogans* serovar *pomona* has been found in many countries to be the commonest infection of farm animals. It has only recently been found in Britain and the strain appears to be different from the one causing abortion in pigs. In many cases there are carrier animals and often these are rodents. The leptospires survive in the environment if conditions are wet. However, they are inhibited at a pH less than 6 or greater than 8. Temperatures below 7–10°C (44.5–50°F) or above 34–36°C (93–96°F) are detrimental. The organisms can survive over four months under wet conditions but only 30 minutes when the soil is dried. It often survives in the environment in average conditions for about one and a half months.

Most infection is spread via contaminated feed or water. It must be remembered that most serovarieties are able to infect many species including man.

Mortality rate is usually low at about 5 per cent.

Signs

Acute: The cow is often ill with a pyrexia of 40–41°C (104–106°F) with dullness and anorexia. The milk yield drops and often there are haemorrhages under the mucous membranes, and there is often jaundice and haemoglobinuria. In some cases there is synovitis or a necrotic dermatitis. Occasionally, meningitis has been recorded.

Subacute: In this form the signs are milder with a temperature of 39–40°C (102–104°F). The animal has a reduced milk yield and is dull. Jaundice occurs in some cases and there is usually some haemoglobinuria. In some cases abortion occurs about a month later.

Chronic: This is not common and results in abortion.

Necropsy

Acute: There are often submucosal and subserosal haemorrhages, jaundice, anaemia and haemoglobinuria. In some animals there is ulceration of the abomasal mucosa and emphysema. Histological examination often shows an interstitial nephritis as well as centrilobular hepatic necrosis.

Subacute or chronic cases are more likely to show a progressive interstitial nephritis with white foci on the surface of the renal cortex.

Diagnosis

This depends on finding the organism. Otherwise, paired serum samples can be examined for a rise in *Leptospira* titres.

Differential diagnosis

Any form of haemoglobinuria will need to be eliminated, including babesiosis (p. 748), which is usually seen in the summer in tick areas. Kale poisoning (p. 941) and postparturient haemoglobinuria (p. 792) should be partly diagnosed by the history and the low plasma phosphorus levels in the latter. Bacillary haemoglobinuria (p. 719) will be differentiated by the presence of clostridia.

Treatment

The main therapy is usually antibiotics such as dihydrostreptomycin or the tetracyclines. Treatment should be given as soon as signs develop. Blood transfusion often helps. The farmer should be warned of possible human infection.

Control

Separate the infected cow. If it is partly due to rodent build-up, control the rodents. Ensure removal of brackish water and provide good drainage. Vaccination could be used, as with *L. interrogans* serovar *canicola* or *icterohaemorrhagiae*, but as cases are usually sporadic this does not tend to be used.

***Leptospira hardjo* infection (flabby bag)** (see p. 580)

Aetiology

Infection with *Leptospira borgpetersenii* serovar *hardjo* (*Hardjo bovis*) and *Leptospira interrogans* serovar *hardjo* (*Hardjo prajitno*), spiral organisms.

These are a common cause of abortion in Britain, although they have only recently been readily diagnosed. *Leptospira borgpetersenii* sv *hardjo* appears to be better adapted to cattle; it is excreted in large numbers in urine although it is less frequently isolated from aborted fetuses whereas *L. interrogans* sv *hardjo* appears to be less well adapted in cattle (possibly more in sheep), while isolated from Britain, India, Nigeria, Malaysia and the USA, it has not been seen in Australia and New Zealand; urine shedding of organisms is low, but it is more frequently found in aborted fetuses and is relatively more pathogenic.

Up to 50–60 per cent of British farms may be infected. In Northern Ireland 41.6 per cent of randomly selected aborted fetuses were infected (Ellis *et al.*, 1982) and the level rose to 68.9 per cent of fetuses from farms with abortion problems. A very common problem in New Zealand, most cases are in the dairy herd rather than beef cattle. Humans can be infected but they must be exposed to concentrated infection, i.e. contact via urine while milking. Although infection is present in the milk, it quickly dies off once taken from the udder. Meat does not carry infection. Spread occurs more rapidly in wet seasons in low-lying areas. Colostrum-derived protection normally lasts about three months. Serological rises in *L. hardjo* titres following infection tend to be short-lived, i.e. a few months to a year or so. It was originally considered to be a winter disease. However, carriers often stop or reduce excretion on silage. Most infection now occurs in the summer, often with abortion in the summer or early autumn. Serology in individual animals is difficult to interpret because the bacteria are in the lumen of the kidney or uterus.

The spread of infection takes place cow to cow via urine, fetuses and uterine discharge, and from bull to cow by infected semen. The source of infection is via carrier cows or infected calves, which may be chronically infected, but it may possibly be spread by contaminated water or sheep on the farm.

Signs

There are two main syndromes, the udder form and abortion.

Severe udder form: In a cow or heifer the udder signs will not be apparent until the animal has calved. This form occurs soon after the infection enters a herd. There is a sudden drop in milk yield affecting all four quarters, with pyrexia usually between 40 and 41.5°C (104–107°F). The udder secretion becomes thickened and clotted, occasionally it is bloody or it can be yellow and colostrum-like. The udder itself is not swollen or inflamed but tends to be flaccid. In a six to eight-week period, 30–50 per cent of the herd may be infected. The condition usually resolves over seven to ten days (see p. 580).

Mild udder form: Many cows are infected and show only a slight drop in milk yield.

Abortion: This usually occurs six to twelve weeks after the dam is infected. Abortion can occur on its own or be preceded by the milk drop syndrome. Most cases of abortion occur in the second half of pregnancy. If infection occurs late in pregnancy then an infected calf may be born. There may be some apparent infertility in the herd (see p. 580).

Necropsy

Abortion: There are usually no useful macroscopic features in the aborted fetus.

Diagnosis

Udder form: History helps in diagnosis, in particular the sudden onset of the problem. The signs, sudden loss of milk, flaccid udder, are useful. The Californian Milk Test is positive and there is a high milk white cell count. Identification and culture of the organisms from urine (it can occasionally be isolated from milk and blood in the acute stages) is a definitive diagnosis. Paired serum samples can be used for the complement fixation test, microscopic agglutination test and plate agglutination test. High titres over 1/300 indicate recent exposure to infection. Microagglutination titres are found from 10 days after infection; their peak and duration depend on the serotype and route of infection. IgM titres appear first but peak two to three weeks after infection whilst IgG levels appear later and peak 12–30 weeks post infection (G.S. Dhaliwal, pers. com.). Serum and vaginal mucus antibody tests are also available.

Abortion: Identification of the bacterium in the fetus, especially in the lungs, kidneys or adrenal glands, by fluorescent antibody studies, is the main method of

diagnosis. It can also be isolated from abortion or post calving discharge. Culture of the bacteria can be undertaken. Fetal serology can also be used. Antibodies may be detected in post calving discharges and cervical mucus. Serology of the dam can help but often antibody titres may be static or falling by the time of abortion. It is very difficult to detect carrier animals, as up to 25 per cent are serologically negative. Bulk herd milk samples can indicate the presence of infection and also give some suggestion of infection levels.

Differential diagnosis

Other leptospiral infections (p. 734), salmonellosis (Chapter 15), foot-and-mouth disease (p. 700), and mastitis (Chapter 23) must all be considered in the udder form. In abortion, (p. 578) salmonellosis, mucosal disease, brucellosis, *Neospora carinum* infection (pp. 283, 584) and infectious bovine rhinotracheitis are some common causes to be differentiated.

Treatment

Large doses of dihydrostreptomycin (25 mg/kg body weight) may help remove the organism and prevent kidney and liver damage. All cattle due to calve should be vaccinated. In countries where dihydrostreptomycin is not available, amoxycillin appears to be equally effective.

Control

Vaccination is possible with a killed strain (p.1015). The vaccines available may contain *Hardjobovis* or *Hardjoprajitno* strains; there is not always cross-protection between the two strains. *Hardjoprajitno* vaccines may produce a longer duration of immunity (G.S. Dhaliwal, pers. comm.). Both vaccines will control abortion and improve fertility in endemic herds. Vaccination of young stock may also produce benefits. Vaccination involves two initial doses at least four weeks apart. If cattle are young when vaccination commences then two doses are required after five months of age. An annual booster is recommended but two vaccinations a year may be required in herds that calve in the autumn. It does not affect animals that already have milk drop syndrome. Vaccination does help prevent abortion but infected cows may still excrete bacteria. It is therefore advisable to treat all adult cattle with dihydrostreptomycin before commencing a vaccination programme.

Any bought-in animals, and especially bulls, should be isolated and treated with antibiotics and vaccine

before entering the herd. Reducing exposure to potentially contaminated water supplies and to pasture grazed by sheep is a sensible management control.

***Haemophilus somnus* infection**

(see p. 907)

Aetiology

A Gram-negative small rod-shaped organism. Most strains of the organism are antigenically similar.

Epidemiology

It is seen in North America and Europe. Inapparent infection occurs more frequently than clinical disease. Problems occur more frequently in younger animals. The portal of entry of infections is often via the respiratory tract although it is also found in the reproductive and urinary tracts. Disease is probably a septicaemia with localization. Single or several cases may occur.

Signs

The peracute form often causes sudden death. The acute form is often seen as the sleeper syndrome or thromboembolic meningoencephalitis (TEME) in growing cattle. The animal is depressed, with closed eyes, and recumbent. Usually there is pyrexia (40–42°C, 104–108°F). Nervous signs can be of muscle tremors and hyperaesthesia. The animal may be blind with retinal haemorrhage. Other syndromes include synovitis with initial lameness. Pneumonia is a common finding, particularly in calves, and often associated with pleurisy (see Chapter 17). Abortion can occur and so can chronic bloat.

Pathology

There may be focal or diffuse cerebral meningitis with characteristic haemorrhagic infarcts in the brain. Haemorrhages can occur in other organs. In the joint form the synovial membranes are oedematous with petechial haemorrhages. There is often inflammation of the pericardium, peritoneum and pleura which may be serofibrinous or fibrinous. Histologically there is often a vasculitis and thrombosis, often with infarcts and accumulation of neutrophils.

Prognosis

Recumbent cattle often do not recover and usually, if there is no response after three days' treatment, the condition is irreversible.

Treatment and control

High doses of intravenous tetracyclines for at least three days can be useful. Otherwise ampicillin, amoxy-cillin, florfenicol, novobiocin, sulphonamides or potentiated sulphonamides can be administered. Once disease is diagnosed, extra observation must be undertaken of in-contact animals. Control is difficult, although in North America an aluminium hydroxide adjuvanted vaccine is now used.

Pyaemia

Pyaemia is defined as a clinical or pathological state characterized by the formation of multiple secondary abscesses in a number of organs and/or tissues.

The primary pyogenic infection may occur in a number of sites and the formation of metastatic lesions in other organs and tissues follows the entry of organisms into the circulation. Small numbers of organisms may intermittently gain entry via the lymphatic drainage of the primary lesion, to produce a bacteraemia, followed by localization and the formation of secondary abscesses. More frequently, however, a septic thrombus is formed within the primary lesion and portions of this become detached to form emboli, which are then arrested in the capillary bed of an organ or tissues to form the metastatic lesions. The most frequent sites for secondary abscess formation are the valvular endocardium, myocardium, lungs and joints, although the liver and kidneys may sometimes be involved.

In cattle, pyaemia is often associated with septic metritis and mastitis, and *A. pyogenes* is the organism most frequently incriminated. Staphylococcal mastitis may also lead, in some cases, to pyaemia. On occasions, hepatic abscesses and foul in the foot caused by *Fusobacterium necrophorum* may also result in pyaemia.

Because pyaemia is a form of generalization of a primary infection, the clinical signs, diagnosis and treatment must be considered in relation to the primary infections referred to above and which are discussed in the appropriate sections of the text.

weeks, and by late autumn *H. bovis* has reached the epidural fat within the vertebral column and *H. lineatum* the submucosa of the oesophagus. The larvae remain in these sites during the winter, moulting to their second stage of development. At the end of the winter they resume migration both reaching the subdermal tissue along the back in the spring. They make a hole in the overlying skin through which they respire while developing to the third stage, which reaches a length of 2–3 cm and is characterized by rows of small spines on the posterior margin of most of its segments and posterior spiracles on a terminal tuberosity. The creamy-white larvae emerge from the back of the animal in April and May and fall to the ground to continue development by pupation, eventually emerging as adults five weeks later. They have a short lifespan as adults, mating, laying eggs and dying within two weeks of emergence.

Pathogenesis

The larvae are most pathogenic during two phases of their development. The first is during the late autumn and winter, when they are in epidural fat or oesophageal wall respectively. If present in large numbers, or if treated killed *in situ*, the anaphylactic reactions may cause damage to the spinal cord that can result in either spinal paralysis or difficulty in swallowing and eructation, which can lead to bloat. The second is during their pre-emergence development, where they damage the subdermal tissue and skin of the back and cause subsequent downgrading of hides and trimming of carcasses, and cause irritation and loss of growth in the live animal.

Signs

In the late autumn and winter, occasionally there can be damage to the spinal cord resulting in paralysis, difficulty in standing or bloat. In the spring, there are swellings under the skin 55–75 cm either side of the midline containing pus, a breathing hole and a third stage larva.

Diagnosis

If disease results during their winter development, the symptoms have to be differentiated from other causes of spinal or oesophageal paralysis. There is an ELISA test available that detects antibody to migrating larvae and, although originally designed to aid eradication programmes, it may be helpful in diagnosis. When larvae are in their pre-emergence sites on the back their presence is unmistakeable since no other condition causes similar lesions, especially if a heavy infection is present.

Treatment

The larvae are susceptible during their migration to systemic organophosphorus insecticides and the anthelmintics ivermectin, doramectin, eprinomectin, abamectin and moxidectin. Care should be taken not to treat cattle when larvae are in their overwintering sites, as death *in situ* and subsequent lysis may result in anaphylaxis. For that reason statutory eradication policies have compulsory treatments applied before mid November, coupled where necessary with inspection and further treatments in the following spring.

The organophosphorus treatments are normally applied dermally as pour-on preparations. A large number are available, the most popular currently being phosmet and crufomate. Mass treatment has resulted in eradication from many islands although it has proved more difficult on large land areas. Avermectins, although highly effective, are not normally used in mass eradication campaigns since their primary use is as an anthelmintic, although if a single animal in a herd is found to be infected the entire herd is usually treated with them. Although prophylaxis against adult flies is not actively undertaken, slow-release devices such as ear tags impregnated with organophosphorus compounds or synthetic pyrethroids do reduce the possibility of oviposition by adults.

Lice (*pediculosis*)

Lice are ubiquitous parasites of cattle. In large numbers they cause skin irritation and have been associated with anaemia and may act as vectors of pathogenic organisms (see p. 880).

Aetiology and epidemiology

Lice are host-specific parasites and are classified into two types: (i) sucking lice and (ii) biting lice. Five species infest cattle, four sucking and one biting. The former are *Haematopinus eurysternus* and *H. quadripertitus*, 'short-nosed' sucking lice; *Lignognathus vituli*, 'long-nosed' and *Solenopotes capillatus*, 'small blue' sucking lice. The biting species is *Damalinia bovis*. As might be construed the sucking lice have mouthparts adapted for piercing skin and sucking blood; the biting lice ingest skin and hair detritus, blood and scabs. Each species has a preferential area on animals, but if large numbers are present can be found anywhere on the body surface. Normally, *H. eurysternus* and *D. bovis* are found on the poll, neck and head and the latter also along the mid dorsal region of the body. *Lignognathus vituli* and *S. capillatus* also favour the head, neck and frequently the ventral surface of the neck, dewlap and axillae. *Haematopinus quadripertitus*

is restricted to subtropical areas and is usually found in the area of the tail and posterior lumbar regions.

The life cycle of lice is direct. Adults live for approximately one month during which time they lay a few hundred eggs, which are tightly attached to hair by a glue-like substance produced by the louse. The eggs hatch within a few days and the first nymph, which resembles a small softer adult, emerges. It undergoes three moults to second and third stage nymphs and finally adults, each nymphal stage taking one week. The entire life cycle from egg to adult occupies approximately three weeks.

There are seasonal variations, especially marked in temperate areas, in the number of lice found on cattle. In these areas numbers on susceptible cattle increase during autumn and early winter, peaking late winter and early spring. There are two reasons for this: (i) cattle are frequently housed in autumn and lice are easily transferred from infested to non-infested animals, and (ii) climatic conditions favour louse activity; strong sunlight and high skin temperatures have been shown to inhibit lice and the converse occurs in winter. Within groups of infested cattle there are always those that carry heavier burdens than others, and it is generally accepted that very large louse populations are indicative of stress or intercurrent illness, poorly fed cattle parasitized by nematodes and trematodes being frequently and characteristically louse infested.

The pathogenic effects of louse infestation have been the subject of much research. It is now considered that light or moderate infections have little effect on cattle. Heavy infestations lead to skin irritation, scratching and rubbing, with resultant damage to hides. Some reports have indicated that large sucking lice burdens may also cause anaemia and weight loss, although it has also been noted that these effects can be prevented by adequate high quality nutrition. Lice may also act as vectors for blood-borne organisms, and have been implicated in the transmission of *Eperythrozoon wenyonii*.

Signs and diagnosis

Louse infestations are usually evident by the presence of eggs adhering to hairs, on the edge of bald areas and on parting of hair careful examination of preferential niches with a magnifying lens will reveal adults and nymphs.

Treatment and control (see p. 1030)

Lice are fairly easily killed by the application of organophosphorus, amitraz or synthetic pyrethroid preparations, either as sprays, pour-ons or dusting powders, although resistance to the last of these has been reported. The residual activity of synthetic

pyrethroids is generally of longer duration. This aspect is important because for complete removal of all lice the activity must not only kill adults but nymphs emerging from eggs. The anthelmintics ivermectin, doramectin, eprinomectin and abamectin because of their long half-life are also extremely effective, removing all sucking and more than 98 per cent of biting lice. If used as a pour-on preparation they are even more effective, and will remove 100 per cent of both species. For preventative purposes, housed cattle can be treated at housing, sometimes complemented by removal by electric clippers of a 15 cm band of hair from the poll to the root of the tail.

Arachnids

Mange

Mange is the descriptive term used for infection of animals by mites, the smallest arthropods of the order Acarina. They are obligate parasites transmitted from infected non-infected animals by direct contact. There are four species that parasitize cattle and two others which are facultative parasites of them and other animals (See p. 881).

Aetiology and epidemiology

Although of the same order, the mites have different morphologies and habitats, and some are classified as 'burrowing' and others as 'non-burrowing'. For these reasons they are described separately.

Non-burrowing mites: One species, *Chorioptes bovis*, is specific to cattle. *Psoroptes ovis*, although primarily a parasite of sheep, can become permanently adapted to cattle. Non-specific mites are those species of harvest mites present on pasture, the larvae of which can infest many different species of animals: the mite species are *Neotrombicula* and *Eutrombicula*.

(1) *Chorioptes bovis*. The most common mite found on cattle. It reaches a length of 0.75 mm and is recognizable by its cup-shaped suckers on short unjointed pedicels. It is seen most frequently during autumn and winter in housed cattle, frequently on the hind legs but also on the neck, the head and root of the tail. It is a surface feeder and produces mild hair loss, lesions increasing in size only slowly. The lesions are obviously itchy as affected cattle will rub affected areas on walls, doors, etc., incurring damage to the skin and subsequent quality of the hide after death.

(2) *Psoroptes ovis*. The mite is normally found on sheep and is the cause of sheep scab, which is notifiable

and government regulated in many countries. The mite is a similar size to *C. bovis* but is characterized by long jointed pedicels with funnel-shaped suckers on the legs. Although similar to *P. ovis* from sheep, which is transferrable experimentally both to cattle and rabbits, the rarity of cases of mites transferring from sheep to cattle and vice versa in nature has led to the conclusion that some adaptation to specific hosts takes place, and that infection of sheep by cattle strains does not occur.

The mite, although a surface feeder, is much more irritant than *C. bovis* since its mouthparts are adapted for piercing skin, causing the formation of serious vesicles, which can coalesce and eventually become scabs. The life cycle is typical for both *P. ovis* and *C. bovis*. Female mites lay approximately 90 eggs. The hatching of eggs and subsequent development from larva to nymph to adult occupies approximately 10 days. Adult mites can live for a maximum of six weeks.

Affected cattle become restless because of the skin irritation. The areas commonly affected are the abdomen, tail root and perineum, and they can become further damaged by scratching. In extreme cases animals may cease to feed adequately and lose weight.

(3) *Forage mites*. The adults and nymphs of the family Trombiculidae are free-living on pasture. Eggs are laid on soil, and larvae crawl on to vegetation and to animals that lie on or brush through the foliage. The larvae are skin-piercers, causing vesicles. Animals become hypersensitive to their secretions and the subsequent rubbing and scratching increases the damage to skins.

Burrowing mites:

(1) *Sarcoptes scabiei*. Mites of this species are host specific although they are morphologically identical to those infesting other animal species. The adults are slightly larger than half the size of *P. ovis* and *C. bovis*. They are characterized by a rounded shape and the presence of triangular scales on the posterior of the dorsum. Adult females burrow tunnels in the epidermis. They lay eggs in tunnels, hatching taking place within a week. The hatched larvae crawl to the surface and create further epidermal tunnels in which they moult through the stage of nymphs to become adults. Males and females mate either in tunnels or on the skin surface and the cycle resumes, the entire length of which occupies three weeks.

Sarcoptes scabiei infections cause extreme irritation. On cattle the preferred sites are the neck and the lumbar area adjacent to the tail, resulting in the colloquial description of 'neck and tail mange', but it can be

found in other areas. Early small lesions exhibit hair thinning and slightly thickened scaly skin, but soon the irritation and resultant rubbing combined with expansion of infected areas result in total loss of hair and thickened, crusted and excoriated skin. Affected animals may become so preoccupied with the irritation that they reduce their food intake, leading to loss of weight or milk production, and secondary bacterial infections may ensue on the most severely rubbed lesion.

(2) *Demodex bovis*. This mite is considered to be a normal commensal found on bovine skin; as for all members of the family Demodicidae it becomes pathogenic only when the efficiency of the immune controls of its host is reduced. The mites are characteristically cigar-shaped, 0.2 mm long, with four pairs of short legs close to the anterior end. Their preferred niches are in hair follicles and sebaceous glands and because of this deep location are not transmitted unless prolonged contact occurs. For this reason it is presumed that the young become infected shortly after birth during feeding from their mother, and as a result lesions are usually seen in cattle on the muzzle, head, neck and back. The lesions take the form of small, 0.75 cm diameter nodules and are follicles or glands filled with mites and caseous pus. In some countries a high proportion of hides may be affected, but in the UK the average prevalence is 17 per cent (Urquhart *et al.*, 1987). The lesions do not normally seriously affect cattle and treatment is not usually necessary.

Diagnosis

All of the mites are too small to be easily seen with the naked eye, and microscopic examination of skin scrapings is necessary, as it is for differentiation of most skin conditions. Mites are normally most easily found in scrapings taken from the edge of lesions. The scrapings are boiled in sodium or potassium hydroxide and centrifuged prior to examination of the sediment by microscope.

Treatment and control (see p. 1030)

Mites are affected by amitraz, some organophosphorus compounds, synthetic pyrethroids and the anthelmintics ivermectin, doramectin, eprinomectin and moxidectin. For topical applications the problem is to ensure that the chemical can come into contact with the parasite and it may be necessary to remove scabs before application. The organophosphorus compounds used frequently are phosmet, propetamphos and diazinon, and the synthetic pyrethroids flumethrin, deltamethrin and

cypermethrin. Organophosphorus compounds and ivermectin, doramectin and moxidectin should not be used on dairy cows giving milk for human consumption unless withdrawal periods are observed. Eprinomectin is safe to use in such cattle.

Tick infestations (see p. 1030)

In tropical regions ticks play an important role in causing and spreading disease. Many actively suck blood and can cause death by anaemia. Some ticks cause paralysis, particularly in young animals. The life cycles vary considerably, with some ticks spending all their time on a single host, others are only parasitic at certain stages and some spend each stage of the life cycle on a different host. Those spending all their time on a single host (one-host ticks) are easier to control than those on different hosts for each development stage (three-host ticks)

- One-host ticks: *Boophilus* spp.
- Two-host ticks: *Hyalomma* spp.
Rhipicephalus bursa
R. evertsi
- Three-host ticks: *Amblyomma* spp.
Argas persicus spp.
Dermacentor spp.
Haemaphysalis spp.
Hyalomma spp.
Ixodes spp.
Rhipicephalus spp.

Ixodoidea

Their life cycle involves egg, larva, nymph and adult. Almost all ticks at each development stage require a blood meal. The unfed stage varies in its ability to survive depending on the amount of moisture present.

The engorged stage drops off the host and then does not move from where it is deposited. The group is divided into two main families, the Argasidae ticks and the Ixodidae or hard ticks.

Argasidae family

These have a cuticle without a hardened dorsal scutum and their mouthparts cannot be seen from above. They are mainly found in arid or semi-arid areas. When feeding they rapidly engorge with blood. They are able to survive for long periods, i.e. months or years, without the presence of suitable hosts for feeding. The nymphs and adults can repeatedly feed, which allows greater capacity for transfer of infection.

There are three genera: *Argas*, *Ornithodoros* and *Otobius*.

Ixodidae family

These have a hardened scutum that covers almost all the dorsum in adult males but only one-third of the dorsum in unfed larvae, nymphs and adult females. The mouthparts are visible. There are nymph and larval stages. All stages including the adult females feed only once. Adult males remain on the host and feed often. Up to half the engorged weight can be taken in with one feed.

The family includes one-, two- and three-host ticks and there are ten ixodid genera of which seven have veterinary importance: *Amblyomma*, *Boophilus*, *Dermacentor*, *Haemaphysalis*, *Hyalomma*, *Ixodes* and *Rhipicephalus*.

Control: This can be directed at the ticks on or off the host. The latter is easiest to perform, but is ecologically damaging as other non-dangerous insects are also affected. When off-the-host-control is performed it includes the use of pasture spraying with anti-tick dips, which involves keeping stock off the area for as long as possible to allow death of the ticks. It works best where the ticks are short-lived as in warm arid conditions. It is best performed by treating pastures in rotation. The effectiveness of pasture spraying depends on whether alternative hosts, either domestic or wild, are available. The practice often means underuse of pasture. However, the overuse or intensification in grazing often increases the tick population. Another method of control often under-rated is that of pasture burning.

In most areas the only effective method of tick control is on the host. This is usually done by hand dressing, spraying or dipping, and in some countries by vaccination. Hand dressing is laborious and has to be done efficiently. It can be done by the use of dusting powders, creams, pastes or in a liquid form by hand spraying, paint brushing or application by washes. In large herds sprays or dips are used. In general, dips provide a more effective overall control. Both effective spray races and dips are expensive to install. The compounds used tend to be organophosphates, synthetic pyrethroids and traditional compounds. The last group includes arsenic preparations such as sodium arsenite. It is cheap but has no residual effect and it can be toxic. Resistance to arsenic dips occurs in some areas. Organophosphorus dips are effective but have limited residual activity. They can be toxic, especially when used by unskilled staff. Organochloride compounds are now prohibited in most countries because they are persistent for long periods and affect the human food chain.

Synthetic pyrethroids are good and relatively non-toxic but some resistance to them is developing, and occurs also when ticks are DDT resistant.

The number of dippings depends on several factors and often means the interval between dippings varies according to the season of the year. It depends on the duration of the ixodicide's activity, the toxicity of the dip, the seasonal activity of the ticks, the time the ticks spend on the host and whether it is required to control or try to eradicate the parasite. Thus one-host ticks, which remain on the host for three weeks, are far easier to deal with than three-host ticks, which only feed for a day or two. Generally, at its height, dipping will be once a week for one-host ticks and twice a week for three-host ticks. Such frequent dipping does allow tick selection for resistance. However, often where tick control is not achieved it is more likely due to not dipping frequently enough or the dip being too weak, improperly mixed or the wrong type or concentration for the stage of the tick to be killed. Where resistance does occur it can be overcome by changing the type of agent in the dip. Many farmers alternate the type of dip used on a routine basis.

Vaccination is carried out in Australia and a few other countries to the one host tick *Boophilus microplus*. The vaccine consists of recombinant antigens to the microvilli of the tick intestinal epithelium. As a result ingestion of blood from immunized cattle disrupts the digestion of the tick which leads to death or reduced fertility. After some years of vaccination the local tick population is therefore drastically reduced. Vaccination needs to be repeated at least annually as the immunity is not boosted by antigens from natural infection.

Fly problems (see p. 1030)

Mosquitoes

There are many species of mosquito including *Aedes* spp., *Anopheles* spp., *Culex* spp., *Mansonia* spp. and *Psorophora* spp. They can cause problems when in large numbers due to annoyance of man and animal. Mosquitoes cause some loss of blood by feeding as well as transmitting diseases such as Rift Valley fever and probably other conditions such as lumpy skin disease and bluetongue. The mosquito life cycle is aquatic for the larva and pupa and takes 5–21 days to reach the adult stage.

Control of the insect over large areas involves drainage of still surface water or by treating water with oil, synthetic pyrethroid or other insecticide. Oil is easiest to use and can involve waste engine oil with kerosene or diesel oil. Applying repellents to cattle tends to be too expensive and self-applicators are often

used. Otherwise, for small groups of animals the use of mosquito screens will stop contact.

Blackflies

These belong to the family Simuliidae and include blackflies, buffalo flies and sandflies. They are small (<5 mm long) and black or grey in colour. They occur in most countries and when in large numbers they are an annoyance. It is thought that there may be toxic factors in the saliva. The bites result in vesicles and these in turn can result in ulcers and secondary infection. The larvae and pupae are attached to reedy stems and branches in running water. They take about three to four weeks to pass from egg to adult. They are active during the summer months. The flies tend to gather in swarms and annoy animals. They bite the legs, belly and head, causing the animals to stamp and kick their legs. Occasionally they stampede. Cattle may wallow in mud or kick up dust to keep off the flies. Control depends on attacking the larval stages by spraying breeding sites with insecticide. However, rapid reinfection of the areas will occur. Treatment of the adult is difficult but a repellent such as dimethyl phthalate is helpful. Regular dipping of cattle for ticks, etc. also reduces fly levels.

Midges

These are extremely small flies (1–3 mm long) of the family Ceratopogonidae, the important genera being *Culicoides* and *Lasiohelia*. These suck the blood of animals and man. They transmit ephemeral fever, bluetongue and other pathogenic viruses. The larvae are found mainly in swamps, where they live either in wet mud or free-standing water. Some occupy more restricted habitats such as rotting vegetation. Besides acting as vectors of arboviruses they can cause hypersensitivity reactions.

Control is by draining the breeding sites. Otherwise, spraying the areas with oil or DDT gives good results. Repellents, particularly dimethyl phthalate, are effective on a short-term basis. Mosquito screens are of no use. Fires at times of biting activity will assist in herd protection.

Horseflies and deerflies

Horseflies are of the *Tabanus* spp. and are also called March flies or breeze flies. Deerflies are of the *Chrysops* spp., *Haematopota* spp. and *Pangonia* spp. They are large, brown, robust flies that bite and suck blood. They act as vectors of diseases such as anthrax, anaplasmosis and trypanosomiasis. *Haematopota* spp. are thought to help transmit summer mastitis. The eggs are laid on the

leaves of plants growing close to or in water. The larval and pupal stages occur in the water or mud and the life cycle takes about four to five months to complete. The flies tend to be active during the day in summer months, particularly when it is hot and sultry, and are mainly found on the ventral abdomen and legs. Control is difficult but depends on drainage of wet areas. Breeding sites can be treated with oil or insecticide. Otherwise, repellents such as dimethyl phthalate and γ -dimethyltoulamide are useful but last only a few days. Some products are available to apply to the cows' udders.

Houseflies

The common housefly (*Musca domestica*) has a worldwide distribution. They cause worry to animals by settling on them as well as acting as vectors of diseases such as anthrax, erysipelas, brucellosis and possibly summer mastitis. They cause aggravation at wounds or other areas where there is blood, exudate, pus, etc. They cause infections by discharging some of their stomach contents, so-called vomit drop, on to the food to moisten it and often they also defaecate. This means that they are able to transfer many pathogens effectively. Eggs are laid on rotting vegetable material or faeces. The life cycle involves an egg producing a larva (a maggot), which takes about 10 days to mature, thereby completing the cycle in about 12–14 days in warm weather.

Control methods include removing all manure and organic material at least every three days. This can be stacked so as to ferment, ideally in a bunker or pit. Otherwise, it should be turned over every few days or better still treated with insecticide. Faeces can be burnt. Fly traps (Baber's) can be used to collect flies and larvae. Buildings should be kept as clean as possible and can be sprayed with insecticides, or insecticide strips can be placed in areas with little air movement. Electrocutors can be used to which the flies are attracted by an ultraviolet light. Cattle can have insecticide-impregnated ear tags but these are not too effective against the housefly.

Bush flies

These include *Musca sorbens*, *M. fergusoni*, *M. teraeregina* and *M. hilli*. They are found particularly in Australia. They tend to be found all the year round in northern Australia but only in the summer periods in the south. The flies often appear in large numbers and can be found on the lips, eyelids and other mucous membranes and by wounds. They are considered to transmit infectious bovine keratoconjunctivitis. Control is difficult but involves fly spraying cattle and buildings.

A repellent such as dimethyl phthalate can be of use. Synthetic pyrethroids can be successful.

Face fly

This is *Musca autumnalis* a small fly resembling, and slightly bigger than, the housefly, found in Europe, Asia and North America. Numbers tend to be greatest in the summer and particularly cattle outside are worried. Fresh cattle faeces are the only fly breeding grounds. Flies are particularly seen on the face around the nostrils and eyes where they feed on the secretions. They are thought to transmit infectious bovine keratoconjunctivitis. There are no wholly successful control measures although plastic insecticide-impregnated ear tags are useful and powders or cream containing organophosphorus compounds assist.

Head fly

The fly *Hydrotaea irritans* is the same size as the housefly but has an olive abdomen and yellow wing tips. It is found in Great Britain and Europe. It is a nuisance fly and does not bite although it does feed off exudate around wounds. It occurs in large swarms from July to September. The life cycle is annual and it involves periods of development in the soil. Sores on animals are made larger due to self-inflicted aggravation because of irritation. *Hydrotaea irritans* is incriminated in the transmission of summer mastitis (see Chapter 24). It is probably also concerned with infectious bovine keratoconjunctivitis. Control is difficult and involves the use of parasite sprays and dipping. Plastic insecticide-impregnated ear tags are useful.

Stable fly

The stable fly, *Stomoxys calcitrans*, is about the size of the housefly. It is grey in colour, has a sharp proboscis and when it settles it sits with its head upwards. It is a bloodsucker and feeds on the host causing great irritation. Wounds often bleed freely after the flies have fed. The eggs are laid in faeces, rotting hay or straw and the life cycle is complete in two to three weeks. The larval and pupal stages take place in organic matter. Warm damp environments encourage the flies' growth and survival. They cause considerable nuisance and worry with reduced milk and meat production and possibly anaemia. In cattle there can be a hypersensitivity of the forelimb skin, which in turn has blisters that coalesce to form bleeding sores. *Stomoxys calcitrans* can transmit anthrax. Another species, *S. nigra*, occurs in South Africa.

Control of the fly involves the frequent removal and disposal of bedding and faeces from buildings. Destruc-

tion of the flies is difficult because they feed for only a short time. It can be helped by the use of insecticide-impregnated plastic ear tags or spraying with suitable sprays, spraying of walls and shaded areas of pens.

Horn flies and buffalo flies

Horn flies include *Liposcelis* or *Haematobia irritans*, *H. minuta* and *L.* or *H. exigua*. This last is also known as the buffalo fly. The flies are greyish, smaller and less active than stable flies. At rest their wings are completely closed but are held away from the body. They thus spend more time on the host except when laying eggs, etc. Many have a limited geographical range. Thus *H. irritans* is found in the USA and Hawaii, *H. minuta* in Africa and *H. exigua* in Australia and south-west Asia. They are most common on cattle and buffalo and occur in large numbers, causing much irritation. Although bloodsuckers they are not known to transmit diseases. Severe infestations lead to weakness and death. They also produce large sores.

The eggs are laid in fresh faeces and can only survive with high humidity and warm temperature. They pupate in the soil and the life cycle takes eight days to three weeks to complete. Control of the flies is difficult but removal of dung is important. The cattle and buildings should be sprayed frequently with insecticide. If tick dipping is undertaken this reduces fly numbers. The anthelmintics doramectin, ivermectin and eprinomectin are effective because of their residual activity, and will protect cattle for periods of up to three weeks. The use of plastic insecticide-impregnated ear tags is helpful. Otherwise, applying insecticide at regular intervals will assist.

Horse louse flies

These include *Hippobasum equina*, *H. rufipes* and *H. maculata*. *Hippobasum equina* is the most common, is slightly larger than the housefly and is a reddish-brown, fast, glossy fly that causes problems to cattle and horses. It feeds on blood and is found on the inside of the hind legs and the perineum. The eggs are laid and develop in dry soil. They can act as mechanical vectors of disease. Plastic insecticide-impregnated ear tags are of use in control as are spraying or dipping of cattle.

Tsetse flies (see p. 760)

The *Glossina* species are an important African fly that act as the true vector of trypanosomiasis (p. 756). They are 6–13.5 mm long, thin-bodied, yellow or brown flies. The wings are folded over each other and there is a slender proboscis. There are 20 species of *Glossina* and all are found in tropical Africa. They occur in a variety

of environments but are usually found in one of three terrains: (i) forest, where they inhabit thickly wooded areas with a high humidity; (ii) riverine, where they live on the edges of forest but by streams, lakes and rivers; and (iii) savannah grasslands, where the tsetse are the most important species for spreading animal disease.

Both the male and female tsetse flies feed on blood and most of the species are attracted to certain host species. In tsetse flies the eggs hatch in the uterus and so they are larviparous. The larvae are deposited on shady dry soil and pupate there. One larva is produced every 10 days and the pupal stage lasts 28–56 days. As the adult female survives three or four months eight to twelve larvae are produced.

Control depends on surveying an area to determine the species of the tsetse fly present and their habitats. Then the possibility of control can be assessed. Methods of eradication or control are direct using insecticides to remove adult flies, removal of pupae and use of repellents on cattle. The indirect approach depends on removal of nesting sites and dry weather refuges, and the use of traps. Insecticides including DDT and diel-drin are of long duration but have been considered by some to cause too much long-term pollution. Shorter term insecticides that are biodegradable such as synthetic pyrethroids. are now favoured (see p. 760).

Tumbu fly

The tumbu or mango fly is *Cordylobia anthropophaga*. It infests man and animals but rarely cattle. It is about the size of a housefly and lays eggs in the soil or sand. The hatched larva attaches to the skin of a host where it produces a painful irritant swelling with a dark central hole. Once mature the larva passes out to the soil where it pupates. The adult lives on food and animal excreta. In light infestations each larva can be manually removed by covering up the airhole with liquid paraffin in Vaseline. The parasite will push its posterior abdomen out of the hole and it can then be pressed out gently. In severe infestations avermectins such as doramectin, eprinomectin and ivermectin will control infection and insecticides, such as organophosphorus compounds, can be applied.

Blow flies and screw-worm flies

These result in blow fly infection or myiasis. The flies involved include several genera: *Calliphora*, *Callitroga*, *Chrysomyia*, *Lucilia* and *Sarcophaga*. Cattle are less affected than sheep. The flies are really scavengers and mainly live on dead meat. However, true screw-worm flies only lay their eggs in fresh wounds. They are, however, attracted to dying flesh on live animals. Even the small wounds of ticks attract the flies. The

larvae feed and grow quickly and mature in three to five days.

A local dressing of a larvicide and an antiseptic is useful after clipping away the hair. The most effective treatments are the avermectins doramectin, eprinomectin and ivermectin. They normally promote a complete kill in about 12 hours. All wounds should be treated with an antifly preparation. Dipping or spraying the animals with insecticides can be helpful. Otherwise, the number of flies can be reduced by trapping and quick disposal of carcasses. Chromosomal translocation of males to produce sterile or lethal mutant offspring has been tried with some success. The American screw-worm fly *Callitroga americana* has been controlled by the release of irradiated males. They mate with the females, which lay sterile eggs, thereby ultimately reducing or eliminating the fly population.

TICK AND ARTHROPOD-BORNE DISEASES

Protozoal diseases

Babesiosis (redwater)

Babesiosis is caused by an intra-erythrocytic protozoan of the genus *Babesia* transmitted by hard ticks of the family Ixodidae (see p. 744). Unlike many other parasitic diseases, it affects adults more severely than young cattle in which infection is frequently subclinical. It causes fever, haemoglobinuria, haemoglobinuria, anaemia and death.

Aetiology and epidemiology

The four most important species of *Babesia* that affect cattle are *B. bovis*, *B. bigemina*, *B. divergens* and *B. major*, the first three being much more significant than the last. Two are considered 'small' Babesia and two 'large', and there is one large and one small species for both tropical and temperate climatic areas (Table 45.1).

The parasites are transmitted by hard ticks, which are also affected by their role as intermediate hosts in the babesial life cycle. When an infected tick attaches to the skin of cattle its mouthparts penetrate the skin and it

starts to suck blood. Bloodsucking is not continuous but takes place in short periods of activity until the tick becomes fully engorged. Full engorgement for larvae requires three to five days, for nymphs five to six days and for adults seven to ten days. *Babesia* spp. are not transmitted by infected ticks until the end of the engorgement period because the babesial stages in the tick have to develop and move to the salivary gland prior to becoming infective sporozoites. The sporozoites are injected into the host with saliva and then invade erythrocytes. They proceed to divide asexually in red cells, forming two pear-shaped merozoites. Each erythrocyte ruptures when the merozoites leave to infect new cells. The reproduction time in erythrocytes is in the order of 12–15 hours depending on the species. When sufficient multiplication has taken place for parasites to be visible in very low numbers in blood smears the animal will show a febrile reaction. The length of time required is usually approximately one to three weeks after infection, but depends on the number of *Babesia* in the infective inoculum, and in very large syringe-passed infections may be as short as two to three days. Thereafter the parasitaemia may build up and in extreme cases more than 20 per cent of erythrocytes may be infected, although the percentage infected varies with the species involved, e.g. the parasitaemia of *B. bovis* is usually less than 1 per cent in venous blood whereas *B. bigemina* and *B. divergens* on average reach 3–8 per cent. At this point the affected animal has a febrile reaction and may exhibit the characteristic haemoglobinuria that produced the colloquial term of 'redwater' for the disease, and unless treated it may die. After treatment the animal becomes a carrier of the organism and may suffer from occasional recrudescences of parasitaemia. Ticks become infected by feeding on parasitaemic cattle. Infected adult female ticks pass the infection to their eggs, the infection being termed *transovarial*, and the larvae, nymphs and adults up to the F2 generation. Some *Babesia* spp. may remain infected in the absence of feeding on carrier bovines, although for *B. bovis* infection ceases with larvae. Transmission from larva to nymph to adult is termed *transtadial* infection, and is observed with *B. bigemina* and *B. divergens*.

The epidemiology of the *Babesia* spp. is governed by the local climate and behaviour of its tick vectors. As a result they merit separate consideration as tropical or non-tropical species.

Tropical species: *B. bovis* and *B. bigemina*. These species are found in Australia, Africa, South and Central America, Asia and the very south of Europe. In Australia and the Americas the tick *Boophilus microplus* is the sole vector, in Africa other *Boophilus* and *Rhipicephalus* species. *Boophilus* spp. are one-host

Table 45.1 *Babesia* spp. infecting cattle.

| Species | Size | Climatic preference |
|---------------------|-------|-------------------------|
| <i>B. bovis</i> | Small | Tropical or subtropical |
| <i>B. bigemina</i> | Large | Tropical or subtropical |
| <i>B. divergens</i> | Small | Temperate |
| <i>B. major</i> | Large | Temperate |

ticks, i.e. all stages of the life cycle take place on one animal, only the engorged female dropping to the ground before laying eggs. Some vectors in Africa, e.g. *R. evertsi*, are two-host and *R. appendiculatus* is a three-host tick.

Babesia bovis merozoites in erythrocytes measure $2 \times 1.5\text{ }\mu\text{m}$ and those of *B. bigemina* $4.5 \times 2\text{ }\mu\text{m}$. Parasitaemia in venous blood is low with *B. bovis* but it may be high in capillaries and cause sludging of blood, which if in the brain causes early death. It also produces enzymes with severe effects on the blood coagulation system, and is generally considered the most pathogenic of the bovine *Babesia* spp.

Babesia bigemina infection results in much higher venous parasitaemia but it has few other effects other than to cause a febrile reaction and straightforward haemolytic anaemia.

Temperate species: *B. divergens* and *B. major*. *Babesia divergens*, the merozoites of which measure $1.5 \times 0.4\text{ }\mu\text{m}$, is common in areas of permanent pasture in north-western Europe and is transmitted by the three-host tick *Ixodes ricinus*. *Babesia major* ($3.2 = 1.5\text{ }\mu\text{m}$) is found only in south-eastern England and on islands off the coast of The Netherlands and is transmitted by *Haemaphysalis punctata*.

Babesia divergens behaves rather similarly to *B. bigemina*, i.e. it can cause a high parasitaemia, which results in fever and severe haemolytic anaemia. It has little effect on blood coagulation systems in comparison to *B. bovis*. Its epidemiology is closely bound to the ecology of its vector *I. ricinus*. In Europe, *I. ricinus* is generally active only between May and November, and in most areas has spring and autumn population increases, although in the most northerly climates it may only have one in midsummer. The ticks quest more actively in warm conditions and outbreaks of babesiosis are frequently observed two weeks after fine weather. The epidemiology of *B. major* is still only slightly investigated, but such isolations as have been reported have taken place in May and June.

Signs

Early: There is slight dullness with a pyrexia often of $40.5\text{--}41^\circ\text{C}$ ($105\text{--}106^\circ\text{F}$). The animal shows diarrhoea and because of spasm of the anal sphincter there is a narrow stream of diarrhoea (pipe-stem diarrhoea). There is also haemoglobinuria. Slight dehydration is often seen as a slightly sunken eye.

Mid: After 24–36 hours the mucous membranes tend to become pale and the pulse rate is increased. The animals tend to slow up and there is a reduction in appetite and thirst. The urine tends to become very

dark in colour and reduced in quantity. The faeces may return to normal but less tends to be passed although there is still spasm of the anus.

Late: In another 24–36 hours the rectal temperature is often subnormal with the animal having blanched mucous membranes, a poor appetite and drinking little. There is marked constipation and a greatly increased heart rate.

Pregnant cows may abort following infection.

Necropsy

The carcass may be very blanched and there is sometimes jaundice. The liver is often swollen and pulpy, with the kidneys dark and enlarged. The bladder contains red-brown urine. There are ecchymotic haemorrhages under the epicardium and endocardium.

Diagnosis

Cattle suffering from babesiosis frequently have a history of recent movement to tick-infested pastures either through grazing management or after purchase, and in Europe may have suffered from tick-borne fever a week or so before babesiosis is evident. Examination of the cattle, especially the preferential feeding sites of the vector ticks, will reveal evidence of recent tick bites or engorging ticks. Clinical babesiosis is unlikely to be observed in cattle less than nine months old; such cattle can be infected and show febrile reactions but the resultant parasitaemia remains low and haemoglobinuria mild. In areas of large tick populations, most cattle are infected at an early age and become immune thereafter, the situation being described as enzootic stability. In the early stages of the disease, haemoglobinuria may not be present and diagnosis requires careful examination of stained blood smears (see Fig. 45.1). Once haemoglobinuria is present, the parasitaemia may be more obvious. Differential diagnosis requires elimination of other conditions causing haemoglobinuria, e.g. anaplasmosis (p. 761), eperythrozoonosis, leptospirosis (p. 734), postparturient (p. 792) and bacillary haemoglobinuria (p. 719).

Treatment and control (see p. 1029)

There are two aspects to treatment: firstly, treatment with a babesicide and secondly, the need for supportive therapy such as blood transfusion and fluid replacement. There are few babesicides now available. The only treatment now licensed in the UK is imidocarb, which is given at a dose rate of 1 mg/kg body weight. It is used widely in South America and other countries. It is highly effective and relatively non-toxic, but does have tissue residues for several weeks after its use.

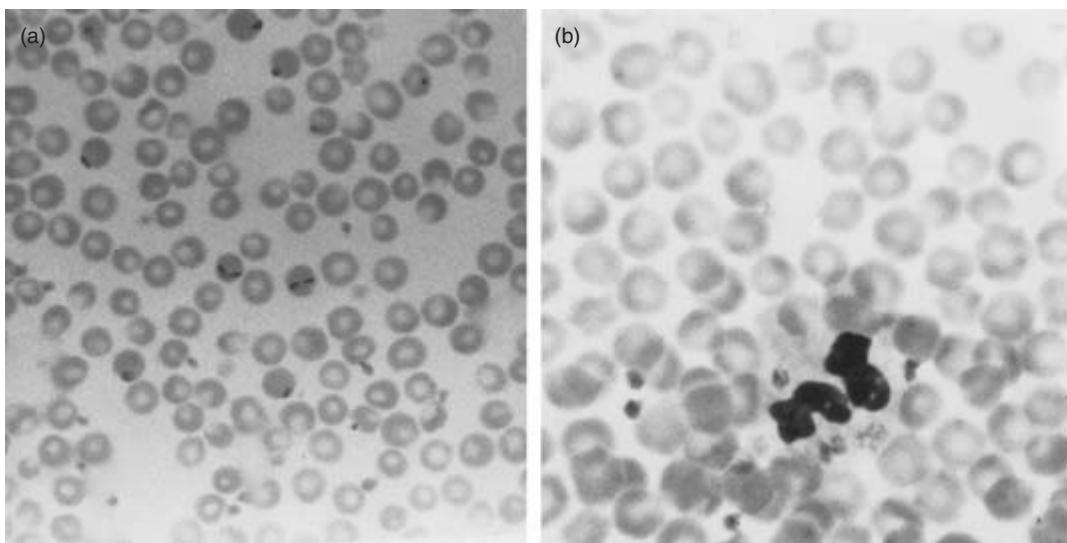

Fig. 45.1 (a) Bovine blood infected with *Babesia divergens* ($\times 630$). (b) Bovine blood smear showing *Ehrlichia phagocytophila* in a neutrophil ($\times 630$).

It can also be used at twice the therapeutic dose as a chemoprophylactic, giving protection from infection for up to six weeks. It is used in this way to administer to cattle that will be exposed to ticks, or that have been vaccinated with live *Babesia* with the hope that cattle will become mildly affected but protected from clinical illness and immunity to further infection will be stimulated.

Live vaccines for *B. bovis* and *B. bigemina* have been available in many countries for many years, notably Australia and South America. For *B. bovis* the vaccines consist of live organisms made avirulent by repeated rapid syringe-passage through splenectomized calves. In the case of *B. bigemina* rapid passage did not reduce virulence and vaccines available are either developed by 'slow' passage from recrudescences of parasitaemia or are fully virulent organisms, which are used in schemes involving infection and subsequent treatment. There are no vaccines currently available for *B. divergens*, although much research is being carried out to develop inactivated recombinant vaccines for that species and *B. bovis* and *B. bigemina*.

Blood transfusion is frequently required for severely affected adult cattle and is normally achieved by collection of 5 l of blood from an unaffected healthy cow into a 22 per cent solution of the anticoagulant acid citrate dextrose (ACD), the mixture being immediately transfused into the recipient animal. Such single transfusions without cross-matching of blood are usually successful, but repetition can lead to problems of incompatibility of blood antigens.

Table 45.2 Species of the genus *Theileria* in cattle.

| Species | Synonym | Disease |
|---------------------|---|-------------------------------------|
| <i>T. annulata</i> | <i>T. dispar</i> <i>T. turkeistomica</i> | Mediterranean coast infection |
| <i>T. lawrencei</i> | <i>T. bovis</i> | Corridor disease |
| <i>T. mutans</i> | <i>T. orientalis</i> | Benign bovine theileriosis |
| | <i>T. buffeli</i> | |
| <i>T. parva</i> | | East Coast fever |
| <i>T. sergenti</i> | | Mediterranean coast fever (Russian) |

Theileriosis

This comprises a group of infections caused by protozoan parasites of the genus *Theileria* (Table 45.2) and transmitted by ixodid ticks. They occur in a variety of ruminants and wild animals. Both members of the genus *Babesia* and the genus *Theileria* occur within red blood cells. They are collectively called piroplasms and the infections caused by the two are thus sometimes known as 'piroplasmosis'.

East coast fever (ECF) (pp. 73, 753)

The disease is a major constraint for production in countries where it occurs.

Aetiology: The cause is a protozoan parasite, *Theileria parva*. There is some disagreement about its classifica-

tion. *Theileria lawrencei*, a parasite of buffalo, causes a high mortality in cattle, but if passed through cattle it reverts to a parasite indistinguishable from *T. parva* and producing a syndrome similar to ECF. Thus it has been suggested that the cattle parasite should be called *T. parva parva* and that of the buffalo *T. parva lawrencei*.

Epidemiology: The disease occurs across a large area of East and Central Africa and is endemic in Burundi, Kenya, Malawi, Sudan, Tanzania, Uganda, Zaire and Zambia. It may also occur in Ethiopia and southern Somalia. It is possible to eradicate the disease and this has been done in Mozambique, South Africa, Swaziland and Zimbabwe, although it can return if preventive measures are not maintained. It is a disease of cattle but can infect Indian buffalo (*Bubalus bubalis*) and African buffalo (*Synacerus caffer*). Infection is restricted to countries with a temperature and rainfall suitable to allow the survival of *Rhipicephalus appendiculatus*, a three-host tick. The tick is found from sea level to 2135m (7000 feet) provided there is adequate vegetation and a rainfall in excess of 50cm (20 inches). In many areas where ECF occurs rainfall is seasonal and disease follows the onset of rain and thus tick activity. In some highland areas or close to water or sea, where the rainfall is more or less constant, tick activity and ECF can occur virtually all the year round. Although *R. appendiculatus* is the main arthropod host, eight species of the genus *Rhipicephalus* and three species of the genus *Hyalomma* can be experimentally infected. In areas where there is a constant challenge then the cattle will be continually exposed to infection from the tick. If challenge is heavy then the calves die. However, those that survive are resistant to further challenge and they can thrive in these areas. In marginal areas where challenge is intermittent or seasonal then cattle previously exposed may lose or have reduced immunity. Thus if a heavy challenge occurs at the start of the rainy season the cattle are again susceptible and go down with disease. Immunity is only to challenge by a similar strain. Cattle previously exposed may be partly or totally susceptible to infection by other strains. Recovered cattle have a sterile immunity, which lasts more than three years. Levels of immunity to piroplasm antigens peak often four to six weeks after infection and persist for six months.

Life cycle: The life cycle of *T. parva* is still not completely understood but most of it is now known or extrapolated. Firstly, at the stage of introduction of infection to the cow there is the period of schizogony. Sporozoites from infected ticks are injected with saliva into the cattle while the tick feeds. There is usually a

delay of three to five days after attachment before this occurs. If the tick infects a susceptible animal there is a period of five days before the parasite can be detected in the local drainage lymph node closest to the tick bite. What happens during this period is not known but it is likely that sporozoites rapidly enter target lymphocytes. By doing this the sporozoites escape the phagocytic, lytic and immunological defences of the host. Then there is a transformation of the lymphocyte to lymphoblast with larger, less dense nuclei and increased cytoplasm caused by the parasite, which in turn differentiates into a macroschizont in the cell cytoplasm. As the disease progresses the macroschizont grows to an average size of 4.8 μm . The lymphoblasts rapidly proliferate, probably stimulated by the presence of the parasite, which becomes aligned along the spindle and divides by synchrony. As the infected lymphoblast divides both daughter cells are infected. Some macroschizont-infected cells degenerate releasing free macroschizonts, which invade other uninfected lymphoid cells. How this occurs is not known but it may be through membrane fusion of cells in close apposition. From about day 14 after tick attachment macroschizonts differentiate to microschizonts. The mechanism of differentiation is not known. Microschizont-infected cells then rupture and release micromerozoites (1–1.5 μm in diameter). The released micromerozoites enter erythrocytes where they form piroplasms 3–5 μm , which tend to be rod or comma-shaped. The piroplasm-infected erythrocytes are then available to infect ticks feeding on the blood of the cattle host. *Theileria parva* piroplasms rarely divide within erythrocytes, which is different from *T. mutans* and also *Babesia* spp.

Following feeding on the infected bovine the tick, usually *R. appendiculatus*, will inject piroplasm-infected blood that is around the stage of gametogamy. The tick is a three-host tick with all three stages (larva, nymph and adult) feeding on separate hosts. Infection is transitional so an infected larva can transmit infection as a nymph but not as an adult. There appears to be no transovarial transmission as occurs with *Babesia* spp. Once in the tick gut the erythrocytes lyse releasing the piroplasms, many of which are digested but some of the many forms develop into male microgametes or female microgamonts. Fusion of these by process of anisocytosis is then thought to occur to produce zygotes, which invade gut cells and thus differentiate into a motile kinete of about 19 μm . The kinete breaks out from the gut cell and enters the haemolymph. The stage of sporonts is then reached. The kintes invade the acinar cells (usually type III acinars) of the salivary glands. The kintes round off and nuclear division occurs to produce a sporont or primary fusion body. The sporont

invaginates and forms buds. Further development is delayed until such time as the tick starts to feed in its next instar. When this occurs primary sporoblasts develop from the sporont buds and form cystomeres or the secondary fission stage. There is hypertrophy of the host cell and the cell nucleus. There is then division of the primary sporoblasts to produce secondary sporoblasts or the tertiary fission stage and sporozoites ($1-1.5\mu\text{m}$) are produced. This stage is rapidly completed in three days from the onset of the tick feeding. The sporozoites are released into the salivary duct with peak sporozoite production by day 5. The host cell and nucleus degenerate and the parasite residual bodies remain. The sporozoites persist during the whole period of feeding, which may be up to 10 days for female ticks and intermittently over a long period for male ticks.

Mortality in susceptible adult cattle is 80–100 per cent, with an incubation period of 10–15 days.

Signs

Peracute: There is marked pyrexia and death with swollen lymph nodes in a few days.

Acute: Usually the first sign is an enlargement of the lymph nodes for the region draining the area where the infected tick has fed. The preferred feeding sites for *R. appendiculatus* are the ears and so usually the first lymph nodes to swell are the parotids. One to two days after the swelling occurs the animal becomes pyrexic with a temperature rising to $39.5-42^\circ\text{C}$ ($103-108^\circ\text{F}$). The temperature tends to remain high until the animal either recovers or dies. Other lymph nodes begin to swell and this tends to become generalized. Some of the superficial lymph nodes such as the parotids, prescapulars and precrurals become very enlarged. Anorexia gradually develops and there is consequent loss of condition. In many cases lacrimation and nasal discharge occur. The breathing becomes rapid and dyspnoeic, and there is diarrhoea or dysentery. As the animal deteriorates and approaches death, the temperature falls and there is severe dyspnoea and recumbency. Nasal exudate pours out of the nostrils. The animal dies of asphyxiation from lung oedema. Death is usually about 18–24 days after infection, but occasionally this is reduced to 14 days. The mortality tends to be near 100 per cent in susceptible animals.

Occasionally, nervous signs develop and this is known as ‘turning sickness’. Foci of Koch’s blue bodies are found in the cerebral tissue. The animal appears to turn often rapidly and become giddy with collapse. The less severe form involves slower turning and frequent head pressing. Both nervous forms are fatal and are consid-

ered by some to be due to a massive infection in partially immune cattle.

Chronic: This is usually seen in animals that are partially immune or exposed for long periods to low levels of infection. It often occurs in calves in endemic areas. The lymph nodes tend to be enlarged and there is intermittent pyrexia, anorexia and loss of condition. These animals frequently recover. In cases of concurrent helminthosis, malnutrition or other disease and a constant population of *T. parva* some animals become severely retarded and never reach their full production potential.

Pathology: The lesions will depend on the duration of signs. The most consistent finding is one of hypertrophy and hyperplasia of the lymph nodes initially, followed by lymph node oedema and some haemorrhage and necrosis later on. There is destruction of lymphocytes leading to destruction of lymphoid cells. Lymph node biopsy shows hypertrophy of lymphoid cells and often after the 11th day they may show macroschizonts that increase in number and size. Damaged lymphocytes are seen with free schizonts. Microschizonts are then present, either intact or branching out of cells as micromerozoites. Blood examination reveals a progressive panleucopenia. A noticeable rapidly developing anaemia is only seen in the terminal stages.

The examination reveals froth at the nostrils and the most striking feature is massive pulmonary oedema, hyperaemia and emphysema. The alveoli, bronchioles, bronchi and trachea are filled with frothy pulmonary exudate. There can also be pleural and pericardial exudate. There are excessive haemorrhages and these may be present on most serous and mucous membranes. In the abomasum the mucous membrane is red and inflamed and there may be ulceration or erosions, especially in the pyloric region. In chronic cases there are ulcers in Peyer’s patches. The cortices of the kidneys show haemorrhage and are often congested, and nodules of lymphoid tissue projecting from the kidney surface may be seen and are a characteristic feature when they occur. The spleen may or may not show changes and it can be enlarged or shrivelled. The liver is often enlarged with mottled grey areas. Degeneration of the organs is rapid after death.

Diagnosis: The signs are relatively specific and infection can be confirmed by the presence of piroplasms in the blood or schizonts in lymph node biopsy smears stained with Giemsa. There is also panleucopenia and then anaemia.

Post-mortem findings are helpful but they are similar to those of malignant catarrhal fever. Differentiation of

T. parva from other *Theileria* spp. depends on the acuteness of the disease, the number of piroplasms present in the blood and the number present in lymph nodes. Complement fixation, capillary titre agglutination and indirect haemagglutination tests have all been used in diagnosis but are less reliable. The indirect fluorescent antibody test (IFAT) is considered more reliable. An enzyme-linked immunosorbent assay (ELISA) test is also being increasingly used.

Treatment (p. 1029): Animals in good condition prior to infection have lower morbidity. Parvaquone and the more recently developed buparvaquone are effective if treatment is not delayed until the animal is too severely affected. Oxytetracycline is effective if given at the same time as infection occurs. It is also able to reduce the severity of clinical disease and appears most effective when given by injection. Chlortetracycline given at any stage of infection at a dose of 10mg/kg body weight either parenterally or by mouth reduces the severity of parasitaemia and pyrexia.

Control: In endemic areas indigenous calves have a high degree of resistance to disease. However, calves of European breeds are very susceptible to infection and often die. Those that survive often succumb to further attacks. Adult cattle of any breed brought into the areas are highly susceptible to disease and probable death. The immunity is more cellular than humoral.

Thus where disease is endemic there is legislation to control ticks, to slaughter infected animals, quarantine cattle and restrict cattle movement. While it has been shown in South Africa and Zimbabwe that eradication of ECF is possible, it is expensive and in many countries the legislation is not enacted as rigorously as it might be. However, individual farmers can do much to reduce problems on their own premises by sensible cattle management and tick control. Efficient and well-maintained fencing will reduce the access of nomadic cattle or game to the farm. Areas particularly suited to ticks can also be fenced off. Grass burning, rotational grazing, alternate grazing with other species such as goats or sheep, alternate grazing with immune cattle or rotating land between grazing and crop all reduce the problem. Cattle should be quarantined on entry to the farm. Should disease break out its effects can be reduced by slaughtering infected cattle, stopping movement of cattle, other animals, people, hay or feed from infected areas and then creating a buffer area between the infected and clean areas.

It seems that for effective immunization of cattle against ECF it is necessary for the infection to be established in the host. Vaccination is not widely used as it often leads to unpredictable results, with disease break-

ing out due to poor immunity or deaths due to vaccination. However, animals can be vaccinated with stabilate produced by freezing down emulsions from infected blood. After injection of the stabilate long-acting oxytetracycline or buparvaquone is given; otherwise short-acting oxytetracycline or paravaquone can be used. Cattle so treated become resistant to disease and they show little or no apparent reaction. In some cases more than one strain of *T. parva* is introduced, possibly together with a strain of *T. lawrencei*. A sporozoite vaccine is now being tried.

Mediterranean coast fever

This is in many ways similar to East Coast fever but is caused by a different *Theilera* species.

Aetiology: The cause is a protozoan parasite, *Theileria annulata*. Morphologically, the parasite is similar to *T. parva* and the macroschizonts and later microschizonts are found in the lymphoid tissue. *Theileria annulata* piroplasms in the erythrocytes tend to be oval or round in shape. In Russia, there is a similar disease due to *T. sergenti*, which is different from *T. annulata* both morphologically and immunologically.

Epidemiology: The condition is found around the Mediterranean including south-eastern Europe, Russia, the Middle and Far East, India, Sri Lanka, Egypt and Sudan. Both cattle and water buffalo (*Bubalus bubalis*) are susceptible to the infection. The condition involves a development cycle in ticks of the genus *Hyalomma* and seven species are known to be vectors. The ticks involved are one-host, two-host or three-host ticks. It is believed that in most tick species there is no transovarian transmission. Thus infection is acquired in the nymph or larval stages and is transmitted in the adult. When the tick is attached to the host it must feed a considerable amount before infective stages of *T. annulata* are produced and enter the cattle. Piroplasms appear in the erythrocytes shortly after the first detection of schizonts. The intra-erythrocytic form remains in the blood for many years and in natural infections they tend to have a ring or oval shape.

The disease is seasonal, depending on the activity of the ticks, which hide during the winter in crevices between rocks, walls, etc. The result is the infective adult stage being produced in late spring or early summer. Thus infection tends to be seen mainly in the summer and early autumn. Infection can also be transmitted by injecting blood or tissue from ill or recovered animals. Intra-uterine transmission has been recorded on occasion. Infection of calves in endemic areas usually

produces a mild disease, although up to one-quarter of calves can die.

In the Russian form involving *T. sergenti*, infection is said to be transmitted by only one species of the genus *Haemaphysalis*.

Signs

Peracute: This occurs in completely susceptible animals entering endemic areas. The animals develop marked pyrexia with anorexia, depression and weakness and they die in three or four days.

Acute: This is most commonly seen in susceptible animals moved into endemic areas and in marginal areas of tick activity. The animals develop pyrexia, which may persist for several days. It is accompanied by inappetence, lethargy, swelling of the superficial lymph nodes, oculo-nasal discharge and ruminal stasis. This is followed in a few days by anaemia with pale mucous membranes, exercise intolerance and a rapid heart rate. Later on jaundice may become apparent. Constipation is common when pyrexia first occurs but later there is diarrhoea and bloodstained faeces. The animals lose condition rapidly and about 90 per cent die over a period of eight to eighteen days after signs occur.

Subacute: There is intermittent fever for two to four weeks with moderate progressive anaemia and jaundice. Many of these animals die but some recover over a long period. Some of these cases change into a more acute phase and die.

Chronic: This is often an even more prolonged form of the subacute disease. Recovery can occur but is very protracted. However, some cases suddenly develop the more acute form and die.

Necropsy: There is a pale, anaemic carcass with the mucous and serosal membranes showing numerous petechial haemorrhages. The lymph nodes are enlarged, cystic and oedematous. The liver tends to be pale brown or yellow, enlarged and friable with an enlarged friable spleen. The kidneys tend to be pale and on occasions show pseudoinfarcts. The abomasum is red, inflamed and may show haemorrhagic ulceration. There are epicardial and endocardial haemorrhages and these may be petechial or ecchymotic. The lungs contain oedema, often red-tinged, and congestion.

A lymph node smear may show schizonts present in lymphocytes but they are more common in the liver and spleen.

Diagnosis: The area, type of animals affected and signs help in diagnosis. Lymph node smears show schizonts. In some cases a liver biopsy is needed to differentiate. Serological tests used for *T. annulata* include the complement fixation test (CFT), indirect fluorescent antibody test (IFAT) and enzyme linked immunosorbent assay (ELISA).

Treatment: Many cases of *T. annulata* infection show spontaneous recovery. There have been few controlled trials of treatment. Both oxytetracycline (by injection) and chlortetracycline (orally) have been claimed to give relief. However, buparvaquone is at present the best therapy.

Control: Following natural infection there exists a pre-immunity that lasts for many years. There is no cross-immunity to other *Theileria* spp. Immunization is practised in several countries by taking blood from recently recovered cattle passaged through susceptible cattle. This is continued until no piroplasmic forms of the parasite occur. Then citrated blood is injected into susceptible stock, usually calves. Most animals show only limited reaction to such vaccination, although a few die. As there are no piroplasms in the blood ticks are not infected. Immunity can then be enhanced by injecting a virulent strain. It has been possible to culture schizonts on various tissue culture cell lines and these have then been used to vaccinate susceptible cattle. They do not produce piroplasms and so the animal cannot infect ticks.

Prevention otherwise involves control of the tick and cattle movements. Cattle can be sprayed or dipped with acaricide. Some walls and buildings can be sprayed to kill off the overwintering stages. Carrier animals still contain infection in their blood and if moved to new farms or countries will take the disease with them to infect local ticks. Thus detection of carriers is of use and can be done by taking blood from the animal and injecting into susceptible cattle.

Corridor disease

This condition is very similar to ECF but it has a different cause.

Aetiology: It is caused by *Theileria lawrencei*, which is primarily a protozoan parasite of buffaloes. However, it is transmissible to cattle and produces a similar type of disease to ECF. The schizonts tend to be smaller and fewer in number and the piroplasms relatively rare in the blood. If *T. lawrencei* is passaged through cattle it

quickly reverts to a parasite indistinguishable from ECF. It has therefore been suggested that *T. parva* is a cattle-adapted strain of *T. lawrencei*. It has also been proposed that the nomenclature for the two parasites should be *T. parva parva* and *T. parva lawrencei*.

Epidemiology: The disease has mainly been described in South Africa, Zimbabwe and Kenya. It is transmitted by the three-host tick *R. appendiculatus* and it is possible that distribution of *T. lawrencei* is over the whole area occupied by the tick. The buffalo (*Synerus caffer*) is considered to be the natural host and cattle brought in to the area tend to be susceptible. Those brought up in the region that survive the first few months are immune but those in marginal areas or where tick levels have only been partially introduced are not. *Theileria lawrencei* is transmissible from carrier buffaloes via ticks to cattle. It can be passed from cattle to cattle via the ticks. The recovered cattle can then act as carriers of infection. Morbidity in susceptible cattle is variable at about 60–80 per cent.

Signs: The signs are similar to those seen with *T. parva*.

Peracute: The animal develops pyrexia, lymph node enlargement and dies in a few days.

Acute: This is the most common form in susceptible cattle. There is pyrexia and swelling of the lymph node closest to the site of the infected tick bite. Other lymph nodes then start to swell and there is general dullness. There is lacrimation, nasal discharge and oedema occurs, particularly of the eyelids, face and throat. The animal becomes weak and develops diarrhoea containing blood and mucus. The respirations become laboured and dyspnoeic.

Mild: In this form there is a mild rise in temperature, swelling of the lymph nodes and some pyrexia.

Pathology: The lymph nodes are swollen and show hypertrophy and hyperplasia followed by oedema and haemorrhage. There are extensive haemorrhages on most of the serosal and mucosal surfaces. The abomasum tends to be red, inflamed and with ulcers, especially in the pyloric region. The spleen may be enlarged. The kidney cortex is congested and may show nodules of lymph and tissue raised above the surface. The liver is enlarged and a mottled grey colour. The lungs are grey and contain blood and fluid with froth in the alveoli, bronchi, bronchioles and trachea. Lymph node biopsy smears show hypertrophy and hyperplasia of the node.

A few lymphocytes contain schizonts and there are one or two piroplasms in the erythrocytes.

Diagnosis: The condition is similar to ECF, anaplasmosis and babesiosis and the peracute form is similar to heartwater. The signs, and area, help in diagnosis, particularly of those cattle associated with buffalo. However, where *T. parva* infection is common then disease caused by *T. lawrencei* may be missed. A lymph node biopsy helps as schizonts in the lymphocytes tend to be few and small in size. Blood samples show only a few erythrocytes to contain piroplasms. There is also no marked anaemia as in anaplasmosis or babesiosis.

Treatment: Use of oxytetracycline by injection reduces the intensity and duration of signs. Similarly, chlortetracycline has an effect and can be given by mouth. The naphthoquinones, parvaquone and buparvaquone are now successfully used.

Control: Infection can be controlled by tick dipping, controlling movement of susceptible cattle, grazing tick areas with less susceptible species such as sheep or goats and ensuring no contact occurs between cattle and buffalo or other game animals. Cattle that are exposed to infection and recover are immune. However, there is not complete cross-immunity with *T. parva* infection, although it does seem that cattle previously infected with *T. parva* have a good immunity to *T. lawrencei*. When cattle are initially infected with *T. lawrencei* there is only limited resistance to *T. parva*. Stabilates of ticks infected with strains of *T. parva* have been injected into cattle followed by treatment with oxytetracycline or parvaquone, which has given some immunity to *T. lawrencei*. Some stabilates have included a *T. lawrencei* strain.

Benign bovine theileriosis

This disease tends to be less severe than ECF, Mediterranean coast fever or Corridor disease.

Aetiology: The cause is a protozoan, *Theileria mutans*, which is very similar to *T. parva*.

Epidemiology: The condition affects cattle as well as the Indian water buffalo (*Bubalus bubalis*) and the African buffalo (*Synerus caffer*). It occurs in most parts of the world except countries north of latitude 55°N and South America. It is thought that transmission is by a wide variety of different ticks but it has been proved to be so with *R. appendiculatus*, *R. eventsi* and

Amblyomma variegatum. Injection of parasitized blood can produce infection. The disease is maintained by a premute state of recovered cattle, which allows continued infection of ticks. Infection often occurs with other diseases such as anaplasmosis, salmonellosis, heartwater or babesiosis.

Signs

Acute: This rarely occurs but it has been reported in Australia, India, Japan, Kenya, Korea and South Africa (where it is known as Tzaneen disease). In this case the disease involves fever with swelling of the lymph node closest to the infected tick and then more generalized lymph node swelling. There is a progressive anaemia and some of the cattle die. In Africa there is a cerebral form of the disease known as turning sickness where the animal will tend to walk in circles or head press.

Subacute: There are very few clinical signs other than a mild pyrexia with a swelling of the lymph nodes and a mild anaemia.

Pathology: In acute cases there is hyperplasia and oedema of the lymph nodes. There may be haemorrhages of the serosal and mucosal surfaces. The abomasum may be reddened and ulcerated. The kidney cortex is congested with swollen lymphoid areas. The liver is enlarged and tends to be grey in colour. The lungs contain fluid in the bronchioles, bronchi and trachea. The spleen is swollen.

Usually in the subacute form there is mild hyperplasia of lymph nodes, which contain a few schizonts. Anaemia occurs but is slight. There are only a few piroplasms in the blood and schizonts in lymph node sinuses.

Diagnosis: Diagnosis is helped by the mild nature of the signs but is not helped by the presence of only very few piroplasms in the blood or schizonts in lymph node biopsies. In addition the schizont is morphologically similar to *T. annulata* and *T. parva*. The best method of differentiation is by serology and the most effective test at present is IFAT.

Treatment: Quinoline drugs such as pamaquin are of use in the erythrocytic stage.

Control: As the disease is mild, deliberate control or eradication is not usually undertaken. However, control of ticks will result in control of disease. Cattle maintain immunity by a form of premunity, with piroplasms remaining in small numbers within the blood.

Besnoitiosis

This disease was previously known as globidiosis.

Aetiology

It is due to a protozoan called *Besnoitia besnoiti*.

Epidemiology

It is mainly seen in cattle and horses as intermediate hosts in south-west Europe and in Africa. Transmission has not been elucidated but is probably via the faeces of infected cats which are the final host. Morbidity can be up to 10 per cent and recovery is often protracted.

Signs

In many animals there are no signs. In the cow there may be lesions on the teats. There is pyrexia and warm swellings develop on the ventral parts of the body resulting in reduced movement. The lymph nodes are palpably swollen and there is diarrhoea. Pulse and respiratory rates are elevated. Pregnant cattle may abort. There may be excessive lacrimation and increased nasal discharge, which is at first serous and then purulent. There are small, white, raised nodules on the conjunctiva and nasal mucosa. There then follows severe dermatitis over most of the body associated with infected cutaneous cysts.

Diagnosis

This is based on clinical signs, especially the cysts on the scleral conjunctiva, and on the geographical area and can be confirmed by the detection of cysts containing spindle-shaped spores in scrapings of skin lesions or the conjunctiva.

Treatment

Nothing specific is available.

Control

A vaccine produced by *B. besnoiti* grown on tissue culture is effective.

Trypanosomosis

Trypanosomes are blood-borne protozoa with flagellae. Infections are widespread in wild and domestic animals and cattle are susceptible to infection with several species, the most important of which are those cyclically transmitted by tsetse flies (*Glossina* spp.) throughout

much of sub-Saharan Africa, namely *Trypanosoma congolense*, *T. vivax* and *T. brucei*. *Trypanosoma vivax* infections also occur in cattle in the absence of the tsetse fly in Central and South America and have been recorded in Mauritius. In tropical and subtropical areas other than sub-Saharan Africa, cattle are commonly infected asymptotically with *T. evansi*.

Tsetse fly-transmitted trypanosomes are commonly grouped together under the name 'nagana' (p. 1030). Their distribution lies within the tsetse fly belts of Africa, which extend from 14°N to 20°S in south-west Africa and 29°S in Mozambique, covering an area of 10 million km². Many species of wild animals are symptomless carriers of nagana trypanosomes and provide a sylvatic reservoir of infection in which the trypanosomes are cyclically transmitted naturally from host to host by tsetse flies. The principal carriers of these trypanosomes are wild bovids and suids, e.g. kudu, giraffe, buffalo, warthog and bushpig. Cattle, other domestic animals and man are infected when they come in contact with these wild animal carriers and are bitten by infected tsetse flies as a result.

Tsetse flies can be classified as falling into three groups, namely forest, riverine and savannah. The forest tsetse flies are found in the tropical rainforests of Central and West Africa and in scattered areas of East Africa. Although they are efficient vectors of trypanosomes, they are of least importance as cattle rarely come in contact with them due to the lack of suitable grazing in the forest regions. Riverine tsetse flies, as their name implies, infest riverine vegetation, but virtually only in river systems draining into the Atlantic Ocean. Their distribution is thus confined to Central and West Africa, largely overlapping with that of forest flies. Although they are less efficient vectors of trypanosomes than forest or savannah flies, because they infest vegetation near essential water supplies, riverine flies are important vectors of trypanosomosis of humans (Gambian sleeping sickness) and of domestic livestock including cattle.

Savannah tsetse flies are the most important group of flies because they infest large tracts of land potentially suitable for grazing and browsing by domestic livestock. They are also efficient vectors of trypanosomes and so when cattle and other livestock encroach into tsetse-infested savannah, they are at risk of being bitten by the fly and contracting infection.

Tsetse flies become infected when they take a blood meal from an infected animal. The trypanosomes then undergo cyclical development within the alimentary system, eventually developing to the infective or metacyclic forms within the fly mouthparts. These infective forms are then transmitted to another susceptible animal host via the saliva during the next fly feed(s). The development in the tsetse fly is an essential part of

the life cycle and hence nagana is unique to Africa. The one exception of the nagana trypanosomes is *T. vivax*, as mentioned earlier. In Central and South America it is assumed that *T. vivax* is mechanically transmitted by biting flies. This raises the possibility that it may also be transmitted mechanically in Africa, and indeed there is increasing evidence that this is the case.

Infection with *T. evansi* is also transmitted mechanically by biting flies. Infection of domestic livestock is widespread worldwide throughout the tropics and subtropics, but is absent from tsetse-infested areas of Africa. It is an important pathogen of camels, horses, dogs and buffaloes but cattle, although commonly infected, rarely suffer clinical disease. However, they may be important reservoirs of infection for other more susceptible livestock.

Aetiology

Tsetse-transmitted bovine trypanosomoses are caused by *T. vivax*, *T. congolense* and *T. brucei*. All are motile, extracellular, spindle-shaped, flagellated protozoan parasites ranging from about 10 to 30 µm in length. *Trypanosoma vivax* and *T. congolense* are essentially parasites of plasma, although *T. vivax* may leave the circulation in small numbers and invade extravascular tissues particularly of the heart (Losos, 1986). *Trypanosoma congolense* has a predilection for the microvasculature where it attaches to the endothelium of small blood vessels, particularly the heart and brain (Banks, 1978). *Trypanosoma brucei* as well as being a plasma parasite has a predilection for interstitial spaces and tissue fluids.

Trypanosoma evansi is related to *T. brucei* to which it is morphologically similar and has a similar infection pattern in the animal host.

Pathology

The pathogenesis of bovine trypanosomosis is complex and not fully understood but is characterized by a chronic and progressive anaemia. Uncomplicated tsetse-transmitted infection can be considered as following a course comprised of three phases (Murray, 1978).

Phase I (fluctuating parasitaemia and fever): Following an infected tsetse fly bite, trypanosomes multiply locally, causing an inflammatory reaction (chancre) within a few days at the site of the bite. Chancres are a regular feature of experimental infections, but have not been reported in natural infections. About this time, trypanosomes invade the circulation via the lymphatic system, causing reaction and enlargement of locally draining lymph nodes. Trypanosomes then appear in

the bloodstream, the prepatent period following initial infective tsetse bite varying with species thus:

| | |
|----------------------|------------|
| <i>T. congolense</i> | 12–16 days |
| <i>T. vivax</i> | 8–10 days |
| <i>T. brucei</i> | 5–20 days |

A fluctuating but diminishing parasitaemia then develops and parasitaemic peaks at approximately 12-day intervals are associated with febrile responses. Anaemia becomes evident early in infection and is believed to be haemolytic in the first instance, but haemolysis wanes and is superseded by anaemia caused by erythrophagocytosis due to stimulation and expansion of the mononuclear phagocytic system resulting in splenomegaly.

This initial phase of fluctuating parasitaemia and fever may last from a few weeks to a few months during which cattle lose condition and, depending on the severity of infection, some may die. Cattle that survive this phase enter the second phase.

Phase II (low-grade parasitaemia and progressive anaemia): Over the next few months, infected cattle have a low fluctuating parasitaemia during which the parasites may be difficult to detect. Despite the apparent reduction in parasites, the erythrophagocytosis and anaemia continue, although the spleen may return to normal size and cattle continue to lose condition.

Phase III (apparent aparasitaemia but continuing anaemia): Cattle that survive the second phase suffer chronic disease during which the parasites apparently disappear, although anaemia due to erythrophagocytosis continues. Affected animals are cachectic and normally die within six to twelve months of initial infection.

Infection at any stage may lead to congestive heart failure and death due to a combination of anaemia, circulatory failure and myocardial damage. At autopsy, post-mortem findings are not pathognomonic. They include emaciation, visceral pallor and enlargement of the heart. Cattle that die early in disease may have enlarged haemorrhagic lymph nodes and splenomegaly (Stephen, 1986).

Despite the large volume of literature on bovine trypanosomosis, good accounts of the pathology of natural disease are scarce and the above account represents a brief synopsis of the generally accepted picture. Cattle at risk may be infected by several species and strains of trypanosomes and the pathology and clinical signs will be influenced by various factors, e.g. the age, breed and nutritional status of infected cattle, the degree of tsetse challenge and the strains and species of infective trypanosomes. Thus strains of *T. vivax* in West Africa tend to cause a more acute disease in cattle than those of East Africa, whereas strains of *T. congolense* in East

Africa tend to cause a more chronic form of the disease. *Trypanosoma brucei* is the least pathogenic to cattle and normally regarded as of minor importance.

Although infection with more than one species is commonly reported in the field, virtually no studies have been done on mixed infections. Cattle infected experimentally with *T. congolense* and *T. brucei*, either simultaneously or one year apart, developed cerebral trypanosomosis with encephalitis and associated clinical signs and both species of parasites were isolated from the cerebrospinal fluid (Masake *et al.*, 1984). The authors suggested that the higher incidence of cerebral trypanosomosis in mixed infections than in single infections suggests an interdependence between *T. congolense* and *T. brucei* in the pathogenesis of cerebral trypanosomosis, possibly resulting from *T. congolense*'s predilection for the brain microvasculature facilitating the entry of parasites into brain parenchymal extravascular spaces. The possibility of such interaction between different species in natural infections merits further research.

Signs

The clinical picture of cattle suffering from nagana is influenced by several factors, namely breed and health status of cattle infected, pathogenicity of infecting trypanosomes, duration of exposure to infection and level of tsetse fly challenge, which in itself is dictated by several factors. *Trypanosoma vivax* infections in cattle in West Africa are widespread and commonly produce an acute, rapidly fatal disease in which affected cattle die during the initial phase of fluctuating parasitaemia and fever. Stephen (1986) describes acute *T. vivax* infection as resembling septicaemia in which affected animals have body temperatures of 40–41°C (104–106°F), depression, dyspnoea, elevated pulse and respiratory rates and a jugular pulse. Less severe cases show signs of anaemia, loss of condition (Fig. 45.2) and enlargement of superficial lymph nodes. Abortions and stillbirths may occur in pregnant cows.

The situation in East Africa and parts of Central Africa is different in that *T. congolense* tends to be a more serious pathogen than *T. vivax*, although this is by no means absolute as strains of *T. vivax* are known to cause an acute haemorrhagic disease in cattle in the Coast Province of Kenya (Mwongela *et al.*, 1981). *Trypanosoma congolense* in East and Central Africa tends to produce a chronic disease, although the clinical signs are essentially the same as those of *T. vivax* infection and eventual death is the usual outcome in untreated animals. In the early stages of infection appetite may be normal between periods of fever, but as the disease progresses the anaemia becomes more severe, cattle become depressed and lose bodily condition and in the

Fig. 45.2 Emaciated cattle suffering from trypanosomosis in northern Botswana (courtesy of A.G. Hunter).

terminal stages affected cattle are too weak to rise or eat (Stephen, 1986). Superficial lymph node enlargement is not so pronounced as in *T. vivax* infections.

Trypanosoma brucei infections of cattle, though common, are generally regarded as of minor significance and are usually mixed with the more pathogenic *T. congolense* or *T. vivax*. Parasitaemias from *T. brucei* infections are lower than those of *T. congolense* or *T. vivax* and hence infection can be more difficult to detect, raising the possibility that disease caused by *T. brucei* infection may not always be diagnosed. A few reports of meningo-encephalitis have been recorded, and experimental infection produces a severe diffuse meningo-encephalitis resulting in depression, unsteady gait, head pressing and circling (Morrison *et al.*, 1983). There is a greater incidence of cerebral trypanosomosis in mixed *T. congolense* and *T. brucei* infections as mentioned earlier and the involvement of the central nervous system (CNS) in natural bovine trypanosomosis requires investigation.

Trypanosoma vivax infections of cattle are widespread in Central and South America and the West Indies and were probably introduced with imported cattle from Africa. The importance of *T. vivax* in the New World is not clear, but epidemics of serious disease have been recorded in Venezuela and Colombia (Clarkson, 1976). In general, the clinical signs appear to be the same as chronic forms of *T. vivax* infection in Africa and the swaying gait of infected emaciated cattle may be confused with the clinical signs of rabies.

Trypanosoma evansi infections of cattle, though common throughout the tropics and subtropics, rarely cause clinical disease.

Diagnosis

In tsetse-infested areas of Africa, nagana is well recognized and diagnosis is often based on a history of a

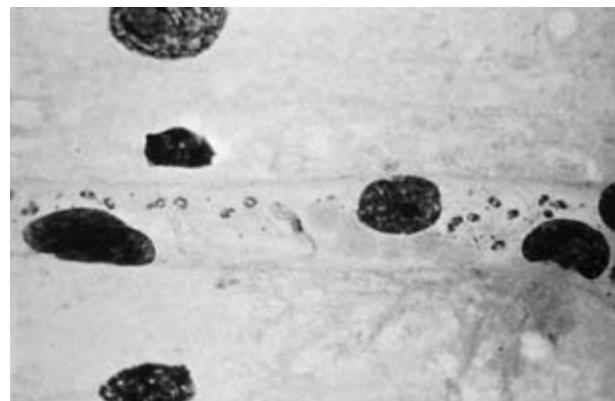

Fig. 45.3 *Trypanosoma congolense* in ox brain capillary (courtesy of CTVM Archives) ($\times 1000$).

chronic wasting condition of cattle in contact with the tsetse fly. Differential diagnoses are babesiosis (p. 748), anaplasmosis (p. 761), helminthosis (Chapter 19) and any condition that causes anaemia and emaciation, notably malnutrition. Nagana can be confirmed parasitologically by demonstrating parasites in the blood of infected animals and various techniques are available (Fig. 45.3). These techniques were reviewed by Paris *et al.* (1982) as follows.

- Microscopic examination of stained thin blood smears. Different species of trypanosomes can be identified by this method.
- Microscopic examination of wet blood films; this must be done at the time of sampling and cannot be used to identify different species of trypanosomes.

These techniques are not particularly sensitive and may not detect animals with low parasitaemias, such as those suffering chronic disease. More sensitive techniques are the following:

- Microscopic examination of the buffy coat-plasma interface of haematocrit-centrifuged blood, either directly through the capillary tube glass or by breaking the capillary tube just below the buffy coat and expressing the contents of the upper part onto a slide for examination by dark-ground or phase-contrast microscopy.
- Microscopic examination of stained dehaemoglobinized thick blood smears.
- Subinoculation of bovine blood into laboratory rodents. This is the most sensitive technique for *T. brucei* and is usually good for *T. congolense*, but most strains of *T. vivax* do not infect laboratory rodents.

In practice, many field programmes of monitoring cattle for infection are based on routine screening of stained thick and thin blood films; thick films are

examined to detect infected animals and thin films to determine the species of the infecting trypanosomes.

Trypanosoma vivax infections in the New World may have to be differentiated from conditions causing wasting and anaemia such as anaplasmosis, babesiosis and helminthosis and in addition, as mentioned earlier, rabies (p. 908; Chapter 70). In general the same techniques as described can be used to confirm diagnosis.

Serological tests are not in general use for diagnosis although several are under study. Trypanosomes display the phenomenon of antigenic variation during infection in the mammalian host in which successive parasitaemic populations of trypanosomes have a different antigenic composition. Thus the host mounts successive immune responses to sequences of different antigenic populations and a test developed to detect serum antibodies to one antigenic population may not detect serum antibodies against different antigenic populations of the same strain of trypanosome. These variable antigens are confined to the surface glycoprotein coat of the parasites and, although tests have been developed based on these variable antigens, they are largely confined to research in antigenic variation and have little routine diagnostic use.

Tests based on internal common somatic antigens may have potential diagnostic use as problems of cross-reactions between species become solved by monoclonal technology (Nantulya *et al.*, 1987). Of various tests developed, the IFAT and ELISA appear to have the greatest potential and the ELISA can be used to detect circulating trypanosomal antigens as well as antibodies (Rae & Luckins, 1984).

Treatment and control (see p. 1029)

Because of the phenomenon of antigenic variation, no vaccine has been developed against trypanosomiasis and is unlikely to be in the foreseeable future. In Africa this leaves tsetse control as the main method of prevention. Tsetse control programmes are widespread throughout Africa but will only be considered in summary here. Tsetse control is usually under the direction of the veterinary department and requires specialized expertise. The methods in use are as follows:

- Application of insecticide to tsetse habitat, either on the ground by hand or from the air by helicopters or fixed wing aircraft. This is the main method.
- Use of fly traps. These are used extensively in francophone West Africa and Zimbabwe.
- Removal of the tsetse habitat. Tsetse flies have to rest in certain bushes and trees, which can be cleared by felling and bulldozing, rendering the area unsuitable for the fly. This is expensive, however, and is now largely confined to main-

taining tsetse-free barriers around areas freed of tsetse.

- Settlement of land freed of tsetse. Housing, cropping, etc. may alter the vegetation to a form unsuitable for tsetse flies, so preventing reinfestation.
- Destruction of wild animal hosts. This is now unacceptable except in establishing animal-free corridors, possibly in conjunction with the third method, above.
- Release of sterile male tsetse flies to interfere with breeding of wild tsetse populations. Because of the very low reproductive rate of tsetse flies, only small numbers of flies can be reared in colonies. Therefore this method has limited application, usually in conjunction with other methods.

Thus, the commonest form of prevention is avoidance of the fly by cattle herders who build up local knowledge on when and where pastures are safe to graze. Savannah tsetse flies retreat and disperse during the dry and rainy seasons respectively, so that certain pastures may be tsetse infested for part of the year only. In addition, grazing tends to be safest at midday, when flies are least active, and most dangerous around sunset, when flies are most active (Pilson & Leggate, 1961).

In the absence of a vaccine cattle can be protected prophylactically, although effective prophylactics are now limited to one drug, isometamidium chloride. Isometamidium has certain disadvantages. It causes severe reactions at the site of injection, and there is considerable risk of resistance developing to the drug if cattle are exposed to infection after the active ingredient in blood has fallen to below a trypanocidal level, usually three months after injection. Thus where the risk of infection is constant, injection of the drug must be repeated at regular intervals to maintain effective levels. Despite this, under good management cattle can be efficiently reared in tsetse areas under isometamidium protection, as has been demonstrated on the Mkwaja Ranch in Tanzania over the last 30 years (Trail *et al.*, 1985).

Treatment against trypanosomosis, in order to be effective, should be given early in the disease during the initial phase of fluctuating parasitaemia. As no new drugs have been developed against the disease for nearly 30 years and some have been withdrawn because of resistance, treatment is now essentially limited to two compounds, diminazene aceturate and homidium (either chloride or bromide). Resistance has been recorded against both drugs and undoubtedly will be an increasing problem. As there is little likelihood of pharmaceutical companies developing new trypanocides because of the cost and uncertainty of the market, in many of the countries concerned the management of the existing drugs will require great care in the future.

Trypanosomosis is normally seen as a herd problem and mass chemotherapy is widely used on a herd or area basis, ideally in conjunction with some form of routine monitoring of blood smears of a percentage of cattle to indicate level of infection. Whiteside (1962) pointed out that when drugs are used regularly to treat cattle for trypanosomosis resistance may develop and when this occurs the drug in use must be changed to one against which there is no resistance and that should cure infections resistant to the first, i.e. a 'sanative'.

Resistance was rarely reported against diminazene, which consequently was recognized as the best sanative. The concept of 'sanative pairs' was introduced in which drug usage regimens were devised to alternate diminazene with another trypanocide to minimize the development of resistance. Thus the alternative to diminazene was used for treatment of clinical cases for as long as possible and then changed to diminazene for one year to ensure treatment of any resistant infections in circulation. Thus depending on the level of tsetse challenge, the regimen shown in Table 45.3 for treatment using drugs in current use was advocated.

In practice, it is virtually impossible to rear cattle in areas of very high challenge.

Because treatment is now limited to diminazene and homidium and their use must be managed very carefully, Whiteside's recommendations are possibly more valid today than when first advocated.

Diminazene acetate is the drug of choice for treatment of *T. vivax* infections in the New World.

Use of trypanotolerant breeds of cattle

It has long been recognized that dwarf humpless breeds of cattle in West Africa have a low susceptibility to trypanosomiasis and can survive in tsetse-infested areas where zebu types or European breeds cannot. Until relatively recently these breeds were regarded as having poor productivity and were of minor significance, however new research indicates this may not be the case; their potential is now under extensive investigation and the situation concerning these so-called

Table 45.3 Regimen for treatment of trypanosomosis to minimize development of resistance.

| Tsetse challenge | Drug alternatives | |
|-------------------------|--------------------------|-------------------|
| | Homidium | Diminazene |
| Very high | 6 months | 1 year |
| High | 1 year | 1 year |
| Medium | 2 years | 1 year |
| Low | As long as possible | 1 year |

'trypanotolerant' breeds was reviewed by Hoste (1987). Trypanotolerance has also been identified in Orma Boran cattle of East Africa (Njogu *et al.*, 1985) and the future prospects of greater utilization of breeds of cattle with natural resistance to trypanosomosis are very real.

Rickettsial diseases

Anaplasmosis

This is an infectious and transmissible disease of cattle that is seen in most continents of the world. It is non-contagious and is transmitted by ticks.

Aetiology

The cause of the disease is an intra-erythrocytic parasite, usually *Anaplasma marginale*. The red blood cells contain round inclusion bodies called anaplasma and they are peripheral in location, hence the name 'marginale'. There are three *Anaplasma* species and of the other two, *Anaplasma centrale* causes a mild condition in African cattle, as does *Anaplasma caudatum*.

Anaplasma marginale, when mature, is 0.3–1.0 µm in diameter and more than one can be present in the same erythrocyte. The parasite transfers from cell to cell in the form of an inclusion body. This is normally oval in shape and measures 31 µm in diameter and can penetrate the red cell envelope.

A member of the genus *Paranaplasma*, *P. caudatum*, has been found in a mixed infection with *A. marginale* in cattle in the USA state of Oregon. The inclusion bodies of *A. caudatum* can be shown with special staining techniques to have unusual appendages such as rings, loops or beads in the erythrocytes. However, these are not found when deer erythrocytes are infected.

Epidemiology

The disease is particularly seen in tropical and subtropical parts of the world and it exists in some temperate areas. Africa, North, South and Central America, the Far and Middle East, India, Russia and southern Europe all have the disease present. While mainly a bovine disease, buffalo, bison, antelope, deer, gnu and wildebeeste can all be infected. All ages of cattle are susceptible, but calves under six months old show few if any signs. The severity of signs depends on the age and previous exposure to infection. Generally, the older the animal at first exposure, the more severe the signs. Ticks are the natural hosts of the disease and at least 20 species have been shown to transmit infection. Little is known about the developmental life cycle in the tick,

although most infection is transmitted transovarially. The main genera of ticks concerned are *Argas*, *Boophilus*, *Dermacentor*, *Haemaphysalis*, *Hyalomma*, *Ixodes* and *Rhipicephalus*. Horseflies (*Tabanus* spp.) are experimentally and epizootologically the most important insect vector. They directly transmit the disease from an infected to a susceptible animal. Other arthropods that can be involved include stable flies (*Stomoxys*), deer flies (*Chrysops*), housefly (*Musca*) and mosquitoes (*Psorophora*). Cattle can be carriers of the disease as well as deer. The incubation period is usually two to six weeks, but it may be up to 12 weeks.

Signs

Peracute: This usually involves cattle over three years old experiencing infection for the first time. It is most commonly seen in high-producing purebred dairy cattle and is frequently fatal. There is a pyrexia with rapid loss of milk production. Anaemia occurs with very pale mucous membranes. The breathing is rapid with excessive salivation. Some cattle show nervous signs and abnormal behaviour.

Acute: This is seen in cattle up to three years old and is occasionally found in cattle between one and two. Signs often develop unexpectedly. The animal develops a progressive pyrexia over a few days, reaching 41°C (106°F). There is a loss of milk yield with a progressive anaemia and weakness. In addition there is depression, inappetence, dehydration and laboured breathing. The lymph nodes tend to be enlarged. Some cattle will exhibit jaundice, there is frequent micturition of normal-coloured urine and some cows abort. Bulls may show a temporary loss of fertility. Recovery takes a period of weeks. If death occurs it is within one to four days of the onset of signs.

Chronic: The signs may follow an acute infection with gradual emaciation.

Mild: This form is mainly present in cattle infected under one year old. Signs are usually few with a mild pyrexia.

Necropsy

The main signs at post mortem are of an acute anaemia and there is often jaundice. The spleen is enlarged and the gallbladder obstructed. The heart is usually pale and flabby and petechial haemorrhages may be present on the epicardium and pericardium. The lymph nodes are enlarged and oedematous. The blood shows a marked reduction in erythrocytes and haemoglobin. The mor-

phology alters to include anisocytosis and poikilocytosis and leucocytosis is often present.

Diagnosis

In typical cases the signs presented plus the presence of anaplasma inclusion bodies in stained peripheral blood smears are sufficient for diagnosis. Giemsa stain is usually used but toluene blue and acridine can also be helpful. The diagnosis of carrier or chronic cases is more difficult and normally depends on complement fixation, capillary tube agglutination and agglutination tests.

Treatment

The tetracyclines, i.e. tetracycline, chlortetracycline and oxytetracycline, are the only approved drugs that are effective in treatment. Administration can be oral or parenteral. Their use in the acute phase slows down the parasitic life cycle and so reduces the crisis. Latent infections can be eliminated by tetracyclines. They act more effectively and more quickly when given by injection rather than orally. Experimentally, other compounds of the dithiosemicarbazones have been shown to be effective. It is also important to provide good management for the animals and in valuable animals blood transfusions may be necessary.

Control

The main methods of control involve reduction in the vectors of disease, which can be done by ectoparasite dipping, but this does not entirely control the problem. Susceptible cattle can be separated from other carrier cattle and wild animals or carrier cattle can be detected and eliminated, although the tests used are not completely reliable. Otherwise immunization can be undertaken.

It was thought that cattle in indigenous areas do not normally show signs due to an infection immunity or prematurity. However, when there is intercurrent infection or the animal is stressed in other ways then signs are evident, although it does seem that in preimmune animals there is also a cell-mediated immune response. Both cell-mediated and humoral responses are required to provide protective immunity to anaplasmosis. In addition, continuous antigenic response is dependent on a perpetual low-level exposure to infection. Immunity using a live, laboratory-attenuated *A. marginale* ovine-origin vaccine gives good protection. Inactivated *A. marginale* vaccines of bovine and ovine origin require annual boosters. Their protective effect appears to be low. Experimentally, a more effective inactivated vaccine booster has been produced. Recently, a soluble

organism-free cell culture derived from *A. marginale* antigen has been developed.

Eradication is possible where ticks can be removed. Carrier cattle can be detected by a serological test, then the non-infected cattle need to be kept away from potential domestic or wild animal carriers. Movements of the cattle need to be controlled and it is necessary to reduce the level of biting flies. In such circumstances no live vaccination programme must be undertaken.

Tick-borne fever

Tick-borne fever is caused by the rickettsial-like organism *Ehrlichia phagocytophila*. It causes a prolonged febrile reaction, neutropenia and immunodepression in cattle in northern Europe (see Fig. 45.1b).

Aetiology and epidemiology

Ehrlichia phagocytophila is transmitted by the tick *Ixodes ricinus* during engorgement, but unlike babesiosis, infection takes place almost immediately after ticks start to feed. The circumstances and timing of infections are dependent on the ecology of the tick and typically take place most often during spring or autumn tick-activity periods, but can take place at any time between April and November. Infection in ticks persists transtadially, but not to the following generation of larvae.

After infection the organism enters or is phagocytosed by white blood cells, usually neutrophils, but infected eosinophils and monocytes are occasionally observed. The 'elementary body' can be seen in blood smears stained with Giemsa or Leishman stains as a pale blue dot in the cytoplasm of neutrophils. It enlarges to become a morula, after which the neutrophil ruptures and the elementary bodies of which the morula is composed infect further cells (Fig. 45.1b). The disease becomes apparent five to nine days after transmission by infected ticks. The animal develops a high fever, which can persist for up to 10 days. During this period the continuous destruction of neutrophils leads to a severe neutropenia and for as yet unknown reasons to a reduction of packed cell volume (PCV) of 30 per cent. As a result of the neutropenia the animal becomes immunodepressed and susceptible to other infections such as pneumonia, infectious pododermatitis and babesiosis due to *B. divergens*, which is frequently observed in susceptible cattle eight to twelve days after tick-borne fever. The 'parasitaemia' subsides but recrudescences occur periodically thereafter. Immunity develops slowly and persists only for a few months as cattle may be affected, albeit less severely, for some years following their infection.

Signs

Affected dairy cattle suffer an abrupt drop in milk production, which may last despite treatment for four weeks, and beef cattle lose a significant percentage of their body weight.

Diagnosis

The history is usually similar to that of cattle affected with *B. divergens*, i.e. recent purchase or movement to tick-infested pastures. Diagnosis can be confirmed by examination of blood smears for the presence of *E. phagocytophila* (see Fig. 45.1b).

Treatment and control

Tetracyclines are the antibiotic of choice and long-acting preparations have proved most successful.

Treatment of cattle with pour-on synthetic pyrethroids has been used to prevent tick infestation, reducing the tick population for two to three weeks. It has been less successful than when used on sheep, which retain higher concentrations of the pyrethroids on skin and wool for longer than cattle. The fact that transmission of *E. phagocytophila* occurs early in engorgement, in contrast to *B. divergens*, has resulted in the observation that protection of cattle against tick-borne fever using pyrethroids is less successful than against babesiosis, as accumulation of chemicals is more likely to kill the tick before transmission.

Bovine petechial fever (Ondiri disease, ondiritis)

This condition is a rickettsial infection of ruminants, but is restricted in area of occurrence.

Aetiology

The cause is a rickettsia-like organism, *Cytoecetes (Ehrlichia) ondiri*. The infection initiates in the spleen, and there it parasitizes the circulating granulocytes and, more rarely, monocytes. The organisms are pleomorphic and occur in cytoplasmic vacuoles, particularly in neutrophils. The organisms possess a rippled cell wall and they can be small (0.2–0.4 µm) or large (1–2 µm) bodies. In some cases there are mixed groups of large and small bodies.

Epidemiology

The disease appears to be confined to the highlands of East Africa. It mainly involves cattle exotic to the

region. Very well defined areas are often involved. The indigenous cattle and wild ruminants such as the bush-buck (*Tragelaphus*) and duiker (*Silvicapra* spp.) do not show clinical infection. The vegetation common to all sites is the edge of forest or thick bush. Experimentally, infection can occur in cattle, sheep, goats, impala, bush-buck, Thomson's gazelle and wildebeeste. Most of these develop latent infections. Thus carrier animals are produced from which it would seem highly likely infection could be spread by an arthropod vector. However, as yet, despite intensive investigations, the arthropod involved (probably a tick) has not been detected. The incubation period is variable, from four to 14 days, and in natural outbreaks disease has occurred 10 days after entering into an infected area. Mortality is around 20 per cent and occurs within a few days of onset of signs, but some animals will die two or three weeks after disease develops.

Signs

Peracute: These signs are seen in recently imported exotic cattle. They develop marked pyrexia and a drop in milk yield. The signs usually coincide with a parasitaemia. After two or three days petechial haemorrhages occur on mucous membranes, and in some cases that are fatal there is general congestion, with pulmonary oedema, dullness, weakness and a staring coat. Most of the cattle collapse and die within four days.

Acute: These types tend to occur over a longer period. The temperature is high but fluctuates. There is inappetence with reduced milk yield and abortion. Although petechial haemorrhages occur in some animals on the day after the onset of fever, in most animals they have appeared by three days. The haemorrhages disappear to be replaced by fresh ones within seven to ten days. They occur on the vulva, vagina, conjunctiva, labial surface of the gums and ventral surface of the tongue. Any normal discharge and faeces may be bloodstained. In some cases a characteristic 'poached egg eye' occurs with a swollen tense eyeball with the aqueous humour containing blood, the conjunctiva swollen and haemorrhagic and the eyelid everted.

Subacute: Affected animals show a transient, non-fatal condition with pyrexia and petechiation of the mucous membranes.

Inapparent: No signs are present.

Necropsy

The main findings are usually of an animal in good condition with submucosal and subserosal haemorrhages,

which may be large and distributed throughout the body. There is oedema and lymphoid hyperplasia. Often there is subcutaneous and intramuscular haemorrhage and melaena. The heart shows large haemorrhages into the epicardium and endocardium. There are also haemorrhages and oedema in the respiratory tract and the mucosa and serosa of the alimentary tract. The lymph nodes show hyperplasia and oedema. Both the liver and spleen may be enlarged and show petechiae. Histologically, there is marked evidence of petechiation. Characteristically, hyperplasia of large areas of the lymphoid sinus are seen. The rickettsiae can be found in impression smears of that surface of the spleen and liver. There is a characteristic absence of eosinophils, followed by markedly reduced numbers of lymphocytes and then neutrophils.

Diagnosis

Diagnosis is often difficult as the condition resembles anthrax (p. 717), bracken poisoning (p. 946), arsenic poisoning (p. 941), haemorrhagic septicaemia (p. 728), heartwater, acute trypanosomosis (p. 756) and acute theileriosis (p. 750). It is usually based on the history plus the area where it has occurred. *Ehrlichia ondiri* can be detected in blood or spleen smears stained with Giemsa, where it is particularly seen in granulocytes and monocytes. Often by the time clinical signs develop the parasitaemia is low or absent. In such cases it may be necessary to collect blood in EDTA or a suspension of spleen or lung and inject this intravenously into susceptible cattle or sheep. The granulocytes and monocytes in blood smears from the recipient, stained with Giemsa, should be examined daily for 10 days after inoculation.

Treatment

The most effective time to treat is during the incubation period when tetracyclines prevent disease. Once overt signs are present, double the usual therapeutic dosage of these antibiotics will reduce clinical signs and limit the parasitaemia. A single intravenous dose of alphaethoxyethylglycoxal dithiosemicarbazone at 5 mg/kg body weight will also reduce signs and the parasitaemia more effectively than tetracyclines.

Prevention and control

Eradication is impossible because wild animals act as a reservoir of infection. Clinically infected cattle are resistant to reinfection for several years, but they probably carry latent infections of *E. ondiri*. Losses due to the disease can be reduced by restricting access to areas of known infection. Clearing the undergrowth and

scrub aids this. If susceptible animals are to enter infected areas they should be watched daily and when infection is present a single dose of dithiosemicarbazone may then allow them to recover and become immune to infection.

Heartwater (*cowdriosis or malignant rickettsia, blacklung*)

This is another rickettsial condition that infects both domestic and wild animals.

Aetiology

The infection is caused by the rickettsia *Cowdria ruminantium* and is transmitted by at least five species of *Amblyomma* ticks. It is first found in reticuloendothelial cells and then parasitizes vascular endothelial cells. It is seen as close packed colonies consisting of less than ten to many hundred cocci. The agent is pleomorphic but the rickettsia in any one group tend to be of similar size. The organism varies between groups from 0.2 µm to greater than 1.5 µm. Division is by binary fission and it produces morula-like colonies in the cytoplasm. The small granules tend to be coccoid, with larger ones looking like rings, horseshoes, rods and irregular masses. It has been suggested that differences in the size and shape of the organisms are the result of a growth cycle.

Epidemiology

The disease has been reported in many African countries south of the Sahara desert. Distribution coincides with that of the *Amblyomma* ticks, which require a warm humid climate and bushy grass. Experimentally, five species of *Amblyomma* are able to transmit infection. These are three-host ticks. Transmission usually appears to be transtadial and so infected larvae are usually free from disease. Transovarian transmission can occur, but is thought to be very infrequent. Infected larvae are found on non-susceptible animals, but if they do become infected it can pass on to both nymph and adult stages. Infected ticks do not transmit infection immediately; they become attached to the animals, but a variable time after they start to feed. In many cases the level of infection is unknown as indigenous domestic and wild animals often show no signs. It is only when susceptible exotic species are introduced that infection becomes apparent. Besides cattle, sheep, goats, Asian buffalo, antelopes and deer are susceptible to infection and disease. Indigenous cattle undergo inapparent infection. Calves under three weeks old, even from susceptible stock, are difficult to infect. Heartwater can occur throughout the year, but incidence declines in the

dry season due to reduced tick activity. The incubation period is variable, from 7 to 28 days, with fever starting on average after 18 days. Mortality can be up to 60 per cent in exotic breeds, but less than 5 per cent in local cattle.

Signs

Peracute: This occurs in exotic breeds introduced to the region. The animal appears clinically normal, but if examined will have a marked pyrexia. It may then suddenly collapse, go into convulsions and die. Thoracic auscultation will often reveal oedema in the lungs and bronchi.

Acute: The course of infection is three to six days and consists of pyrexia (often over 41°C, 106°F), with nervous signs that may include ataxia, circling and abnormal posture. In other cases signs develop only to stimuli and there is then an excessive blink reflex, frequent tongue protrusion, a haggard, pained expression and muscular tremors. Pregnant cows may abort. If the condition progresses there are convulsions, paddling movements of the limbs, nystagmus, opisthotonus and chewing movements. Often a fetid, profuse diarrhoea is present or there may be blood in the faeces. A mild cough may be heard. On auscultation hydrothorax, hydropericardium and lung oedema are noted.

Subacute: The signs are like those of the acute form but they are much less severe with a transient fever and sometimes diarrhoea. Disease may last for over a week and the animal usually improves gradually. A few cases progress to collapse and death. This is often the most severe form seen in indigenous cattle and those previously infected.

Inapparent: These cattle include almost all the indigenous stock as well as some of those introduced to the region. In addition they often follow cases of reinfection.

Pathology

The lesions present are very variable and not pathognomonic. In the peracute form there are few gross lesions, but in some there is marked lung oedema with tracheal and bronchial froth. In the acute form there is usually ascites, hydrothorax, hydropericardium and lung oedema. The lymph nodes are often swollen. Petechial haemorrhages can occur in the heart, lungs and gastrointestinal tract. The liver is often engorged, with the gallbladder distended. The spleen is occasionally enlarged. There may be congestion of the meningeal blood vessels.

Diagnosis

There is no completely specific method of diagnosis in the living animal. Provisional indication can be from the history and clinical signs. Lymph node material can be aspirated to examine for vacuoles containing organisms in the cytoplasm of the reticular cells. There is a method of taking brain cortex so that the capillaries of the brain can be examined for rickettsia. Blood can be obtained and injected into susceptible animals. Eosinophils also decrease in number during the course of the disease. Serum can be examined using a capillary flocculation test. Diagnosis is easier at post mortem as the organism can be discerned in brain tissue capillaries that have been fixed in methyl alcohol and stained with Giemsa.

Differential diagnosis includes anthrax (p. 717) and acute theileriosis (p. 750) in peracute cases, and in nervous cases rabies (p. 908), tetanus (p. 733), strychnine poisoning, cerebral theileriosis (p. 752), cerebral babesiosis (p. 749) and hypomagnesaemia (p. 787).

Treatment

Therapy is most effective when carried out early in disease. Tetracyclines can be used and do not interfere with development of immunity.

Control

Disease can be prevented by controlling the vector *Amblyomma* by dipping cattle at weekly intervals with reliable acaricides. However, the ticks of this genus are less susceptible than those from other genera. As the tick may transmit infection after a day on the host, better control is obtained by applying acaricide by dipping or spraying every three days. However, *Amblyomma* have in some cases shown resistance to organophosphorus and arsenic. Care should also be taken not to introduce *Amblyomma* on infected animals or in forage to uninfected cows.

In areas where disease is endemic most cattle are immune. A carrier state develops after infection and remains for several weeks. Non-infected resistance persists a variable time, lasting from a few months to several years. After this time reinfection can occur. Ideally, an effective vaccine should be used. However, at present *C. ruminantium* is difficult to culture serially or to adapt to growth in laboratory animals. One method is to inject susceptible stock intravenously with 5–10ml of blood from an infected animal. As infected animals cannot always be available then infected blood can be stored in a freezer or liquid nitrogen provided it is frozen rapidly after addition of dimethyl sulphonate. The infection can also be retained in deep frozen brain emulsion or, more recently, in a supernatant of

homogenized engorged *Amblyomma* ticks. The recipient animal is monitored and then treated with tetracyclines as soon as pyrexia develops. Treatment continues twice a day until the fever subsides. Pregnant cows should not be treated in this way.

Jembrana disease (Tabana disease)

Aetiology

The cause of the condition is not known, but it is thought to be a rickettsial infection. Groups of small coccobacillary organisms have been found in cytoplasmic vacuoles present in circulating monocytes and in impression smears of cut organ surfaces. Some consider the disease may have a viral aetiology.

Epidemiology

The disease was first recognized in the Jembrana District of Bali Island, Indonesia, in 1964. Subsequently, the condition has only been detected in Indonesia. The disease is found in cattle as well as buffalo. Sheep and goats are infected with no apparent signs, but pigs are refractory to infection. In cattle there is apparent age resistance to infection and cattle over two years old rarely die from the disease. Animals that recover are carriers, but the duration of infection is not known. There is no direct infection from animal to animal and so it is not contagious. *Boophilus microplus*, a pantropical cattle tick, appears to be the natural vector and it is believed that infection can pass through the egg phase. The incubation period appears to be about a month to six weeks, although it is considerably shorter after injection of infection. Mortality is about 25 per cent and is usually within a week of onset of signs. Some animals relapse with infection at later dates.

Signs

Invariably there is a pyrexia of about 41°C (106°F) with anorexia, nasal and lacrimal discharge, which can persist for one to nine days. This is soon followed by enlarged lymph nodes. Often there is excessive salivation and erosion of the oral mucosa. Petechial haemorrhages may be found on the visible mucous membranes and haemorrhage is seen within the aqueous humour of the eye. Blood tends to ooze from the skin (so-called 'blood sweating'). Diarrhoea occurs early on and persists; it is often bloodstained.

Pathology

There are widespread haemorrhages and oedema. Usually, generalized lymphadenopathy occurs, with the

lymph nodes being hyperplastic and often showing disorganization. Splenomegaly is common and the blood vessels show vasculitis and perivasculitis. Surrounding the blood vessels there is proliferation of lymphoreticular cells in many organs except the liver. Rickettsia-like organisms can be detected in impression smears.

Diagnosis

This is based on the area and history. Confirmation depends on the haematological changes, which include a progressive anaemia, thrombocytopenia and transient leucopenia, which particularly involves the lymphocytes. As the disease progresses 'foamy' monocytes appear and large lymphocytes with coarse nuclei are seen. However, confirmation is difficult unless the animal dies. It is then dependent on detection of organisms in impression smears of cut organs and the vascular changes. In some cases blood is taken into EDTA from suspect cases and then injected into susceptible cattle.

Differential diagnosis includes rinderpest (p. 707), haemorrhagic septicaemia (p. 728) and plant poisonings (Chapter 54).

Treatment

Tetracycline injections during the course of the disease appear to have little effect on disease severity or duration, but they do seem to reduce mortality.

Control

Not enough is known about the disease to initiate control measures. Recovered animals are often carriers of infection and so resist further challenge.

Viral diseases

Bovine ephemeral fever (BEF)

This is also known as bovine epizootic fever and three-day sickness. Although signs occur they are quite mild and seem only to affect cattle. It is caused by a rhabdovirus, which can be present in the blood where it appears to be mainly in the leucocyte-platelet fraction and is transmitted by insect vectors. At present there is only a single serological type of the virus, although in Australia several rhabdoviruses with a distinct relationship to BEF have been isolated.

The condition is present in most of Africa except possibly the north. However, the incidence varies widely between regions and countries. It is also present in Asia, Australia and New Guinea. It does not occur in North

or South America. The disease is transmitted by vectors from infected host cattle, which explains the seasonality of the condition. If disease enters a new region it can cause epizootic infection with a morbidity of about 100 per cent, but mortality is usually less than 1 per cent. In the enzootic areas the condition is sporadic, with a morbidity of 5–10 per cent.

The cause of transmission is thought to be midges, probably of the *Culicoides* spp. and *Ceratopogonidae* family. Transmission is not direct between animals, indicating the need for maturation in the vector. Spread mainly depends on the number of insects infected and the direction of winds. Viral development in the insect is suspected to be cyclic. More losses occur in adult cattle, although calves from three months old are susceptible. Often the disease seems to disappear only to return again as an epizootic once resistance in the cattle population is reduced.

Signs

The incubation period is two to ten days and is followed by a marked pyrexia of 40.5–41°C (105–106°F). This is often very transient and so is missed. Other animals have intermittent pyrexia. There is a drop in milk yield, which is the main loss caused by the disease, with anaemia, oculo-nasal discharge and increased salivation. Alimentary signs are variable and can include constipation or diarrhoea. Within four days locomotory signs appear, including muscular tremors, which then develop into stiffness and weakness. The animal often becomes lame and the hindlimbs may become stiff. Signs may resemble those of acute laminitis. Occasionally, animals show lateral recumbency.

The animal usually starts to show signs of recovery after two or three days, with appetite and milk yield improving. However, the stiffness and lameness are likely to take several more days to reduce. Recovery is uneventful. Mortality is low and is usually the result of secondary infection, or following aspiration pneumonia after regurgitation of ruminal contents or following lateral recumbency. Abortion does not occur, but semen quality in bulls is often affected for a period.

Necropsy

The lesions are not specific. The main sign is enlargement and oedema of all the lymph nodes. Congestion and petechial haemorrhages of the pleural membranes may occur. Other signs are usually the result of complications such as aspiration pneumonia.

Diagnosis

This depends mainly on the signs of a mild disease with pyrexia and lameness, limb stiffness and muscle

tremors. There is a leucocytosis with a neutrophilia. A fluorescent antibody test will detect virus in blood. An agar gel immunodiffusion test has been successfully used on serum. The virus can be isolated by serial passage in Vero or BHK cell cultures or by intracerebral injection of sucking mice.

Treatment

Treatment is symptomatic but can include antibiotics for secondary complications, with the use of non-steroidal anti-inflammatory agents such as phenylbutazone or flunixin meglumine for muscle stiffness. It is best not to drench animals because of the high risk of aspiration pneumonia. Recumbent animals should be provided with adequate shade and water.

Control

Control of the insect vectors has not been successful. Immunity is long lasting after natural infection and has led to the development of vaccines, which are available in Japan and South Africa. Experimentally, live cell culture vaccines in an adjuvant base have been used with success, but give rise to fears of vector transmission between vaccinated and non-vaccinated stock. Control can also be achieved by dipping cows twice weekly during the peak period of infection when conditions are wet, hot and humid.

Lumpy skin disease (LSD) (see also p. 887)

The disease, also called Knopvelsiekte, results in many pox-like skin lesions and has been associated with a virus that is serologically related to sheep pox and on tissue culture produces three different groups of virus. One, an orphan virus (group I), is generally present on the skin of normal cattle but does not appear to cause the disease. The 'Allerton' virus (group II) causes a condition of a mild nature and is isolated from skin nodules, saliva, nasal secretions and semen. This form appears to be identical with the bovine herpes virus 2 of bovine mamillitis. It has often given rise to the name of pseudo-lumpy skin disease (p. 888). The severe disease is caused by a 'Neethling' virus (group III) and is found in blood, mucus, saliva and semen.

The disease is seen in most parts of Africa and is endemic in southern Africa. The virus is present on the skin even when hides are salted, in blood and in saliva and all can transmit infection.

The method of transmission has not been completely established, but it is believed to be by insects, particularly mosquitoes, as spread can occur without direct or indirect contact. Virus has been isolated from *Stomoxys* and *Biomyia* flies. As the saliva is infected, spread can

also be by feeding at troughs or sucking milk from infected cows. Indigenous cattle are less susceptible than imported purebreds. Experimentally, giraffe and impala have been infected. All ages of stock are susceptible but calves and lactating cows are most likely to be infected. The duration of immunity is not known and appears variable. Reports suggest it to be from 11 months to five years, or even lifelong.

Morbidity rates are very variable, from 5 to 80 per cent, with less than 2 per cent mortality. There can be a rapid spread of the disease.

Signs

The incubation period lasts from two to five weeks in natural infection but four to fourteen days with experimental infection and is followed by a rise in temperature, which may fluctuate. In severe cases there tends to be anorexia, lacrimation and salivation. There is a clear nasal discharge, which later becomes purulent. There is then the sudden appearance of nodules, varying in number from a few to many hundred. The nodules are firm, raised areas within the skin and vary in diameter from a few millimetres to 4–5 cm. These larger areas often have erect hair over them that exaggerates their appearance. The nodules are usually of a uniform size on individual animals and they occur over the whole body, although they are mainly found on the back, neck, brisket, legs, thighs, scrotum, udder and round the muzzle and eyes. Those on the mucosae of the muzzle, vulva, prepuce, nostrils, eyes and mouth are yellow-grey in colour and soft, and if rubbed off there is an ulcer or erosion. When the eye is affected there is keratitis and conjunctivitis. Respiratory lesions lead to dyspnoea and oral ones to salivation.

The associated lymph nodes tend to be enlarged. In some cases oedema develops. This can be of the lower limbs, brisket, udder, vulva or scrotum. The enlarged skin nodules can later ulcerate. These can then persist for several years or develop a dry surface that is lost. This becomes a deep pit, which heals by second intention. These wounds can become secondarily infected. This secondary infection can then spread to associated lymph nodes, the lungs, liver, kidney, etc. The areas of superficial oedema also remain a long time and can then slough, causing suppurative areas. Involvement of the lung can lead to cicatrization and rupture of the tracheal rings several months after onset of the disease.

The disease results in a chronic loss of condition and milk yield. Secondary infection can lead to mastitis, abortion and sterility in bulls.

The 'Allerton' mild or pseudo-lumpy skin form of the disease is less severe and only lasts a few weeks. There is a mild pyrexia followed by nodule formation mainly

on the head, neck and perineum. The nodules are characteristic with a hard, raised, rounded mass with a flat surface and a pit at the centre. Sometimes the skin lesions coalesce. Only the epidermis is affected, unlike the 'Neethling' form. The problem area develops into a hard, dry, necrotic lesion after a week to nine days. This is then lost over the next 10–14 days leaving a hairless area. Hair will grow again.

Necropsy

'Neethling' lesions include the whole depth of the skin, producing a hard white-grey mass. The skeletal muscle may contain grey nodules. Oedema of this is seen as yellow jelly-like liquid. If the oral mucosa is affected it contains soft grey-yellow nodules with necrotic epithelium. Necrotic ulcers with surrounding inflammation can occur in the nasal cavities. In the lungs there are firm grey nodules and the whole tract may show erosions and ulcers. Pulmonary lesions may lead to oedema and a purulent pneumonia. When lymphadenitis is present the nodules are swollen, pale and oedematous. The rumen and abomasal wall can show ulcers and erosions. Microscopically, the stratum papillomis, stratum reticulis and subcutis are involved. Secondarily, the surface epithelium, hair follicles and their associated glands are infected. In the subcutaneous tissues there is oedema, fibroplasia and perivascular inflammation with mononuclear cells, which usually results in thrombosis and overlying necrosis.

Diagnosis

The rapid spread of the disease and the sudden appearance of skin nodules after pyrexia are relatively characteristic signs. However, a biopsy can be taken and inclusion bodies can be found in skin lesions and the virus can be cultured. Other diseases that may be confused are the 'Allerton' form, urticaria (p. 883), dermatophilosis (p. 886), demodicosis (pp. 743, 881), onchocercosis (p. 774), besnoitiosis (p. 756) and severe tick and insect bites.

Treatment

There is no specific treatment but secondary infection may require the use of antibiotics or sulphonamides.

Control

Quarantine has generally not proved to be successful. In some countries a sheep pox virus tissue culture vaccine has been found to be of use. Otherwise, a vaccine produced from attenuated 'Neethling' virus on kidney tissue culture has been used successfully.

Rift Valley fever

This condition, also known as enzootic hepatitis, is a zoonosis but mainly affects sheep and cattle. Camels can be infected and also goats to a limited extent. It is notifiable in many countries. It is caused by an insect-borne RNA virus of one main antigenic strain of the family Bunyaviridae, and genus phlebovirus. The condition is transmitted between animals by insect vectors, usually mosquitoes. The disease was first identified in the East African Rift Valley, which gave rise to its name.

The condition is only found in Africa, particularly the central and southern regions, but the mosquitoes that are responsible for transmission occur on other continents. Thus there is a possibility of spread. Disease is transmitted by various types of mosquito including *Aedes* spp. Other biting arthropods would also cause spread.

Man can be infected by contact with infected animals, such as when undertaking necropsies. Infection may enter skin abrasions. The signs are of an influenza-like disease with pyrexia, severe headache, nausea, joint pains, flushing of the face, sometimes epistaxis and permanently impaired vision due to retinal haemorrhage. Death is rare, but in some instances complications such as sight impairment can occur.

Usually, an epizootic outbreak occurs in cattle followed by long periods, often of five years, between outbreaks. The persistence of infection between epizootics is unknown, but as cattle at the edge of and within forests tend to seroconvert consistently it is considered disease is maintained in wild fauna.

Disease is more common in warm wet seasons. Young animals are more severely afflicted than the adults. Mortality tends to be high in young calves, often reaching 70 per cent. In the adult, a mortality of 10 per cent can occur but the main problem is abortion.

Signs

The signs that develop depend partly on the age of the animals. They tend to be most severe in the calf, where the incubation period varies from 12 hours to three days. Occasionally, death occurs within 24 hours with few characteristic signs other than collapse and colic. Others show high fever, incoordination and collapse. The rare renal form is acute and can occasionally occur in adult cattle. In this type there is pyrexia, a profuse mucopurulent discharge, vomiting and prostration. Up to 70 per cent of affected cattle can die.

In adult cattle abortion is more common than the acute form. However, up to 10 per cent can develop marked pyrexia and die. Other lesions can include erosion of the oral mucosa and dry thickening of the

unpigmented areas of the teats, udder and scrotum. Hyperaemia of the coronets also occurs.

Pathology

The main lesion is one of hepatic necrosis with white or grey foci in the subcapsular area. Other lesions are typical of septicaemia with subserous haemorrhages of the pleura, pericardium, endocardium, lymph nodes and gut. There is often also oedema, congestion or haemorrhages of the gallbladder. Microscopically, there is focal or diffuse necrosis of the liver.

Diagnosis

The history of an outbreak is helpful in that it is in a mosquito area, there is an abortion storm plus calves becoming ill with many of them dying. Post-mortem examination of calves may show typical hepatic necrosis. There may also be evidence of human infection and if sheep are present then again in lambs there is disease of high fever, incoordination, collapse and high mortality, with abortion in ewes. There is usually a severe leucopenia. Serological confirmation is by means of a serum neutralization or complement fixation test.

Treatment

There is no known successful treatment, although interferon is effective *in vitro* and may eventually become available.

Control

The passage from country to country is difficult to control without the exclusion of susceptible animal species. Control of the insect vectors would be uneconomic and impracticable. It is possible that humans could act as carriers. A vaccine from neurotrophic virus passage through mouse brain has been used successfully. However, it can cause abortion. In consequence, a killed vaccine produced on BHK cells has been developed (p. 1018). This involves two injections to produce adequate immunity. Good immunity has been produced in sheep and humans by virus grown in rhesus kidney cell cultures and then inactivated by formaldehyde. A human vaccine is now available from virus raised in diploid fetal lung cells and inactivated with formalin.

Tick-borne encephalitides (flavivirus infections)

There are a series of diseases of animals resulting from tick-borne infection and characterized by nervous signs

and fever (Chapter 51). The causes are included within a complex of flaviviruses. The infections tend to be contained in various geographical areas. As a result there are a number of diseases that are identified by the area where the disease occurs. Thus, in Europe there is Russian spring-summer encephalitis, Omsk haemorrhagic fever and Central European encephalitis. Tropical problems include Kyasanur Forest fever in India and Lanyot in Malaysia.

In almost all cases the viruses maintain their presence in ticks, small rodents and insectivores. In the endemic cases infection of wild and domestic ruminants is inapparent. However, the introduction of new ruminants can result in disease. As yet the infections of Kyasanur Forest fever, which have been found in man and horses, have not resulted in disease in native domestic cattle. Infection in cattle would be via ixodid ticks. Man can be infected by ticks or, more commonly, via drinking infected goat's or sheep's milk. Infections from material submitted for laboratory diagnosis also occur. Immunity following infection is good and lifelong. Colostrum results in passive immunity being conferred to the young calf.

Signs

Disease is almost always only apparent in animals introduced to the tick area. The incubation period is one or two weeks. Pyrexia suddenly occurs and is usually biphasic. It is not until the second period of temperature rise that nervous signs appear. There is then incoordination, muscle tremors, ataxia, photophobia and hypersensitivity. The nervous signs become progressively worse. There can then be a flaccid paralysis, with death within a week. Those animals that recover are often subsequently debilitated.

Necropsy

There are few gross lesions. On histological examination there is necrosis of the neurones, particularly in the Purkinje layer of the motor nuclei, vestibular nuclei, cerebellum and ventral nerves of the spinal cord. Perivascular inflammation occurs throughout the white matter.

Diagnosis

The diagnosis is based on the area, presence of ticks, signs and lesions. The virus can be isolated from the central nervous system, particularly the brain stem and spinal cord. Differential diagnoses include bovine spongiform encephalopathy (p. 909), rabies (p. 908; Chapitre 70), neuromycotoxins, plant poisoning

(Chapter 54), tetanus, hypocalcaemia (p. 781) and hypomagnesaemia (p. 787).

Treatment

There is no effective form of treatment.

Control

Cattle should not be introduced to endemic areas unless they are vaccinated. The vaccines available provide protection for at least a year. Control of ticks by improving grazing and reducing bracken, etc., is useful.

Tick-borne encephalitis (Near East encephalitis)

This condition is still not fully elucidated. However, there are several diseases that have been recognized for many years. The disease is endemic in some countries including Syria, Lebanon, Israel and Egypt and a similar condition is recorded in India and Russia.

In most cases the accidental infection of ruminants results in few cases of disease. Usually, the virus cycles inapparently within birds and ticks. Most clinical disease is in Equidae, but occasionally problems have been recorded in sheep and cattle. The tick vector of Near East encephalitis is *Hyalomma anatomicum*. Infection passes through all stages of tick life including the egg.

All infection is tick mediated and it cannot be transmitted directly between animals. Immunity follows infection in cattle but its duration is unknown.

Signs

The incubation period for the disease is unknown, but may be four weeks. The severity of signs is variable and in the acute form there is a drowsiness and a pyrexia of about 40°C (104°F). However, in a few horses there are epileptiform fits with a progressive paralysis. Collapse and death can soon occur. In the subacute form pyrexia is usually transient and mild. Nervous signs are slight, but in some cases they can persist. Inapparent infections are common.

Necropsy

The alimentary and urogenital tract of the body show mucosal congestion, but there is meningeal blood vessel congestion. On histological examination there is diffuse lymphocytic infiltration, perivascular infiltration, microglial proliferation and neuronophagia and occasional rarefaction of tissues.

Diagnosis

The signs and post-mortem picture are not specific. However, cerebral injection of infected brain tissue into rabbits will aid virus identification. The major disease to be differentiated is rabies (p. 908).

Treatment

There is no effective form of treatment, only symptomatic.

Control

There are no suitable control measures that can at present be suggested.

Japanese encephalitis (flavivirus)

This is mainly a disease of man and has been given several local names, including Japanese B encephalitis, Russian autumnal encephalitis and summer encephalitis. Infection of animals is often from the human source. Most disease is seen as encephalitis in horses, followed by pigs. Mosquitoes are the natural vectors. Usually, infection in cattle and other ruminants is inapparent and of little overall significance.

Other arthropod-borne diseases

There are well over 300 diseases that are arthropod transmitted. Many are of limited geographical distribution. Frequently areas do not produce overt disease. However, where signs do occur, they can be non-specific with malaise and pyrexia. Often indigenous animals and wild animals develop inapparent disease that does not cause them any hazards or reduce production. However, the introduction of new animals will frequently result in overt disease, which can reach a high morbidity level.

Akabane virus (Asian virus)

This bunyavirus is mosquito borne and related to Simbu virus. It is recorded in the Far East as well as Kenya and Australia. The condition in cattle is thought to produce arthrogryposis and hydrocephalus as well as abortion.

Bhanja virus (African virus)

This is mainly an infection of goats but it has occasionally been isolated in cattle, particularly in southern Nigeria, and has also been reported in India. Infection has been found in *Haemaphysalis* ticks. Experimentally,

calves injected with Bhanja virus have developed a viraemia for several days and leucopenia.

Bunyamwera virus (African virus)

This is mainly a condition of goats, but serological evidence has been found in cattle and sheep. The infection occurs throughout Africa and is considered to be mosquito borne.

Cache Valley virus (American virus)

This is found in mosquitoes in Central and North America. Disease has not been recorded but sera of cattle are often positive.

California encephalitis virus (American virus)

In America there is a high incidence of antibody in the sera of cattle. Evidence of infection can also be found in deer and horses. It is a bunyavirus transmitted by mosquitoes. The virus is the most common cause of human viral encephalitis in the USA.

Calovovirus (European virus)

This is a bunyavirus that is mosquito borne. It results in cattle infection.

Congo virus (African virus)

This is a disease of humans and also affects goats and cattle resulting in anaemia, depression and pyrexia. The virus is transmitted by *Hyalomma* ticks and infection between countries is probably accomplished by migrating birds. It is likely that the condition is related to Hazna virus and others in Europe and Asia. The disease is severe in horses and is often fatal. However, in cattle and goats indigenous to Africa it results in a short period of illness that may be seen as anorexia, fever and depression.

Corriparta virus (Australian virus)

The virus is mosquito borne, particularly by *Culex* spp. The disease level is unknown but antibodies are found in the sera of cattle, horses and man as well as kangaroos and wallabies.

Dughe virus (African virus)

The virus appears to be spread by *Amblyomma variegatum* ticks, *Culicoides* and mosquitoes. It is the most frequently isolated arthropod-borne virus in Nigeria. In most cases there are no signs in cattle, but calves can be

infected experimentally and show a short-lasting viraemia.

Germiston virus (African virus)

This is a bunyavirus and is transmitted by mosquitoes. The virus causes infection in humans, usually in laboratories, but in cattle there are usually no signs but seroconversion. The condition is present in cattle, egrets and herons.

Harana virus (Asian virus)

The virus is transmitted by *Hyalomma* ticks and spread to other animals by migrating birds. This virus resembles, and may be identical to, Azo virus. It results in a severe infection of humans, often with haemorrhages and fever. It can be fatal. In cattle the disease is transient and usually results in anorexia, pyrexia and depression.

Ibaraki virus (Asian virus)

It is thought to be arthropod borne and is a double-stranded RNA virus. Antibody surveys show the infection to be widespread in South East Asia and the Far East. The condition is very similar to that of bluetongue. Disease is severe and only recorded in Japan. Signs include pyrexia with oedema and haemorrhaging in the mouth, abomasum and around the horn/skin junction. Degeneration of the muscles follows. There is then dehydration and emaciation due to difficulty in swallowing. Death is commonly due to inhalation pneumonia.

Jos virus (African virus)

This unclassified virus is transmitted by *Amblyomma variegatum* ticks. The disease signs are not really known but the virus has been isolated from indigenous Nigerian cattle.

Kodam virus (African virus)

This flavivirus is found in *Rhipicephalus parvus* ticks. The signs of disease are unknown but antibody is found in cattle.

Kokobera (Australian virus)

The virus has been found in mosquitoes in Queensland. It is a flavivirus. Antibodies have been detected in sera from cattle and horses, although there is no indication that the virus is a pathogen.

Kowanyama virus, Mapputta virus, Trubanaman virus (Australian viruses)

These are all found in tropical Australia and can be isolated from the *Anopheles* mosquito. Their pathogenicity is not known but antibodies are found in the sera of cattle, sheep and pigs as well as kangaroos and wallabies.

Kunjin virus (Australian virus)

This is a flavivirus found in mosquitoes in tropical Australia. There is serological evidence of infection in humans, horses, cattle and poultry. In calves experimentally infected a mild, non-purulent encephalitis develops.

Kotonkan virus (African virus)

This is a rhabdovirus found in *Culicoides*. The disease resembles ephemeral fever virus. The infection is particularly present in Nigeria.

Lokern virus (American virus)

Antibodies to the bunyavirus have been found in cattle, horses and sheep. The infection is found in Californian sandflies and mosquitoes.

Middelburg virus (African virus)

While antibodies can be found in domestic cattle in South Africa, disease has not been recorded. Man is not affected. The virus is spread by *Aedes* mosquitoes.

Murray Valley encephalitis virus (Australian virus)

This is a flavivirus found in mosquitoes and wild birds. It can produce epidemics of human encephalitis in Australia and New Guinea. The infection can be detected serologically in cattle, horses, pigs and dogs. When calves are experimentally infected the disease is symptomless.

Obodhiang virus (African virus)

This is a rhabdovirus found in *Culicoides*. The disease resembles ephemeral fever. It is found in mosquitoes in Sudan and the pathogenicity is not known.

Pongola virus (African virus)

Cattle sera will show antibodies to this virus but disease is not apparent. The name also applies to infection in humans, donkeys, goats and sheep. The condition is

spread by mosquitoes. The virus appears to be related to Rwamba virus.

Rwamba virus (African virus)

Cattle sera will show antibodies to this virus but disease is not apparent. The name also applies to infection in humans, donkeys, goats and sheep. The condition is spread by mosquitoes. The virus appears to be related to Pongola virus.

Sabo virus (African virus)

This virus is found in *Culicoides* in Nigeria. It is also frequently isolated from Nigerian cattle and has been isolated from goats. There is a transient fever and listlessness following infection. The virus is a member of the Simbu group of bunyaviruses.

Sango virus (African virus)

This virus is found in *Culicoides* in Nigeria. It is also frequently isolated from Nigerian cattle. There is a transient fever and listlessness following infection. The virus is a member of the Simbu group of bunyaviruses.

Shamondu virus (African virus)

This virus is found in *Culicoides* in Nigeria. It is also frequently isolated from Nigerian cattle. There is a transient fever and listlessness following infection. The virus is a member of the Simbu group of bunyaviruses.

Shuni virus (African virus)

This virus is found in *Culicoides* in Nigeria. It is also frequently isolated from Nigerian cattle and has been isolated from sheep. There is a transient fever and listlessness following infection. The virus is a member of the Simbu group of bunyaviruses.

Sindbis virus (African, Asian and Australian virus)

The life cycle is believed to involve *Culicoides*, mosquitoes and wild birds. In most cases cattle exhibit no signs but they do develop antibody titres. Infection of humans results in illness. It is a species of the alphaviruses.

Thogoto virus (African and European virus)

The virus is found in ticks in Nigeria and in *Boophilus decoloratus* ticks in Kenya. It has also been isolated in the tick *Rhipicephalus bursa* in Sicily. The infection can also involve humans and sheep. Calves, when experi-

mentally infected, show viraemia and leucopenia but usually there are no other signs.

PARASITIC DISEASES

Onchocercosis (worm nodule disease)

Aetiology

This is a filarial infection of the genus *Onchocerca*. In cattle, *Onchocerca gibsoni* affects the subcutaneous tissues, particularly the brisket and lower limbs; *O. liendis* (synonyms *O. gutturosa*, *O. bovis*) is found in the ligamentum nuchae, other ligaments and stifle joints; *O. ochengi* causes a dermatitis and *O. armillata* is found in the aortic wall. The worms are thread-like and often measure 6cm long with microfilariae 200–400µm long.

Epidemiology

The condition occurs worldwide, but is more common in the tropics and subtropics. The life cycle is indirect. Transmission is by midges (*Culicoides* spp.), sandflies and blackflies (*Simulium* spp.), which ingest microfilaria in the skin and subcutaneous tissue. They develop to the infective larval stage and then infect the final host when the vector again feeds. The larvae migrate to the predilection site where *O. gibsoni* develops into nodules and the others become enclosed in a fibrous cyst. The females produce microfilariae that remain in the skin or subcutaneous tissue.

Signs

There are few clinical signs except for the presence of nodules up to 3cm diameter under the skin, particularly in the brisket. In *O. liendis* infections there are few signs in the ligamentum nuchae but the stifle joint may be swollen. Disability can occur due to the supporting ligaments being affected. Infestation with *O. gibsoni* can result in nodules.

Pathology

There are nodules present. *Onchocerca armillata* is present in nodules in the wall of the thoracic aorta; *O. liendis* is found in the ligamentum nuchae, ligaments, stifle, the omentum, splenic ligament and capsule.

Diagnosis

The presence of infection can be detected by examining skin biopsies. Differentiation from skin tuberculosis (p. 743) and demodectic mange (p. 781) is necessary.

Treatment

There is no specific treatment but diethylcarbamazine citrate 4mg/kg in the food can be helpful, otherwise ivermectin, doramectin and eprinomectin can be used.

Control

The control of insect vectors is not practicable.

Stephanofilariosis

Aetiology

This is caused by parasites of the genus *Stephanofilaria*. These include *S. assamensis*, which occurs in India and Pakistan, *S. kaeli*, found on the legs of cattle in Malaysia, *S. stilesi*, affecting the ventral surface of the body and found in many parts of Asia, and *S. dedosi*, which occurs in Indonesia affecting the head and neck. The parasites are small (2–9mm long) and filariform in shape.

Epidemiology

The parasite occurs in cattle and buffalo in many parts of South East Asia as well as the tropics. The life cycle is indirect and involves anthomyid flies as intermediate hosts. Open skin lesions develop from which the flies feed and ingest the microfilariae. In the fly they develop to the infective larval stage and are then transmitted to the final host when the fly feeds. There appear to be more flies when conditions are moist either due to rain or presence of rivers, streams or irrigation.

Signs

There are only superficial lesions, seen initially as a papular dermatitis. There is then exudate and haemorrhage lasting many months with the skin becoming thickened and dry.

Diagnosis

This is based on the lesions and recent wet weather. Scrapings or smears from skin lesions reveal adult worms and microfilariae.

Treatment

Topical application of organophosphorus compounds is effective, including trichlorphane 6 per cent and coumaphos 2 per cent.

Control

There is no effective control but in some cases fly repellents are used. However, these are expensive for routine use. In adult animals that have been repeatedly infected with *S. stilesi* there is evidence that further infestation is reduced or stops.

Thelaziosis

Aetiology

Disease is caused by infestation with spirurid nematodes of the genus *Thelazia*, in cattle by *T. rhodesii*. The worms are thin, white and can be up to 20mm long.

Epidemiology

It occurs in the conjunctival sac of mammals in many parts of the world. In the species that have been studied the worms are viviparous and produce first-stage larvae that are infective for various Diptera, including *Musca* spp. The flies act as the intermediate hosts where the parasite develops to a third-stage infective larva, which is transferred to the final host when the flies feed.

Signs

There are often no signs, otherwise there may be lacrimation that can be unilateral or bilateral and is often purulent. There can be conjunctivitis, keratitis, corneal opacity, ulceration, protrusion of the eyeball and photophobia. Abscesses may develop on the eyelids.

Pathology

There may be conjunctivitis, keratitis and corneal ulceration and scarring.

Diagnosis

This depends on the signs and finding the worms.

Treatment

The most effective treatments are the avermectins ivermectin, doramectin and eprinomectin at 200 µg/kg. Levamisole can be given orally at 5mg/kg body weight or as a 1 per cent eye lotion. Otherwise, local anaesthetic can be used and the helminths removed manually. Irrigation of the unanaesthetized eye can be undertaken with 1 in 8000 aqueous iodine or 2 per cent boric acid, 3 per cent piperazine adipate or 0.2 per cent diethyl carbamazine.

Control

The condition is not usually severe and so control is not normally undertaken particularly because of the ubiquitous nature of the vector.

Other problems

Tick paralysis

Aetiology

This occurs with a number of different ticks and results in an ascending flaccid paralysis either due to acetylcholine failure at neuromuscular sites or a lack of conduction within the nerve fibres.

Epidemiology

This is seen in ticks in Australia (*Ixodes holocyclus*), North America (*Dermacentor andersoni*, *D. occidentalis*) and South Africa (*I. pilosus*, *I. rubicundus*, *Haemaphysalis punctata*). Most cases coincide with the peak tick populations and particularly at maximum adult activity. At times only one feeding tick may cause the problem.

Signs

The signs involve a change in temperament followed by slight incoordination. Then the animal starts to drag its hindlimbs and as the forelimbs are progressively involved it becomes recumbent. There is respiratory distress and then the animal dies of respiratory failure.

Necropsy

There are no characteristic signs at post mortem.

Diagnosis

If the ticks are removed the animal makes a recovery.

Treatment

Remove as many ticks as possible by hand, then treat with an ixodicide.

Control

Although susceptibility decreases with age, immunity varies from a few weeks to years. Prevention really involves the proper use of dips, sprays, etc.

Sweating sickness (sweetsiekte, notkalersiekte, vuursiekte, schwitzkrankheit, la dyhydrose tropicale, foma, ol macheri)

This appears to be a toxicosis with a dermatotrophic toxin related to tick infestations. Removal of the ticks results in a rapid clinical recovery. The problem is not transferred from animal to animal by the introduction of blood, saliva or tissue from ill animals. Animals appear to be susceptible or non-susceptible. In the former case cattle become ill with each exposure and can die. Only certain strains of the tick *Hyalomma truncatum*, known as the boat-legged tick, are implicated. The disease is seen in Central, East and South Africa. Although cattle are involved, particularly calves, sheep, goats, pigs and dogs are also affected. The signs vary according to individual susceptibility, age of the animal and the number of the correct strain of tick present. The inactive period is about six days, but varies from four to eleven. The morbidity of the condition is very variable and mortality ranges from 30 to 70 per cent. Immediately following recovery from sweating sickness immunity persists for well over a year and in some cases lasts up to four years. There appears to be no passive transfer of immunity to calves in colostrum.

Signs

Peracute: This is fatal in 48–72 hours, with a sudden rise in rectal temperature, hyperaemia, anorexia, dyspnoea, hyperaesthesia of the visible mucous membranes and muscle tremors. There tends to be excessive lacrimation and nasal discharge.

Acute: This only occurs in animals under a year old and presents as a sudden rise in temperature to 40–41°C (104–106°F) for a period of up to eight days. The pyrexia may be continuous or intermittent and lasts longer in the latter case. The mucous membranes become hyperaemic and there is lacrimation, salivation and nasal discharge. The hair is in poor condition and wet eczematous areas develop involving the head, particularly the cheeks under the eyes, nose, ears, then the neck, abdomen and flanks, and especially the groin. In some cases the whole body may be affected and accompanying the eczema there is hyperaesthesia, discharge and loss of the surface epithelium. Many badly affected calves show total hair loss.

Subacute: The signs are a sudden rise in temperature, but to a lesser extent and lasting only two or three days, and the mucous membranes show slight hyperaemia, as can the skin.

Inapparent: These animals show few signs but there is a form of residual immunity to the problem.

Pathology

The lesions depend on the duration of the condition and any concurrent disease. There is a disseminated intravascular coagulopathy with microthrombi (Van Amstel *et al.*, 1987). The oral mucous membranes show ecchymotic dermatitis, inflammation and superficial necrosis. The nasal cavity, pharynx, larynx, oesophagus and omasum show white pseudomembranes. In the thorax there is hydrothorax, hydropericarditis with oedema and emphysema. The liver displays fatty degeneration and the abomasal, small and large intestine mucous membranes show hyperaemia.

Diagnosis

This is dependent on the area and local history of the disease and presence of *H. truncatum* ticks on the animal. Pathological signs are helpful and there is an increased prothrombin clotting time. Peracute cases could be confused with anthrax (p. 717), babesiosis (p. 748), anaplasmosis (p. 761), heartwater (p. 765) and poisonings (Chapter 54).

Treatment

There is no specific drug that will affect sweating sickness, but hyperimmune serum is useful in treatment. The inflammatory nature of the disease suggests the use of anti-inflammatory agents, but corticosteroids are probably contraindicated as there are often high circulating cortisol levels in affected cattle. The use of antibiotics is indicated because of the likely immunosuppression that can occur in the presence of high cortisol levels. As there is severe intravascular coagulation the use of heparin at 10–20iu/kg body weight may be helpful. The liver is often affected and so multivitamin injections, particularly containing cyanocobalamin, choline and methionine, may be of use.

Control and prevention

Effective control of the ticks responsible with acaricides is helpful. Eradication is usually not feasible and so acaricide regimens should be designed to clear short-term infestation with the ticks, insufficient to produce distress but of long enough duration to allow immunity to develop. As the tick needs to be attached to the animal for at least 7–10 days to produce disease, weekly dipping normally produces reasonable control.

Mhlosimge

This is a less important toxicosis that is transmitted by certain strains of *Hyalomma truncatum*. It affects cattle, sheep and pigs. The signs are usually milder than sweating sickness. Cattle do not die of the disease but show pyrexia and anorexia. There is no cross-immunity between sweating sickness and Mhlosimge.

Magudu

This is also a less important toxicosis transmitted by some strains of *H. truncatum*. Again the disease is non-fatal and can affect cattle, sheep and pigs. The signs are milder than those of sweating sickness, including anorexia and pyrexia. Cattle previously infected with sweating sickness are immune to Magudu.

Stomatitis–nephrosis syndrome

This condition is reported in cattle in Zimbabwe. It is a toxicosis but it is not known whether it is of the sweating sickness type or a different *Hyalomma* toxicosis.

Milk fever (parturient paresis, hypocalcaemia, eclampsia)

Milk fever or hypocalcaemia is probably the most common metabolic disorder affecting cattle. It is normally associated with parturition occurring just before, during or immediately after calving although it has been reported in dry cows and, increasingly, during mid lactation. The incidence of milk fever is higher in dairy cows than beef cows and increases with age and yield. Milk fever undoubtedly increased in incidence during the 1970s and 1980s when levels of around 9 per cent per annum were being reported. More recent studies would suggest that the incidence has fallen to around 5–6 per cent, in spite of increased milk yields, and probably the result of improved nutrition of dry cows. The incidence does vary considerably between seasons as well as between farms. In some years the incidence in September and October in the UK can be as high as 60 per cent on some farms, whereas during the winter months when dry cows are housed 0–6 per cent would be frequently reported. The disease does appear to be more common when dry cows are fed grass rather than conserved fodder. Milk fever is a common cause of death and is probably the most common cause of apparent sudden death in dairy cows. It is also a common cause of dystokia and hence stillborn calves.

Predisposing factors

There are several important predisposing factors that influence the occurrence of milk fever and these account for the wide variation of incidence observed in the UK and other countries worldwide.

Breed: The Jersey and, to a lesser extent, the Guernsey are particularly susceptible to milk fever. This would indicate a genetic predilection for this disease and is probably related to the relatively high production level for a small breed.

Age: It is rare for milk fever to occur at the first calving and relatively uncommon at the second. The incidence does appear to increase with age and incidence levels of 20 per cent or more are common at the sixth calving and beyond. The reason is thought to be that the requirement for calcium at parturition increases as milk yield rises with each lactation and the ability to mobilize calcium quickly from the body reserves, i.e. bone, decreases with age.

Seasonal factors: The incidence in the UK is highest in the months of August to October and at its lowest in the winter months of December, January and February. However, this is more likely to be a result of differing feeding regimens of dry cows than a seasonal effect. In countries where there is little change in dry-cow nutrition during the year, e.g. Israel, there appears to be no seasonal differences in the occurrence of milk fever.

Nutritional factors: The wide range of incidence of milk fever observed between seasons, within a season and between farms in the UK is due to the variation of nutritional input given to dry cows. Dry cows that are fed a diet of hay or silage only, which is now commonplace in the UK, will have a low incidence of milk fever at calving. However, if feeds containing high calcium levels are included in the diet, e.g. sugar beet pulp or high calcium minerals, the incidence will increase.

The incidence of milk fever in cows at grass varies considerably with the season. In dry weather the incidence is low, but during long wet spells the level is high. A diet of grass with a low dry matter (DM), whether in the spring or autumn, can predispose to high incidences of milk fever. There is more than one reason for this. One is that such a diet leads to diarrhoea, which probably reduces the calcium available for absorption. The calcium level of wet grass, particularly in the autumn, can be excessively high, often as high as 1 per cent of

DM. Potassium levels may also be high. It has been shown that low magnesium levels in the diet restrict the cow's ability to absorb calcium (Sansom *et al.*, 1983) and the high levels of milk fever found in the spring and autumn in the UK are often due to low magnesium levels in the grass.

Aetiology

Some degree of hypocalcaemia occurs in all cows at parturition, but only when this becomes severe do clinical signs develop. Frequently, hypophosphataemia and hypermagnesaemia accompany the hypocalcaemia, although when milk fever is due to low magnesium intake the blood levels of magnesium will also be depressed. The normal concentration of calcium in plasma lies within the range 2.2–2.6 mmol/l (8.8–10.4 mg/100 ml), but will fall to 1.5 mmol/l (6.0 mg/100 ml) in most cows at parturition without milk fever signs occurring. Usually, when milk fever is present the plasma level will be in the range 0.75–1.5 mmol/l (3.0–6.0 mg/100 ml).

The predisposing factor in the aetiology of hypocalcaemia at parturition is the sudden increase in the requirement of calcium for the production of colostrum. The daily calcium requirement of a 600 kg cow in late pregnancy is approximately 28–30 g; this comprises 13–15 g required for endogenous loss in faeces and urine and 15 g to maintain the growing fetus. At the onset of lactation, approximately 1–1.5 g of

calcium is required for each litre of colostrum produced, so the requirement is increased two- or three-fold in a very short period. In order to meet this enlarged demand and to avoid hypocalcaemia, calcium absorption from the gut is increased and further calcium is available from mobilization of the calcium reserves in bone. This explains why mild hypocalcaemia occurs in all cows at parturition. If the cow does not respond quickly to the sudden increase in calcium requirement the hypocalcaemia deepens and signs of milk fever become apparent.

In the normal cow this adaptation process at parturition is under the hormonal control of the parathyroid hormone (PTH). Hypocalcaemia stimulates the secretion of PTH, which in turn stimulates the production of a hydroxylase enzyme in the kidney that is able to synthesize 1,25-dihydroxycholecalciferol ($1,25(OH)_2D_3$), which is produced from vitamin D₃. The $1,25(OH)_2D_3$ stimulates increased gut absorption of calcium and probably the mobilization of calcium from bone (Fig. 46.1).

Several factors affect the speed of response to this adaptation process:

- Age of the cow, as already mentioned. Older cows are less able to mobilize calcium from the skeleton.
- Oestrogens also inhibit calcium mobilization and as oestrogen levels rise at parturition this will have a negative effect on the adaptation process to maintain calcium levels. Milk fever does occasionally occur during lactation, usually in association with

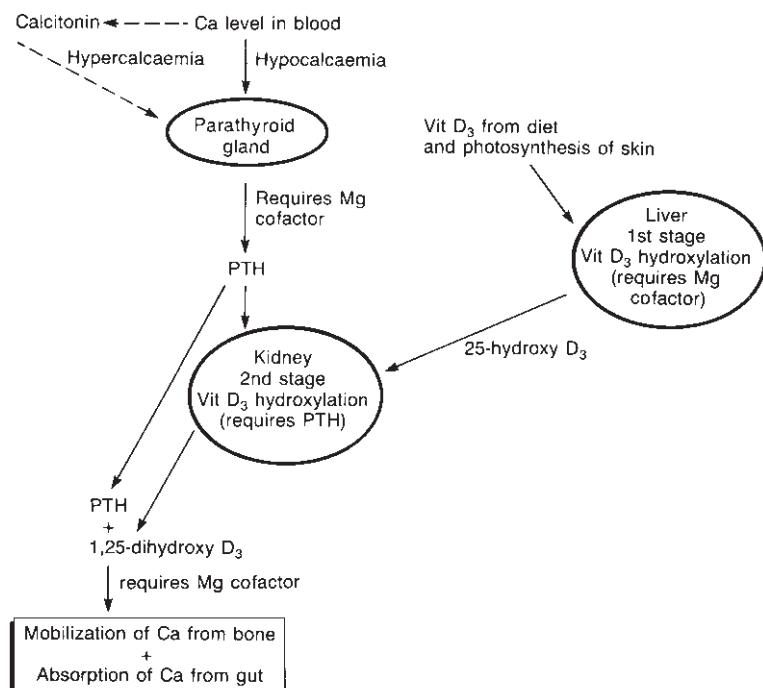

Fig. 46.1 System for mobilizing calcium in cattle.
PTH, parathyroid hormone (Kelly, 1988).

oestrus. This again would be due to the inhibitory effect of oestrogens.

- Food intake is often depressed at or around parturition so the total available calcium in the diet will be reduced. This is particularly the case if diets low in calcium, e.g. straw or cereal-based diets, are fed over the parturition period.
- The calcium intake during the dry period. If high levels of calcium are present in the diet the reduced PTH output that occurs reduces the rate of absorption from the gut, so that when the demand for calcium suddenly increases and the cow's appetite is generally reduced absorption does not satisfy the body requirement (Fig. 46.1).
- A low magnesium intake in the diet reduces by various mechanisms the ability of the gut to allow calcium absorption. Therefore, diets that are deficient in magnesium will predispose to hypocalcaemia by reducing calcium absorption. Hypomagnesaemia also inhibits mobilization of calcium from bone (Fig. 46.1).
- Problems associated with digestion, e.g. acidosis and profuse diarrhoea, will reduce the amount of calcium in the gut available for absorption. This could also explain cases of hypocalcaemia that occur at times other than parturition or oestrus.

Signs

The clinical signs of milk fever are progressive. In the first stage there is a loss of appetite, lethargy and the rectal temperature is reduced by 0.5°C (1°F). This progresses to a stage where the cow stands with the hocks straight and sways laterally, particularly when moving. Constipation is normally seen at this stage. Muscle tremors may be present about the head and limbs. Hyperesthesia is also often evident at this stage and the cow becomes apprehensive. The lateral swaying develops into incoordination and ataxia and the cow will fall over sideways and rise with increasing difficulty until she becomes permanently recumbent.

The recumbent stage is the one most commonly seen by veterinarians in practice. The cow will be sitting in sternal recumbency, often with a noticeable S bend in the neck, progressing to the stage where the head will be resting on her shoulder. The heart rate will be slightly raised but rarely exceeds 90/minute. The pupils will be dilated and the pupillary light reflex will be reduced or even absent. The gut stasis that characterizes this stage of the disease further reduces the availability of calcium for absorption and the disease will progress to the comatose stage. The rumen ceases to function and often becomes tympanic and the cow appears severely depressed. The comatose stage is characterized by lateral recumbency, increased rumen

tympany and total absence of the pupillary light reflex until the cow dies. Death can be due to paralysis of the respiratory muscles, but more often death occurs from bloat. Many cows with milk fever are found in ditches or streams, having fallen in during the incoordination phase of the disease. In these situations death can be due to drowning.

The length of time for the disease to progress from first signs of inappetance to death varies from 10 to 24 hours. Many cows are found dead or near to death by the stockworker at the time of morning milking, having been quite normal the previous evening at 7.00 pm.

If hypocalcaemia occurs at the onset of calving the parturition process will cease due to lack of myometrial contractions. A considerable number of cases of dystokia due to uterine inertia are the result of hypocalcaemia and, if not treated, will result in a stillborn calf or even death of the cow before the calf is born. It is common for the stockworker to find a cow in lateral recumbency in the early morning with the calf presented in the birth canal or even with the head present at the vulva. Frequently, the calf will be dead and occasionally even partially eaten by foxes or other wildlife.

Clinical pathology

The concentration of calcium in plasma is usually below 1.5 mmol/l (6 mg/100 ml) in cows with clinical hypocalcaemia and will fall to as low as 0.25 mmol/l (1.0 mg/100 ml). Phosphorus levels also fall to 1.0 mmol/l from the normal range of 1.4–2.5 mmol/l (4.3–7.8 mg/100 ml). Magnesium levels usually increase to around 1.25 mmol/l (3.0 mg/100 ml), except where the cause of milk fever is related to low magnesium diets when hypomagnesaemia may be present. Hyperglycaemia is also usual during milk fever, but this is frequently seen in normal cows at parturition.

In fatal cases of milk fever there are no gross or histological lesions characteristic of the disease. Bruising of subcutaneous tissue and muscles due to localized trauma may be apparent. The liver is occasionally distended and infiltrated with fat, resulting in a yellow discolouration. Cows with such a fatty liver are thought to be more prone to milk fever, but fatty liver is not pathognomonic of milk fever.

Diagnosis

The diagnosis of milk fever is made on the signs described above and the history of recent or imminent calving. Although blood biochemistry may be considered useful, in practical situations there is not the time available to obtain a result. A cowside test for calcium is now available in some countries but its value is probably limited to differential diagnosis of the downer cow

syndrome or cows failing to respond to treatment for milk fever. The most valuable diagnostic aid available is, once the differential diagnoses have been eliminated, the response to treatment. Intravenous treatment with calcium borogluconate will produce a clinical response within minutes. The cow will become more alert, defaecate and eructate, often before the full dose of calcium has been administered.

Differential diagnosis

Although milk fever is an extremely common disease it is essential that a full clinical examination be made for every case. It is common for the new veterinary graduate to diagnose and treat a recumbent cow for milk fever when the cause of the recumbency is toxic mastitis. The clinical examination must therefore include examination of milk from all four teats, the heart rate and the mucous membranes. Misdiagnosis is now more common as farmers treat their own cases of milk fever and frequently confuse the disease with other causes of recumbency.

The differential diagnoses of milk fever are:

- Acute toxic mastitis (Chapter 23);
- Calving paralysis (p. 438);
- Physical injury (p. 446);
- Hypomagnesaemia (p. 787);
- Downer cow syndrome (pp. 439, 789);
- Inanition and other disease (p. 150);
- Pregnancy toxæmia (p. 796);
- Acidosis (p. 829);
- Hypothermia (p. 930);
- Bovine spongiform encephalopathy (BSE) (p. 909).

Acute toxic mastitis: In acute toxic mastitis from whatever cause the temperature may be raised but is sometimes subnormal, the pulse may be in excess of 120/minute, the eyes are often sunken, the mucous membranes injected and, in acute coliform mastitis, they are frequently a purple colour. Abnormal milk secretion will be found in one or more teats, although in acute coliform mastitis this change in milk character may be less than obvious.

Calving paralysis: The history of dystokia due to fetal oversize and recumbency since calving help in the differential diagnosis, but many cases are not clear-cut. Intravenous calcium together with the response noted is probably the best aid to differential diagnosis.

Other physical injury: This can occur at any time of lactation or the dry period and can include fractured limbs, pelvic damage and severe muscle damage. These can be the result of excess riding behaviour during oestrus,

slipping on ice or slippery concrete or even a collision with a vehicle such as a tractor.

Hypomagnesaemia: This can occur at any time of lactation during the spring or autumn but is sometimes present as a complication of milk fever, particularly during the two seasonal risk periods of spring and autumn. Hyperaesthesia is the main differentiating sign of hypomagnesaemia.

Downer cow syndrome: Initially, this may be difficult to differentiate from milk fever but response to therapy and clinical biochemistry will be helpful. This will be discussed in full later in the chapter (see p. 797).

Inanition: Any condition producing severe weight loss will result in recumbency, particularly in pregnant cows, the most common of which is probably starvation. In seasons where insufficient conserved food is available, recumbency due to starvation is common. Body condition is the obvious differentiating feature. However, any disease that causes considerable weight loss will have the same effect, e.g. liver fluke (p. 276). In seasons when liver fluke prevalence is high, this disease can result in extreme weight loss and anaemia and recumbency prior to parturition is common. Weight loss, red cell count and presence of fluke ova in faeces would be the differentiating features.

Pregnancy toxæmia: This can occur, particularly in beef cows, in the last two or three months of pregnancy. The sweet smell of acetone on the breath, poor condition or excessive fat and a history of unavailability of food should distinguish this problem. The rumen will also be functioning in the early stages of this condition.

Acidosis: Acute acidosis as a result of the sudden ingestion of large amounts of carbohydrate material, usually cereal-based concentrates, will result in recumbency, although hypocalcaemia is often a feature of acidosis. Here the history will help and usually acidosis is accompanied by diarrhoea.

Hypothermia: Mild hypothermia (reduction of 0.5°C or 1°F) is a normal feature of milk fever. However, severe hypothermia (reduction of 3–4°C or 5–7°F) occurs in cows that have been recumbent all night in winter out of doors. Although these cows have some other primary disease, e.g. milk fever or mastitis, treatment will be unsuccessful unless steps are taken to raise body temperature as rapidly as possible.

In summary, there are many diseases and conditions that result in recumbency of the cow. However, careful history taking and a thorough clinical examination will eliminate most differential diagnoses and if one is still

not sure of the diagnosis, response to intravenous calcium will always be a useful indicator.

Treatment

The treatment for milk fever is the slow intravenous infusion of 8–12g of calcium as soon as possible after the onset of clinical signs.

A number of licensed preparations are available for the treatment of milk fever and most are based on calcium borogluconate (CBG) at 20 per cent, 30 per cent or 40 per cent strength (see Table 46.1). It has been shown that 400ml of 30 per cent CBG is adequate to treat milk fever in average size cattle and will provide 9g of calcium. However, the most commonly used product in the UK is 400ml of 40 per cent CBG, which will provide 12g of calcium. During cold weather the CBG solution should be warmed to body temperature. Approximately 85 per cent of cases will respond to one treatment. In many cases cows recumbent from milk fever will rise within 10 minutes of treatment and others will get up 2–4 hours later.

Following the intravenous infusion, which itself should take five minutes, it is essential to sit the cow in a sternal recumbency position and turn her so that she is lying on the side opposite to the one on which she was found. Many cases will eructate and defaecate during the treatment. If the cow does not rise immediately she should be turned to lie on the opposite side every two hours. Following intravenous treatment, milk fever cows should be able to sit comfortably in the sternal recumbent position without the aid of support such as bales of straw. If the cow keeps returning to lateral recumbency following treatment the diagnosis should be reassessed as it is unlikely to be milk fever.

The use of intravenous treatment cannot be overemphasized as it is essential that the blood calcium levels return to normal as quickly as possible to avoid the complications resulting in the downer cow syndrome. Farmers treating their own cases of milk fever commonly use subcutaneous injections of CBG. This is undoubtedly a factor that has increased the incidence

of the downer cow syndrome in recent years. Following intravenous therapy plasma calcium rises rapidly and falls to around 2mmol/l (8mg/100ml) 5–6 hours after treatment. Following subcutaneous therapy, the plasma calcium levels may take 3–4 hours to reach 2mmol/l (8mg/100ml). Furthermore, in severe cases of milk fever the peripheral blood circulation will be impaired, which will inhibit the absorption of any fluid material administered subcutaneously. In practice one is often called to attend cases of milk fever that have not responded to subcutaneous treatment administered by the farmer several hours before and the whole of the treatment solution is still present at the injection site.

As already stated approximately 85 per cent of cows will respond to one treatment. If response is not evident by 5–6 hours, then the cow should be re-examined, the diagnosis reassessed and if necessary a further intravenous infusion of 8–12g of calcium administered. Some practitioners advocate 400ml of CBG intravenously plus 400ml subcutaneously to prevent relapses. Relapse of milk fever occurs in 25 per cent of cases treated and this figure is not affected by additional subcutaneous administration. Blood levels of calcium six hours after intravenous or subcutaneous infusions are similar and by 12 hours after administration all the calcium administered, whether by the iv or sc route, has been eliminated from the body.

Treatment of milk fever should also be accompanied by removal of the calf and advice to the farmer not to milk the cow for 24 hours except to check for the presence of mastitis. As already stated, relapses occur in 25 per cent of cases treated and the likelihood of relapse will be reduced if milk is not drawn from the udder during this 24-hour period. The 8–12g of calcium given is only a small proportion of the daily calcium requirement, so the treatment is only a holding operation until the normal adaptation process is in full operation. Cases of relapse usually occur at 18–24-hour intervals and should be treated in the same way, i.e. by the intravenous infusion of 8–12g of calcium. Occasionally cows, particularly Jerseys, have been known to relapse on up to seven occasions.

There is a tendency amongst farmers to give two bottles of 40 per cent CBG, which would amount to 24g of calcium. Such a procedure is probably counterproductive, as there is some evidence to suggest that too high levels of calcium administration will slow up the adaptation process and actually increase the number of cows that relapse.

Some proprietary CBG preparations also contain magnesium (1.0g) and phosphorus (2.6g) in addition to calcium. If hypomagnesaemia is a complicating factor of milk fever then the addition of the magnesium may be helpful. However, in cases of clinical hypomagnesaemia more than 1.0g of magnesium will be required.

Table 46.1 Licensed products available for the treatment of milk fever in the UK.

| Product | Pack size (ml) | Available calcium (g) | Dose required for 600kg cow (ml) |
|----------------------|-------------------|--------------------------|-------------------------------------|

The presence of the phosphorus has no doubt been added because of the finding that the blood levels of phosphorus in cases of milk fever are also depressed. However, clinical evidence would suggest that the addition of phosphorus has no effect on the percentage of cases that recover or relapse. In fact, it has been shown that plasma phosphorus levels return to normal within a few hours after successful treatment with CBG without the addition of phosphorus.

Historically, the treatment of milk fever was by udder insufflation. This has the effect of slowing down milk production. Plasma calcium levels do rise following udder insufflation and will reach 2.5 mmol/l (10.0 mg/100 ml) by 4–5 hours after treatment. However, the efficacy of CBG intravenously and the danger of mastitis following insufflation have now rendered this mode of treatment almost extinct except that some clinicians have been known to use the technique in cows that persistently relapse.

Prevention

Much milk fever can and should be prevented (see Table 46.2). If an outbreak occurs in any season where more than 10 per cent of cows are needing milk fever treatment the first action the clinician should consider is to blood test a group of six or seven dry cows to measure the concentration of calcium and magnesium. If the magnesium levels are low, i.e. below 0.85 mmol/l (1.8 mg/100 ml), this should be seriously considered as interfering with calcium absorption, in which case supplemental magnesium should be administered to all dry cows within three weeks of calving. Approximately 10–12 g of magnesium administered daily to dry cows will be sufficient to produce normal plasma levels of magnesium and to allow normal calcium absorption. However, this is often difficult to achieve because of the problem of giving supplemental feeds to grazing cows. A supplement of 25 g daily of calcined magnesite mixed with cereal (1 kg/cow) or silage will produce the desired effect, but many farmers are reluctant to give supplemental feeds to dry cows. Recent experience in the UK has shown that the addition of magnesium acetate or

magnesium chloride to the drinking water is a practical and effective way to supply magnesium to cows; 40 g daily of magnesium chloride crystals can be added to drinking water if large enough troughs are available. Trough size should be 20 l/cow. If trough size is limited, magnesium acetate can be added to the water supply using a water proportioner plumbed into the water supply pipe.

If the plasma levels of the dry cows are normal then diets restricting calcium intake may be considered, particularly if the plasma calcium levels are at the high end of the normal range. To be certain to prevent milk fever, dry-cow diets should contain less than 30 g/day of calcium. However, in practice, diets producing less than 50 g/day of calcium will prevent most cases of milk fever. Autumn grass in the UK often contains 8–10 g/kg DM calcium. Thus with daily intakes of 12–14 kg DM, 90–140 g/day of calcium will be available in the diet. It is impossible appreciably to reduce this level of intake without removing the cows from grass and substituting a diet based on maize silage, hay or straw. However, some farmers are prepared to do this to reduce the risk of milk fever and incidence levels of 5 per cent or less are possible. It should be appreciated that if low calcium diets are advocated for dry-cow use, just before parturition a diet containing more calcium should be administered to ensure adequate calcium being available over the risk period. This can be achieved by feeding cattle concentrate or feeds that are high in calcium, e.g. sugar beet pulp (see Table 46.3).

Other methods of milk fever prevention involve dealing with individual cows. Maintenance of appetite is essential and, in the past, appetite stimulation by the use of anabolic steroids has been suggested, but the use of these products is now illegal in Europe. Maintaining adequate calcium intake by drenching cows daily with 150 g/day of calcium chloride on the day before calving and for four days thereafter has had some success in

Table 46.3 Approximate calcium, phosphorus and magnesium contents (g/kg DM) of some common feedstuffs.

| | Ca | P | Mg |
|-------------------------------------|----------|---------|---------|

preventing milk fever and might be considered in cows with a known history of milk fever.

The use of vitamin D₃ and its metabolites given by injection has been advocated in preventing milk fever. The administration of 10 million iu of vitamin D₃ given eight to two days before calving will considerably reduce the incidence of milk fever but the practical problem remains of accurately predicting the time of calving, which in practice has proven more difficult than expected. More recently, the analogue of the vitamin D₃ metabolite 1 α -hydroxycholecalciferol (1 α (OH)D₃) has been used in trials to prevent milk fever. Doses of 350 μ g given at least 24 hours and not more than five days before calving do reduce the incidence of milk fever, but once again the problem remains of accurately predicting the time of calving. Recently, workers in Israel (Sachs, 1988) have suggested that a single dose of 700 μ g of 1 α (OH)D₃ given eight to seven days before expected calving is more effective and that the accuracy of calving date prediction is less important.

Vitamin D₃ or 1 α (OH)D₃ will not be effective if the diet is deficient in magnesium. Before recommending their use the magnesium status of the herd should be assessed by blood testing six or seven dry cows.

It has been found that there is less milk fever when diets are acidic. This is the basis of the dietary cationic-anionic balance (DCAB). It is the balance between cations (Na⁺ and K⁺) and the anions (Cl⁻ and S²⁻) present in the diet. Their levels affect the acid-base balance and thus calcium metabolism. Some diets in the dry period are anionic and the reduction of the balance in favour of a negative balance assists. This is achieved by increasing the feeding of Cl⁻ and/or S²⁻, by reducing the amount of Na⁺ and/or K⁺ present or by feeding maize silage. The target is to achieve in the last two weeks before calving -200 mEq/kg DM. This can be done by using 200–250 g of anionic salts. Practically this is often achieved by the addition of 100 g NH₄Cl and 100 mg of MgCl₂. However, such diets should only be used where there is adequate calcium provision. The system is complex and should only be used on farms with good quality management.

Hypomagnesaemia (grass tetany, grass staggers, lactation tetany, Hereford disease)

Hypomagnesaemia is a common feature of a group of syndromes dominated by hyperesthesia, incoordination, tetany and convulsions that can occur in all ruminants of all ages. Grass tetany or grass staggers is the name given to the syndrome affecting lactating cattle (beef or dairy cows) when grazing grass in the spring or autumn. Subclinical hypomagnesaemia can occur in lac-

tating or dry cows in the spring or autumn and is usually not accompanied by clinical signs. It usually affects the whole herd. Lactating cows will suffer a slight reduction in milk yield and may have a slight nervous disposition, e.g. reluctance to enter the milking parlour. Dry cows will be more prone to milk fever at parturition. If the herd is affected with subclinical hypomagnesaemia some individuals will develop grass staggers, particularly if stressed. Milk tetany occurs in calves fed predominantly milk, particularly calves suckling cows that are subclinically hypomagnesaemic (see p. 253). The incidence of hypomagnesaemia varies considerably from region to region. Some areas of the UK are particularly high in the incidence of the disease in both beef and dairy cows. Overall, the annual incidence in UK dairy herds is approaching 1 per cent.

The clinical disease is most common around peak lactation, presumably reflecting the secretion of magnesium in the milk. It is also a common cause of sudden death. In 1984 in the UK it was estimated that 0.8 per cent of the dairy cow population died from the disease (Whitaker *et al.*, 1984). This was following the introduction of milk quotas in Europe and a dramatic reduction in the use of concentrate feeds for dairy cows, particularly during the summer months.

Aetiology

As there are no readily available body stores for magnesium, the main factors involved in the aetiology of hypomagnesaemia are the reduction of the amount of magnesium available in the food, and hence available for absorption from the gut, accompanied by a high physiological demand for magnesium. Magnesium is lost from the body in milk, urine and faeces. The endogenous loss in faeces has been calculated to be approximately 1.8 g/day (ARC, 1980). Milk contains 0.12 g/l of magnesium so a cow producing 30 kg of milk would lose 3.6 g daily in the milk. Any excess magnesium absorbed will be excreted via the urine, this being the mechanism for stabilizing plasma magnesium levels. If the plasma magnesium levels rise much above 0.8 mmol/l (2.0 mg/100 ml) the excess will be excreted. If magnesium intake levels are excessive, up to 5.0 g/day may be excreted in the urine. However, if magnesium intake falls to the level to maintain homeostasis or below there will no magnesium identifiable in the urine.

To maintain magnesium homeostasis the absorption of magnesium must be continuous so a constant supply is necessary in the diet. Feeds vary considerably in both the content and the availability of magnesium so the choice of pasture is important. Clovers have higher magnesium content than grasses and grasses themselves vary. Fast-growing Italian ryegrasses have lower levels than perennial grasses. Many broad-leaf plants, such as

buttercups (*Ranunculus* spp.), plantains and nettles, have considerably higher magnesium levels than grasses, which probably accounts to some extent for the increasing incidence of hypomagnesaemia seen in recent years in the UK as old permanent pastures have been replaced with ryegrass leys.

Some soils are known to be deficient in magnesium but also the uptake of magnesium by plants may be influenced by cations such as calcium and potassium in the soil. It has been shown that fertilizers containing potassium applied to grazing areas in late winter or early spring will reduce the absorption of magnesium by plants, and soils containing high levels of potassium are particularly prone to producing hypomagnesaemia in grazing ruminants.

Although historically this disease has been one related to spring grass, in recent years it has become increasingly common throughout the whole grazing season from April to October. The occurrence during winter has also increased in the UK; this can be attributed to the increasing use of grass silage made from young leafy grass low in magnesium during May.

Another important factor in the aetiology of the disease is the energy intake of the animals. This is particularly the case in beef suckler cows grazing inadequate pastures, particularly during times of inclement weather. Experiments have shown that reduced energy intake will interfere with the magnesium available for absorption. The availability of magnesium for absorption from the gut is thought to range from 4 to 35 per cent. Calcium, potassium and ammonium (nitrogen) ions are all thought to interfere with body uptake of magnesium.

It is possible to find animals with low plasma magnesium levels but yet clinically normal. It would appear that the critical factor influencing the onset of clinical disease is the level of magnesium in the cerebrospinal fluid (CSF). The speed at which magnesium levels fall also influences the onset of clinical signs. In the spring, magnesium levels fall rapidly and clinical disease may become apparent at blood levels at which in the autumn, when the fall is more gradual, the cows remain clinically normal.

The role of calcium in the onset of clinical hypomagnesaemia is also unclear. Approximately 80 per cent of cows with grass staggers have low plasma calcium levels. It has been shown that cows will develop clinical disease within 24 hours after a fall in plasma calcium levels although they have been hypomagnesaemic for several days.

Milk tetany occurs in calves two to four months old reared on whole milk diets without the addition of magnesium supplementation. In young calves absorption of magnesium is good. However, as the calf grows older the ability to absorb magnesium declines. Thus, if the

two to four-month-old calf is denied feed supplementation other than cow's milk, magnesium absorption will decline to less than requirements and clinical signs will appear. This is seen in suckler calves or veal calves reared on milk or milk substitute that has not been supplemented with magnesium (see p. 253).

Signs

The signs of grass staggers may be classified as subacute, acute or peracute. In the subacute form cows will be apprehensive and hyperaesthetic. The head will be held high and tremors may be seen around the head (particularly the eyelids), over the shoulder and on the flank. These tremors will be exaggerated if the animal is touched or the skin pinched. The legs may become stiff and a staggering gait may be evident. Cows can remain in the subacute phase for several hours or progress to the acute or peracute form, particularly in response to noise or some other stimulus such as attempting to herd them. The peracute cases will stagger for a few steps and fall over with tetanic spasms of the head, neck and legs followed by clonic convulsions. The legs will paddle furiously, the eyes roll and there is frothing at the mouth. The heart will pound fast and furious and death can occur at any time. Cows have been known to be grazing one minute and, in response to noise from a vehicle or other stimulus, to stagger, fall over in convulsions and die in two or three minutes.

The signs in the acute case will be similar but may last for up to an hour or more. In these cases a period of convulsions will be followed by a quiescent period in which the cow may attempt to rise, only to walk a few steps and fall over again followed by convulsions. The rectal temperature, if taken, will be elevated by 1 or 2°C (2–4°F). Cows are often found dead with obvious signs that the limbs had been paddling prior to death, thus disturbing the soil around the feet.

In the subclinical form the majority of the herd are usually affected even if acute cases have not been diagnosed. If acute cases are present it can be assumed that the majority of the herd will be affected subclinically. The cows may be slightly nervous, reluctant to enter the milking parlour or be unwilling to be herded. The milk yield will be depressed slightly.

The signs of milk tetany in calves (p. 255) are much the same as for cows with subacute, acute and peracute cases occurring. Often in peracute cases the animals are found dead.

Clinical pathology

Healthy normal cows should possess plasma magnesium levels over 0.85 mmol/l (2.0 mg/100 ml). Any levels below this must be considered a risk and indicative of

subclinical hypomagnesaemia, although in acute cases the plasma levels will generally be below 0.4 mmol/l (1.0 mg/100 ml). Magnesium levels in the CSF in acute tetany will generally be below 0.6 mmol/l (1.4 mg/100 ml). Hypocalcaemia is present in at least 80 per cent of acute tetany cases and hyperkalaemia is common. Following tetany or in recovered cases aspartate aminotransferase (AST) and creatine kinase (CK) levels will rise to relatively high levels but return to normal quite soon after recovery.

At post mortem there are no pathognomonic signs. Haemorrhages may be present on the heart muscle and occasionally along the aorta. Regurgitation and aspiration of rumen contents may sometimes be seen. The CSF levels of magnesium will be low and magnesium will be absent from the urine, although the bladder is nearly always empty at post mortem.

Diagnosis

The diagnosis of grass staggers is made on the signs described above. The time of year and type of grazing may help in forming a diagnosis. As there is little or no time in acute cases to conduct blood biochemistry, response to treatment will also confirm a diagnosis. It may be useful for the clinician to take a blood sample before treatment so that analysis can be performed at a later stage should this prove necessary. If animals are found dead then diagnosis must be differentiated from other causes of death. Diagnosis at post mortem is difficult because of the absence of obvious lesions. If quantities of soil have been gouged out of the ground by each of the four feet during the paddling phase this is strongly indicative of acute grass staggers. Absence of magnesium from urine would be a useful indicator, but the bladder is generally empty. Blood and tissues are of no value at post mortem because magnesium levels rise rapidly after death. Levels in CSF may be helpful and recently it has been suggested that magnesium levels in aqueous humour taken after death will be depressed in cows that have died from grass staggers. If a cow is found dead and grass staggers suspected from the history and absence of other lesions at post mortem, the wise clinician will blood sample six to seven cows in the group and test for magnesium levels. It is important to make a diagnosis to be able to offer preventive advice for the remainder of the herd.

Diagnosis of death due to milk tetany in calves is possible by measuring the calcium and magnesium levels in bone. A rib or coccygeal bone is usually used for this purpose. A calcium/magnesium ratio in bone of 70:1 is considered normal and 90:1 considered an indication of severe magnesium depletion.

To diagnose subclinical hypomagnesaemia blood sampling seven cows each from a lactating and a dry-

cow group and testing for magnesium is the most useful indicator. Testing urine for magnesium levels has been advocated, absence of magnesium indicating the sub-clinical state. Urine test strips are available in some countries. However, there are real practical problems in getting a number of cows to micturate on demand.

Differential diagnosis

Acute lead poisoning: In lead poisoning (see pp. 906, 944) there may be excitement and occasional convulsions. Hyperaesthesia, as measured by observing muscle tremors in response to pinching the skin, will be absent and blindness is usually a feature of lead poisoning.

Milk fever (p. 783): Some cows in the early stage of milk fever may exhibit hyperaesthetic signs. The history of being close to parturition is the most helpful aid to this differential diagnosis. Many cows are hypocalcaemic as well as hypomagnesaemic and so treatment involves calcium administration; thus being able accurately to differentially diagnose the two conditions is not important in practice.

Acetonaemia (p. 740): Some cows with acute acetonaemia will have hyperaesthetic signs and appear nervous and apprehensive. However, the depraved actions of these cows, such as licking the walls and floor or biting at gates, will usually distinguish this disease from hypomagnesaemia, as will a Rothera's test on a sample of milk.

Listeriosis (p. 904): Acute listeriosis may be confused with acute grass staggers, but the high rectal temperature and absence of true hyperaesthesia in listeriosis cases should be enough to distinguish this disease.

Bovine spongiform encephalopathy (p. 909): The emergence of BSE in the UK in 1986 has sometimes made the differential diagnosis of the subacute form of hypomagnesaemia more difficult. The ataxia, apprehension and mild hyperaesthesia found in BSE are similar to that found in subacute hypomagnesaemia. Diagnosis is usually confirmed by response to treatment and blood biochemistry, a sample being taken before treatment. If there is any doubt in the clinician's mind it would be wise, in cases of suspected BSE, to take a blood sample to eliminate subacute hypomagnesaemia before notifying the suspicion to the authorities.

Others: Lightning strike (p. 930) as a cause of sudden death, some plant poisonings, and in particular Paspalum staggers (*Claviceps paspali* poisoning), are differential diagnoses but can usually be distinguished on grounds of history alone. Rabies (p. 908; Chapter 70)

may cause problems in countries where it occurs, but such animals usually are hyperactive, bellowing and riding other cattle.

Suboptimal production: If production is below expectations, particularly in seasons associated with hypomagnesaemia, then subclinical hypomagnesaemia could be present. Blood biochemistry in the form of a metabolic profile that includes magnesium should be considered (see p. 813).

Treatment

Acute cases of grass staggers must be treated promptly. During the course of treatment the operators should be as quiet and gentle as possible as any sudden stimulus will initiate a bout of convulsions. Hence, actually restraining a staggering acute case will often be difficult and when attempting to place a rope or halter on the animal it will sometimes collapse into a fit of convulsions and may even die before treatment has been administered. The success of treatment is also related to the length of time signs have been present in the recumbent acute case. The longer the cow has been showing convulsions, the less likely it will be to recover.

Intravenous infusions of magnesium salts, e.g. magnesium sulphate, are sometimes recommended for treatment but this procedure is not without its dangers. Intravenous magnesium sulphate may cause cardiac embarrassment or even respiratory failure. If magnesium sulphate is administered intravenously the concentration should be no more than 6 per cent and must be administered very slowly with the heart being auscultated. However, it is also essential to administer calcium in the form of CBG because most cases of grass staggers are also hypocalcaemic.

The treatment protocol favoured by the author is to discard 100ml of fluid from a 400ml bottle of 40 per cent CBG, which also contains magnesium 0.2 per cent and phosphorus 0.5 per cent, and replace this with 100ml of 25 per cent magnesium sulphate solution. The mixture, which then contains 9g of calcium and approximately 6g of magnesium, is infused intravenously very slowly, taking 8–10 minutes. The remaining 300ml of the original 400ml 25 per cent magnesium sulphate is injected subcutaneously. If during the infusion, or immediately after, the convulsions get worse 10ml of pentobarbitone sodium 200mg/ml (euthanasia solution) can be administered intravenously and this will often reduce or even eliminate the convulsions. Following this treatment regimen, if the cow is recumbent, it is important to remain quiet for a further 10 minutes as stimulation even immediately after treatment may initiate convulsions. The recumbent cow should then be

raised into sternal recumbency and left for a further 30 minutes before attempting to stimulate the animal to rise.

Treatment is successful, if early, in 80 per cent of acute recumbent cases and nearly 100 per cent in acute standing cases. If the recumbent case is not able to rise within two hours of treatment the likelihood of success is extremely poor and slaughter should be considered. Subacute grass staggers should be treated in the same way and success is usually near to 100 per cent.

Relapses are considered normal unless preventative measures are taken. Blood magnesium falls to pre-treatment levels within six hours of intravenous administration, although the subcutaneous injection has a more prolonged effect. Daily subcutaneous injections of 200–400ml of 25 per cent magnesium sulphate for five days following treatment have been recommended or the oral administration of four magnesium bullets, which are composed of an alloy of 86 per cent magnesium, 12 per cent aluminium and 2 per cent copper weighted with iron shot (Rumbul bullets, Agrimin Ltd), immediately following the intravenous and subcutaneous treatment.

An individual cow suffering from grass staggers is one of a herd and many cows in the herd could be at risk, of or at least suffering from, subclinical hypomagnesaemia. It is important therefore that a group of six to seven cows be blood tested to ascertain the herd magnesium status, and if the blood levels are below 0.8mmol/l (2.0mg/100ml) herd supplementation with magnesium must be instituted.

The treatment of milk tetany in calves is generally academic, as most cases are found dead. However, very slow intravenous infusion of 100ml of 20 per cent CBG with the addition of 20ml of 25 per cent magnesium sulphate followed by 60ml of 25 per cent magnesium sulphate subcutaneously would be the regimen of choice. Oral supplementation of magnesium must also follow if the calf recovers. Suggested daily doses of magnesium oxide would be 1, 2 and 3g for calves up to five weeks, five to ten weeks and ten to fifteen weeks old, respectively.

Prevention

The simplest method of prevention of hypomagnesaemia is to add calcined magnesite (magnesium oxide) to cattle concentrate that is being fed to the cows. However, the main risk periods in northern Europe for hypomagnesaemia are times when concentrate food is not being fed, e.g. spring grazing and autumn grazing for dry cows. In Australia, New Zealand and Ireland very little concentrates are fed, and in many beef suckler herds other ingenious methods must be devised. The magnesium bullets mentioned above will give

protection for four to six weeks. However, although two bullets are recommended, in severe hypomagnesaemic areas experience has shown that four bullets are required to prevent problems.

Dusting the pastures with magnesium oxide has been attempted using 50g/cow per day of magnesium oxide, or 0.5kg/week applied in the early morning when the dew is on the grass. This works best when cows are strip grazed and the magnesium oxide is applied every morning. Weekly applications are effective in dry weather, but must be reapplied following rain. However, grass staggers is more common in wet than dry weather.

The increasing practice in recent years in the UK of buffer feeding, where a silage supplement is fed to cows during the grazing season, has meant that magnesium oxide at the rate of 50g/cow per day can be mixed with or sprinkled on top of the silage and increases feed passage time.

Supplementation of water supplies using magnesium acetate via a water proportioner is effective but expensive. The proportioner has to be adjusted daily to allow for the variation in water intake that occurs under different weather conditions. The expense and management input required have been a disincentive for this method of prevention to become widespread. The addition of magnesium chloride crystals to the drinking water has increased in popularity in the UK in recent years. It is relatively inexpensive but, to be effective, the trough sizes must be large enough for all cows to drink the medicated water. The addition of 40g/cow per day of magnesium chloride to the drinking water has been shown to give reasonable protection. Addition of magnesium salts to the drinking water will depress water intake if the concentration is too high. Troughs with a volume of 20l/cow are required for this method of control to work effectively. Mineral licks and powders containing high levels of magnesium are relatively useless in preventing hypomagnesaemia because of the uncertainty of all cows consuming enough material to give them protection when it is required.

When discussing the long-term strategies for controlling hypomagnesaemia, fertilizer policy should be included. All potassium-containing fertilizers should be avoided on soils with high potassium levels and on other soils, if potassium-containing fertilizers are used, they should be applied at low levels in the autumn. If necessary, they can be applied later in the grazing season.

Perhaps plant species should also be considered in long-term control strategies. Clover/grass mixtures should be favoured ahead of grass alone, but perhaps above all the use of selective weedkillers should be discouraged. A few buttercups and other wild plants

growing in the pasture may not only be aesthetically acceptable but may reduce the incidence of hypomagnesaemia in grazing animals.

The prevention of milk tetany in calves can be achieved by ensuring magnesium supplementation. Proprietary milk substitute powders are adequately supplied with magnesium. If whole milk is used magnesium oxide at the rates given above should be added to the daily diet (see p. 790).

Hypophosphataemia

Hypophosphataemia is the result of a primary deficiency of phosphorus in the diet (see also p. 792).

Occurrence

Dietary deficiencies of phosphorus are widespread under natural conditions. There is a distinct geographical distribution where large land masses are identified as being deficient in phosphorus and livestock cannot be supported without phosphorus supplementation. These areas will be deficient because of the underlying rock formation. Large areas of southern Africa and Australia are well identified as being deficient in phosphorus. Such areas, however, are unknown or rare in northern Europe and, if they exist at all, will be localized. Although there are areas of Europe where the underlying rock formation contains no phosphorus, continuous application of fertilizers containing phosphorus and cultivation techniques have improved the soil structure and nutritive value. In consequence, primary phosphorus deficiency is probably a rare occurrence in Europe.

Aetiology

Phosphorus deficiency is usually primary, although a severe deficiency of vitamin D (p. 253) may exacerbate the problem. It was once considered that excess calcium would also reduce the availability of phosphorus in the diet and cause deficiencies of phosphorus. Although the calcium:phosphorus ratio in the diet is important in monogastric animals, it is probably of less significance in cattle. The maintenance requirements for adult and growing cattle would be approximately 15g of phosphorus daily. The lactating cow requires approximately 0.75g/kg of milk produced, so a cow yielding 30kg of milk will require 40g of phosphorus daily. This level of requirement is considerably less than that currently being recommended in the UK by the Agricultural Development and Advisory Service, but nevertheless is supported by experimental evidence from the Agricultural Research Council (ARC, 1980).

Signs

In young cattle phosphorus deficiency results in slow growth and rickets. In adult cattle the principal signs are reduced milk yield, weight loss and depraved appetite. Osteomalacia will result from prolonged dietary deficiency of phosphorus. The depraved appetite or pica results in cows eating earth, licking rocks and, where bones are available, osteophagia. The osteophagia frequently results in a high incidence of botulism (p. 721) and in some areas of southern Africa and Australia death from botulism is the most important consequence of phosphorus deficiency. Reduced fertility has been considered a feature of severe phosphorus deficiency, but experimental work has demonstrated that fertility is independent of either calcium or phosphorus intakes. Reduced fertility is a feature of malnutrition and frequently animals that are deficient in phosphorus are also suffering from malnutrition. Low energy intake in such animals is much more likely to be the cause of reduced fertility than any specific mineral deficiency.

Cows in late pregnancy often become recumbent, particularly in drought seasons. This recumbency is probably a result of general malnutrition rather than a specific phosphorus deficiency.

Hypophosphataemia nearly always accompanies hypocalcaemia in cows with milk fever, but this is not thought to be of any significance. Phosphorus levels rarely fall to the levels of 0.3 mmol/l (1 mg/100 ml) seen in severe clinical cases and in any case calcium therapy will result in the blood phosphorus levels quickly reverting to normal.

Diagnosis

The presence of rickets or osteomalacia and/or pica will indicate a dietary deficiency of phosphorus, which can be confirmed by analysis of serum and the diet for the presence of phosphorus. The normal blood level is 1.3–1.6 mmol/l (4–5 mg/100 ml). Levels of 0.5–1.1 mmol/l (1.5–3.5 mg/100 ml), falling as low as 0.3 mmol/l (1 mg/100 ml) of serum in severe clinical cases, will be found in hypophosphataemic animals.

Most pastures in northern Europe contain 1.5–4.5 g/kg DM of phosphorus and at these levels phosphorus deficiency will not occur. Osteophagia will occur with pasture levels of 0.2 g/kg DM of phosphorus and rickets and osteomalacia at pasture levels of 0.1 g/kg DM.

The only commonly used feedstuffs in the UK that are deficient in phosphorus are sugar beet pulp at 0.9 g/kg DM, kale and other *Brassica* spp. crops. These are rarely used at a proportion of the diet high enough to significantly reduce the phosphorus intake to dangerous levels.

Control

Under range conditions, where phosphorus deficiency is the most common, supplementation of the diet with phosphorus is often impractical. Bone meal, dicalcium phosphate or disodium phosphate may be provided in feed supplements or free access mineral mixtures. The dietary intake of phosphorus should be at least 15 g/day. Top dressing pastures with superphosphate fertilizers will correct any underlying deficiency and have the added advantage of increasing the yield and protein content of the pasture. However, this is often impractical in areas where the problem exists.

In acute cases where phosphorus therapy is urgent, e.g. postparturient haemoglobinuria, the intravenous administration of sodium acid phosphate (30 g in 200 ml distilled water) is advocated (see below).

Postparturient haemoglobinuria

One specific syndrome associated with phosphorus deficiency is postparturient haemoglobinuria. This is a disease of cows one to four weeks after calving. Haemolytic anaemia and hypophosphataemia are consistent features.

Occurrence

Postparturient haemoglobinuria was first described in Scotland in 1853 and has been reported from many countries including Australia, USA and most of Europe. The occurrence is sporadic and when it does arise it usually only affects one or two cows within a herd. In recent years its occurrence in the UK has been extremely rare. In Scotland it has been associated with the feeding of beets and turnips, in Holland with the feeding of lush spring grass and occasionally it has been reported to accompany the feeding of sugar beet byproducts and alfalfa.

Aetiology

Diets low in phosphorus are incriminated in the cause of postparturient haemoglobinuria. However, it is probable that there is some additional factor that precipitates the problem in hypophosphataemic cattle. This is likely to be a haemolytic factor present in sugar beet leaves, alfalfa, kale and other *Brassica* spp. plants.

Signs

The principal clinical signs are those associated with anaemia. The cow may be weak and staggering, with mucous membranes pale and heart rate raised. Haemoglobinuria will be a consistent feature. The faeces are

firm and dry. If left untreated the cow will finally become recumbent and may die within two to five days. Less severely affected cases may recover, albeit slowly, in three or four weeks. Pica is frequently observed during the recovery period.

Clinical pathology

Serum phosphorus levels are low, usually 0.15–1.0 mmol/l (0.5–3.0 mg/100 ml). Low phosphorus levels will be encountered in other cows in the herd. Red cell counts, packed cell volume and haemoglobin are all dramatically reduced. Serum bilirubin will increase in the later stages of the disease.

At post mortem the liver will be swollen and infiltrated with fat. The carcass is jaundiced and anaemic and red or red/brown coloured urine will be found in the bladder.

Diagnosis

Postparturient haemoglobinuria must be suspected in any cow that is weak, anaemic and exhibiting haemoglobinuria within four weeks of parturition. The haemoglobinuria must be distinguished from babesiosis (p. 748) and copper poisoning (p. 948). A history of feeding large quantities of kale, beet tops or alfalfa will also be a helpful aid to diagnosis. The diagnosis should be confirmed by demonstrating hypophosphataemia and haemoglobinuria.

Treatment

Intravenous therapy with 30 g of sodium acid phosphate in 200 ml of distilled water followed by the provision of calcium phosphate in the diet is the first line of treatment. In extremely anaemic cases blood transfusion with 5–10 l of blood should be considered. Supportive therapy with large doses of vitamin C intravenously and iron dextran injections will aid the recovery.

Prevention

If brassicas have to be fed to cattle in early lactation their intake should be limited to a maximum of 20 kg wet matter/day. This limitation and an adequate phosphorus intake will prevent the occurrence of postparturient haemoglobinuria.

Acetonaemia (ketosis, slow fever)

Acetonaemia or ketosis is a metabolic disorder of high-yielding lactating cows characterized by reduced milk yield, loss of body weight, inappetance and, occasion-

ally, nervous signs. Ketone bodies, e.g. acetoacetate, β -hydroxybutyrate or acetone, are present in all body fluids. Hypoglycaemia together with increased plasma free fatty acids and liver fat and decreased liver glycogen are also a feature of this disease. These changes are associated with an inadequate supply of the energy that is necessary to sustain high levels of milk production in early lactation. Pregnancy toxæmia, a common disease of pregnant sheep and characterized by hypoglycaemia and hyperketonaemia, can also occasionally affect pregnant cows particularly when carrying twins (see p. 796).

Historically clinical acetonaemia was more common in the winter when cows were housed and being fed conserved forage of dubious quality. The annual incidence in dairy herds is around 0.5 per cent and recent reports have indicated an all year round occurrence with a higher incidence in June, July and August than in the winter months. Cows of any age can be affected and Channel Island breeds, particularly the Jersey, appear to be more susceptible than the Friesian or Holstein. Acetonaemia is less common in the UK now than it was 20 to 30 years ago. This is probably due to higher quality feeds being available although the preponderance of the Friesian breed may have some effect on the disease incidence. Outbreaks are usually restricted to one or two cows but varying numbers of cows in the herd may be affected. If the incidence of the disease is high it can become a severe economic problem due to depressed milk production. The disease usually occurs three to six weeks after calving, when the cow is at her peak milk production but her appetite or DM intake has not yet reached its peak. During early lactation the dairy cow is in negative energy balance. The energy intake in feed is insufficient to meet the energy output in milk. This results in the mobilization of fat reserves to meet the energy deficit and a consequent loss in body weight. This should be considered a normal metabolic situation in high-yielding dairy cows. Such cows will have slightly raised blood ketone levels and may even excrete ketones in urine and possibly in milk. The cow in early lactation is therefore in a delicate metabolic balance and any stress that causes a reduction of feed intake can disturb this balance and result in the onset of clinical ketosis. Factors that can influence the occurrence of the disease include excessive feeding of silage that has a high content of butyric acid, a deterioration in forage quality, sudden changes in types of food on offer and excessive fatness at calving. In the UK the butyric acid content of grass silage is of considerable importance in the aetiology of this disease because wet conditions, so frequently encountered during silage making, predispose to butyric fermentation of the silage. The role of such silage in the aetiology of acetonaemia is probably two-fold. Firstly, there is the direct effect of the presence of butyric acid

and secondly there is the reduced dietary intake that accompanies such silage. Cows that are too fat at calving have lower DM intakes in early lactation and are therefore more likely to suffer acetonaemia.

Acetonaemia is diagnosed in grazing cattle if the grass has a high moisture content and/or when the energy intake is insufficient. Cobalt is required for rumen microbial synthesis of vitamin B₁₂ and is also essential for adequate utilization of propionic acid. In areas of cobalt deficiency acetonaemia will be commonly diagnosed in grazing cows (p. 295).

Secondary ketosis is common, if not more common, than primary ketosis and can result from any disease that causes a reduction in appetite in early lactation. Displaced abomasum (see p. 839) and traumatic reticulitis (p. 837) are two common problems frequently associated with secondary ketosis.

Aetiology

To understand the aetiology of acetonaemia one must realize the precarious metabolic balance that exists in all cows in early lactation. To satisfy the requirements of milk production the cow can draw on two sources of nutrients, food intake and her body reserves. In the first two months of lactation a cow producing up to 45 kg of milk daily will use up to 2 kg of body fat and up to 350 g of body protein per day. As far as the dietary supply of nutrients is concerned 80 per cent of the ingested carbohydrates are fermented by the rumen microflora into the volatile fatty acids, acetic, propionic and butyric acids, which are themselves absorbed. Acetate may be oxidized by various tissues or incorporated into milk fat by the mammary gland.

Glucose is synthesized in the liver and renal cortex by the gluconeogenic pathway. Approximately half of the cow's glucose requirement is derived from dietary propionic acid, which is incorporated into the tricarboxylic acid (TCA) cycle and converted to glucose by gluconeogenesis. Glucogenic amino acids, lactic acid and glycerol can be converted into glucose by this process. Reduced production of propionic acid in the rumen will result in inadequate glucose production and a consequent hypoglycaemia. Hypoglycaemia leads to a mobilization of free fatty acids and glycerol from the fat stores. Hormones such as adrenaline, glucagon, adrenocorticotropic hormone, glucocorticoids and thyroid hormones all influence this mobilization from the body fat stores. Skeletal muscle and heart can utilize fatty acids for energy production when glucose is short. However, the liver has a limited ability to oxidize fatty acids because acetyl-CoA, which is the end product of fatty acid oxidation, cannot be adequately incorporated into the TCA cycle when levels of oxaloacetate, the result of active gluconeogenesis, are low. The excess

acetyl-CoA is converted into the ketone bodies acetacetate and β-hydroxybutyrate and, to a small extent, acetone. Tissues other than liver can utilize ketone bodies but, if their production exceeds the rate they are used by muscle and other tissues, they accumulate and ketosis is the result. Ketone bodies are excreted in milk and urine.

The reduction of propionic acid production by the rumen is usually a feature of underfeeding or a reduced feed intake caused by inappetance. Cobalt deficiency, as mentioned above, will also have the effect of reducing propionic acid production. Butyrate is a precursor of acetyl-CoA and is therefore ketogenic. An increase in butyrate uptake from the rumen will therefore be ketogenic. This explains why silage high in butyric acid will induce ketosis in apparently normal cows.

Signs

Hypoglycaemia is the major factor involved in the onset and development of the clinical signs of acetonaemia. There will have been a gradual loss of body condition over several days or even weeks. There is also a moderate decline in milk yield over two to four days before the onset of the obvious clinical signs, which are refusal to eat grain and concentrate feeds and a more sudden drop in milk output. At this stage a sweet smell (as in pear drops) of acetone is apparent on the breath and the discerning stockworker will even detect the same acetone smell in the milk. Once appetite is decreased weight loss is accelerated due to utilization of body stores. Rectal temperature, pulse rates and respiratory rates are normal in the early stages of the disease, as are ruminal movements. Faeces will usually be firm with a dark 'waxy' appearance.

A small number of cows with acute acetonaemia exhibit nervous signs, which include excessive salivation, abnormal chewing movements and licking walls, gates or metal bars. Incoordination with apparent blindness will also be a feature. Some cows will even show a degree of aggression and will sometimes charge into walls, occasionally injuring themselves. The other signs observed above are also present. The nervous signs often only last for a few hours with the animals showing more normal behaviour in between.

Clinical pathology

Hypoglycaemia, hyperketonaemia and the presence of ketones in the urine and milk are the features of this disease. Cowside diagnosis is obtained by the detection of ketones in milk and urine using the Rothera's test reaction. A drop of milk or urine is added to a small quantity (which consists of sodium nitroprusside 3 g, sodium carbonate 3 g and ammonium sulphate 100 g) of

Rothera's reagent on a white tile or piece of white card. A pink to purple coloration of the reagent confirms the presence of ketones. Urine normally contains low levels of ketones so a diagnosis is only positive when the milk is also positive.

Blood glucose levels are reduced to below 1.4 mmol/l (25 mg/100 ml). Total blood ketone levels are raised to over 5 mmol/l (30 mg/100 ml). The plasma glycerol and free fatty acid levels (non-esterified fatty acid, NEFA) are also elevated. Subclinical ketosis has become more important in recent years with the introduction of the laboratory test for β -hydroxybutyrate (β Hb). The level of β Hb is frequently used on a herd basis as a measure of energy balance in both lactating and dry cows. Herds with subclinical ketosis have been identified using this test. Serum levels of β Hb in excess of 1.75 mmol/l (10 mg/100 ml) will indicate a severe energy deficit in the diet (see p. 807).

Although mortality is not normally a feature of acetonaemia, affected cows do possess fatty infiltration and degeneration of the liver.

Diagnosis

The diagnosis is made on the history of a cow in early lactation with a sudden fall in milk yield, some weight loss, refusing to eat concentrates, with normal temperature, pulse and respiratory rates and normal rumen movements. Many astute stockworkers will recognize the acetone odour on the breath or in the milk and report this to the attending veterinarian. The diagnosis is confirmed by a positive Rothera's reaction on milk and urine and, if this is not conclusive, a blood sample can be analysed for glucose and ketone levels. It is important to differentiate between primary and secondary ketosis so a complete clinical examination must be performed. Many cases presented by the farmer as acetonaemia are in fact suffering from displaced abomasum (p. 839). Some cows with hypocalcaemia (p. 783) may also show acetonaemia.

The differential diagnosis of the nervous form of acetonaemia can be sometimes confusing. The behavioural changes are similar to listeriosis (p. 904), but usually with listeriosis pyrexia will be present. Hypomagnesaemia (p. 788) should be distinguishable by the presence of hyperesthesia, particularly the tremors of the eye-lids and muscle tremors over the shoulders and the presence of tetanic convulsions. Bovine spongiform encephalopathy (p. 909) may also be confused with acetonaemia because of weight loss. However, the apprehension, kicking and progressive nature of BSE should be distinguishing features, besides which blood glucose, magnesium and ketone levels will be normal in BSE. Rabies (p. 908; Chapter 70) is characterized by mania, ascending paralysis and is always fatal.

Treatment

There are three main components of successful treatment:

- (1) To restore blood glucose levels as quickly as possible.
- (2) To replenish oxaloacetate, an essential intermediate in the TCA cycle in the liver, so that fatty acids mobilized from the fat deposits are completely oxidized. This will reduce the rate of production of ketone bodies.
- (3) To increase the availability of dietary glucogenic precursors, notably propionic acid.

An intravenous infusion of 500 ml of 40 per cent glucose will cause a transient rise in blood glucose levels that lasts approximately two hours. This should be accompanied by oral administration of glucose precursors such as propylene glycol (150 ml, twice daily). Propylene glycol is preferred to propionate or glycerol because propionate is fermented in the rumen and may cause digestive disturbances and glycerol is converted to ketogenic acids as well as propionic acid in the rumen. Cobalt salts are frequently added to the propylene glycol and in cobalt-deficient areas at least 100 mg/day of cobalt should be administered.

Glucocorticoid drugs are the most commonly used therapy for acetonaemia, either used alone or in combination with glucose therapy or when followed by oral administration of glucose precursors. Glucocorticoid therapy results in a reduction of ketone body formation due to utilization of the acetyl-CoA derived from fatty acid oxidation and raises blood glucose levels due to a greater availability of glucose precursors in the liver. The commonly used glucocorticoids are dexamethasone, betamethasone and flumethasone and all are effective. Frequently, a single dose is administered but this does often result in relapses two to three days after the treatment, when the injection can be repeated. There is one disadvantage of repeated glucocorticoid therapy and that is that appetite and milk yield are reduced.

For successful treatment in most cases of acetonaemia the following regimen is to be recommended:

- 500 ml of 40 per cent glucose intravenously, followed by
- One dose of glucocorticoid, followed by
- Oral treatment twice daily with 150 g of propylene glycol containing cobalt for three to four days.

Anabolic steroids are also a useful treatment for acetonaemia and were used in Europe before their use was prohibited under the EC hormone ban. They are effective by increasing the levels of the intermediates of the TCA cycle in the liver. They also stimulate appetite,

which ensures an increased supply of the glucogenic precursors. They do not directly raise blood glucose levels. It is important that the cow's appetite returns to normal as soon as possible after treatment so access to good quality fodder is a prerequisite to successful treatment. If butyric silage is implicated in the cause of the problem this should be removed from the diet and only well-fermented silage or good quality hay offered.

If acetonaemia is affecting a high proportion of the herd it would be wise to obtain a supply of ground maize, as it has been shown that ground maize is readily digested in the small intestine and results in a rapid rise in blood glucose levels.

Prevention

The prevention of acetonaemia starts before calving. Cows should not be too fat at calving, a condition score of 2.5–3.0 would be optimum and anything higher would be considered too fat. Access to a plentiful supply of long coarse fibre to promote good rumen digestion is also important during the dry period. Concentrates used during lactation should be introduced in small quantities (1–2 kg/day) two weeks before calving to allow adjustments in the rumen microflora. Changes to diet in early lactation should be made gradually.

Forage containing ketogenic substances such as butyric acid should be avoided in early lactation. Roughage should comprise at least 40 per cent of the diet. In cobalt-deficient areas measures should be taken to ensure adequate cobalt intake, e.g. by spreading cobalt sulphate on to pastures. The concentrates used need to be of good quality. This statement may seem obvious but unfortunately some concentrate manufacturers, under pressure from farmers, will produce sub-standard concentrates at a lower than normal price. By and large the quality of a concentrate food is reflected in its price.

The use of metabolic profiles (Chapter 47) measuring blood glucose and BHB levels in groups of dry cows and cows in early lactation can be useful in the hands of the experienced veterinarian. This will often indicate an energy-deficient diet and one that could predispose to subclinical if not clinical acetonaemia.

As already stated, acetonaemia is less common now than in previous years. This is due mainly to improvements in forage conservation techniques and the use of mixed forages, especially maize silage. Thus cows are fed better quality feeds and there is increased awareness that optimum output comes as a result of optimum input.

Pregnancy toxæmia

Pregnancy toxæmia, although primarily considered a disease of sheep, does also affect cattle, particularly beef

cattle in late pregnancy. The problem is best described as starvation, but the aetiology and pathogenesis are similar to acetonaemia in that an energy deficit in the diet leads to massive mobilization of fat reserves, resulting in hypoglycaemia and hyperketonaemia. The problem is most common in beef cattle grazing marginal land, but has been seen in dairy cattle in late winter in seasons where there has been a shortage of conserved forage. Cows of all ages are affected, but overfat animals and those carrying twins are the most susceptible. Beef cows often have access to good pastures in the summer months and can get overfat. If the same cows do not have access to good quality forage during the winter months, when they are in late pregnancy they will succumb to ketosis because of the deficit in energy intake. In dairy cows the problem can occur at or around calving and is again the result of insufficient energy intake in excessively fat animals.

Signs

The severity of the clinical signs and their speed of onset are associated with the stage of pregnancy and the degree of nutritional stress. Affected cows are usually seven to nine months pregnant and show the same clinical signs as cows with acetonaemia. They become increasingly dull and depressed and the smell of acetone can be detected on the breath. Many cows become recumbent fairly quickly, within a few days of the onset of hyperketonaemia. Often in poorly supervised herds recumbency is the first sign noticed by the stockworker. Recumbent cows are severely depressed, have an increased respiratory rate and faeces are scanty, hard and covered in mucus. Some cows develop blood-stained or fetid diarrhoea in the terminal stages. Most cows die three to fourteen days after recumbency, having fallen into lateral recumbency. This often occurs two to five days after sternal recumbency. Cows affected close to parturition often die during parturition.

Clinical pathology

Hypoglycaemia, hyperketonaemia and ketonuria are consistent findings. In recumbent cases the blood levels of β BHb are much higher than in acetonaemia; levels up to 22 mmol/l (125 mg/100 ml) may be found. Cows affected close to parturition have hypocalcaemia and occasionally hypomagnesaemia. Recumbent cows in the terminal stages have hyperphosphataemia (up to 6.5 mmol/l; 20 mg/100 ml), hyperglycaemia (up to 9.0 mmol/l; 160 mg/100 ml) and raised AST levels. At post mortem the most consistent findings are an enlarged, yellow, fatty liver with fatty changes in the kidney and adrenal cortex.

Diagnosis

Often several cows are affected before veterinary attention is sought. The usual stimulus to seek veterinary help is when one or two cows are dead or close to death. The history, stage of pregnancy and the nutritional status will usually be enough to enable a tentative diagnosis. Raised blood or urine ketone levels and low blood glucose (plus low calcium in cows close to calving) will usually confirm the diagnosis.

Treatment

Treatment as described under acetonaemia (see p. 795) would normally be indicated. However, so severely affected are the majority of these cows that medical treatments almost invariably fail to succeed. Immediate removal of the calf by Caesarean section (p. 1115) may save a valuable cow. This should be followed by the full course of treatment described under acetonaemia.

Prevention

Although the problem is more common in fat cows it is essentially the result of starvation and is predominant in years when insufficient conserved fodder has been made. To prevent further cases developing and becoming recumbent a supply of good quality forage is essential, even if the farmer has to sell a proportion of his herd to obtain fodder for the remainder.

The downer cow

Attending the recumbent cow is one of the more challenging problems encountered by the bovine practitioner (see also p. 439). Often, accurate diagnosis is not possible but prognosis is extremely important and probably more important than accurate diagnosis. It must be remembered that recumbency is the normal course in the terminal stages of any disease so a full clinical examination is essential in every case plus a thorough history, often supported by biochemical examination of blood. Many workers have offered definitions of the downer cow, but the most useful in practice and the one to be used here is: a cow that has been recumbent for 24 hours or more, is in sternal recumbency and is not suffering from hypocalcaemia or hypomagnesaemia, mastitis or any obvious injury to the limbs or spine.

History

It is important that the clinician obtains an accurate history of the case and the following questions must be asked:

- (1) How long has the cow been recumbent?
- (2) When did she calve and was calving difficult?
- (3) Did she rise after calving?
- (4) Has she been treated for milk fever, and if so how often and how much CBG has been used?
- (5) Has the cow moved recently, either spontaneously or with help from the farmer?
- (6) Where did the cow go down, e.g. concrete, ice, in field, in a ditch, and was this likely to affect the pathogenesis?
- (7) Is there adequate bedding?

Examination

The first superficial examination will be the position of the animal, position of the legs and degree of alertness. Lateral recumbency, if not due to hypocalcaemia, hypomagnesaemia or bloat, is indicative of a terminal state and slaughter should be advised as soon as possible. This includes cows which, although they will sit in the sternal recumbency position for short periods with the aid of supports such as hay bales, revert to the lateral recumbent position when they struggle free of the supports.

The position of the legs is a useful aid to prognosis. If the hindlimbs are in the normal position and the cow attempts to rise the prognosis is guarded to hopeful. If the hindlimbs are rigidly extended forwards so the feet are touching the elbows of the front legs this indicates severe sciatic nerve damage, upper hindlimb muscle degeneration or hip problems, e.g. fracture or dislocation, and the prognosis is hopeless. If both the hindlimbs are spread laterally, with lateral flexion at the stifle, the cow has probably 'done the splits' and again the prognosis is hopeless. If one hindlimb is in this position then the prognosis is guarded and careful nursing may succeed. If both hindlimbs are extended behind the animal, and when the position is corrected they return to the original position when the cow attempts to move, again the prognosis is hopeless as this indicates severe muscle degeneration.

The full clinical examination will then be conducted (see Fig. 46.2) and may well reveal other diseases present, e.g. mastitis, metritis (vaginal examination is essential), torn vagina, ruptured uterus, pneumonia, septicaemia, hypothermia or abdominal catastrophe. It is essential that a rectal examination be performed.

Assuming there is no abnormality in rectal temperature, respiratory rate, mucous membranes and the heart rate is below 80/min, then ischaemic necrosis of the hindlimb muscles or, as it is more commonly referred to, pressure syndrome should be considered.

Pressure syndrome (ischaemic necrosis): Experimental work (Cox, 1982) has demonstrated that if a cow is lying in the same position for six hours or more there will be

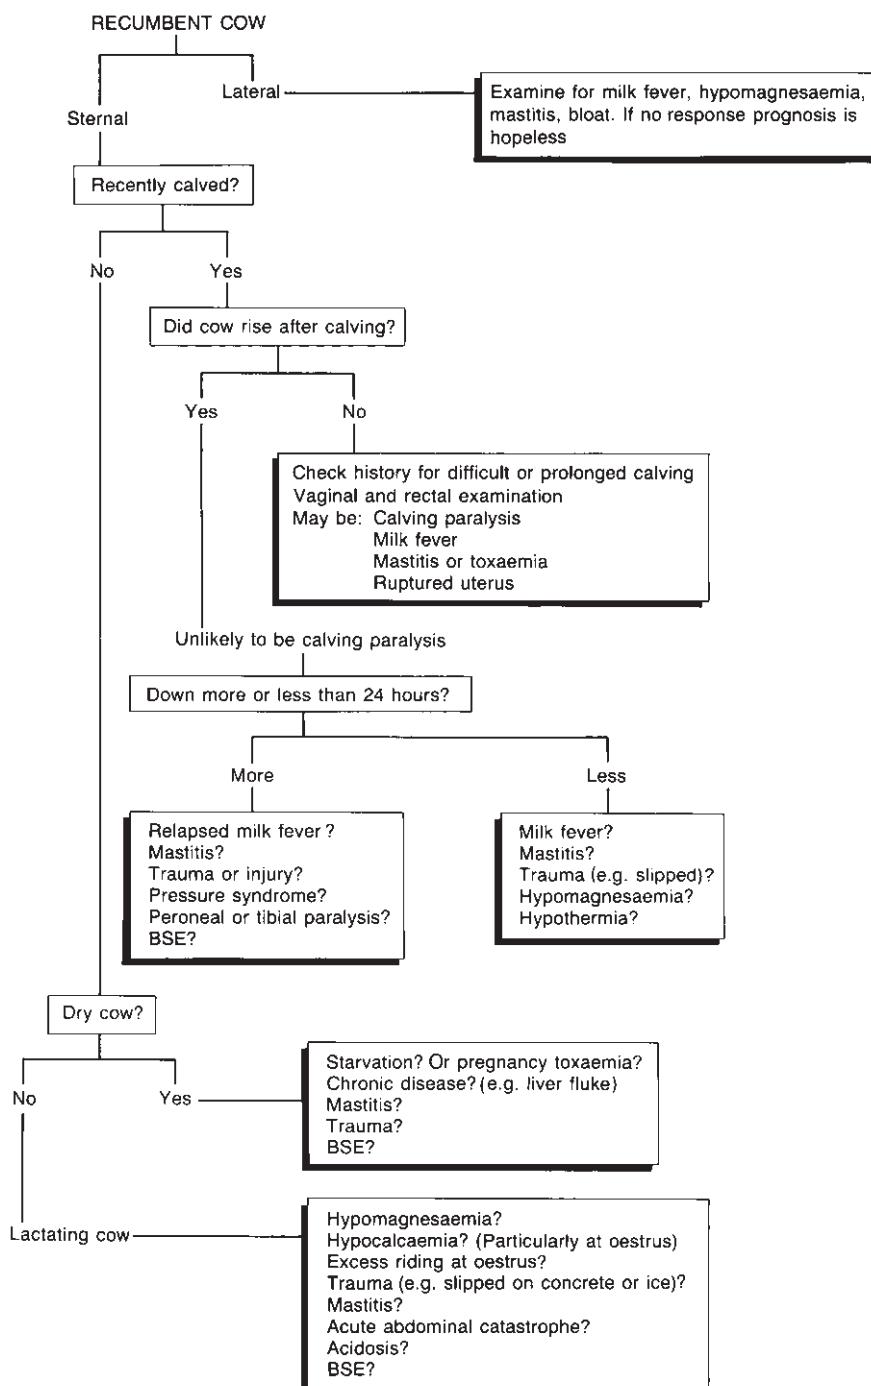

Fig. 46.2 Aid to diagnosis and prognosis of the downer cow.

damage to the musculature of the leg on which the cow is lying. Cox describes this as ischaemic necrosis as a result of pressure. If the cow is in the same position for 12 hours continuously then the damage to the muscle is irreversible and the prognosis is therefore hopeless. This situation is most common following milk fever, particularly where treatment has been delayed or ineffective subcutaneous treatment has been given. Many

cows first seen with milk fever at morning milking will have been recumbent for six hours, and some for almost 12 hours. Many will be suffering some muscle damage, particularly if they have been lying on unbedded concrete. This is why prompt intravenous treatment for milk fever is essential.

Figure 46.3 shows the pathogenesis of ischaemic necrosis.

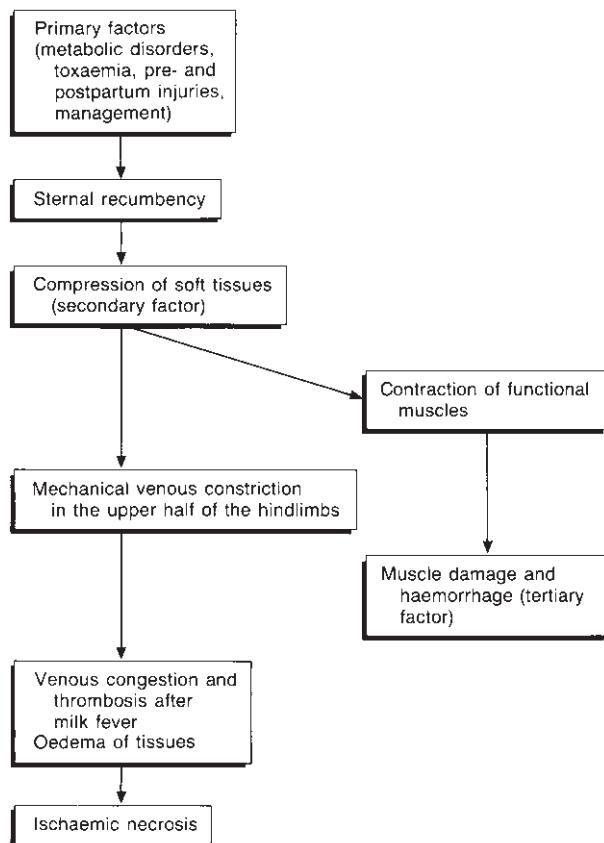

Fig. 46.3 Pathogenesis of ischaemic necrosis (from Andrews, 1986).

Calving paralysis: If the cow has not risen since calving and has not responded to milk fever therapy, and is not suffering from any toxic or septicaemic condition such as mastitis or metritis, then either pressure syndrome or calving paralysis should be suspected. The history should indicate whether calving has been difficult but occasionally a cow will deliver, with difficulty, a large calf but second stage labour may last 3–6 hours. In such cases, calving paralysis may occur. Calving paralysis as a term is preferable to obturator paralysis, sciatic paralysis or other defined nerve paralyses. The damage done to the birth canal during prolonged dystokia will result in a variety of lesions in the pelvic cavity. Generally, the bruising and swelling of the soft tissues of the pelvic cavity will damage the sciatic nerve and occasionally the obturator nerve. Obturator paralysis (p. 438), on its own, whether it is affecting one or both hindlimbs, will not cause recumbency. Such cows can rise, with difficulty, but will show abduction of one or both hindlimbs. Paralysis of the sciatic nerve (p. 439) is more serious and will prevent the cow rising.

Diagnosis and prognosis

Having completed a thorough examination of the recumbent animal that has recently calved and eliminated disease, obvious injury or starvation as a cause of the recumbency, the two most likely problems to be affecting the cow are (i) pressure syndrome (ischaemic necrosis) or (ii) calving paralysis. These cows will be alert, in sternal recumbency, and some will be attempting to rise or crawling along the ground. Appetite for food and water will be good. At this stage it is essential for the clinician to attempt a more exact diagnosis and offer a prognosis. One of the most important inputs that will aid recovery is tender loving care (TLC). The ability and willingness of the stockworker to nurse and attend these cases will be the most important element in successful treatment. So knowledge of the farm and its staff is essential in forming a prognosis, as is the ability to provide soft bedding such as deep litter or a nearby paddock. Diagnosis will be helped if the animal is raised using a Bagshawe hoist and it can be observed if the cow can take weight on one or both hindlimbs and if either or both hindlimbs are abnormal. Abnormalities to observe include the following:

- Flexion of fetlock and extension of the hock, which will indicate paralysis of the tibial, peroneal or sciatic nerve (pp. 438, 439).
- Abduction of one or both hindlimbs will indicate obturator nerve paralysis (p. 438).
- Swelling of the upper hindlimb musculature of one leg would indicate severe pressure syndrome. If the pressure syndrome is so severe that muscle swelling is obvious and one upper hindlimb is larger than the other, prognosis for that limb is hopeless.
- Inability to extend or flex the stifle, hock and fetlock joints.
- The willingness of the cow to take weight on the forelegs. If the cow is so weak she cannot take weight on the forelegs the prognosis is hopeless.

With calving paralysis one can generalize that if both hindlimbs are showing signs of nerve paralysis, e.g. extension of stifle and hocks and flexion of the fetlock, then the prognosis must be hopeless. If only one leg is affected and as long as TLC will be available, the prognosis would be guarded but hopeful. It is surprising how many cows suffering from calving paralysis affecting one hindlimb only will rise seven to ten days after calving.

As an aid to prognosis, several workers have attempted to use blood biochemistry. Serum CK rises to astronomically high levels following muscle damage but its half-life is short and on its own has not proved a reliable indicator of success. Raised serum AST levels will also indicate muscle damage and this parameter is

probably more useful than CK levels. As a prognostic indicator in cows that have been recumbent four days or more AST levels can be quite useful. Interest in serum myoglobin levels has been reported from Sweden (Holmgren, 1988), where early work would suggest that in the first three days of recency serum myoglobin levels could be a valuable prognostic indicator. Levels below 3 µg/ml would indicate likely recovery.

It is unlikely that any one parameter will be shown to be of value for accurate prognosis. However, a combination of biochemical parameters and clinical signs, particularly attempting to rise, should be useful. Cows recumbent for three days or more must be attempting to rise, as well as bright, alert and eating well, for there to be any likelihood of eventual recovery. The quality of nursing available on the farm must also be considered in making a prognosis. Without good nursing, continual attention to bedding, feed and water, prognosis will be poor. Unfortunately, on many large dairy farms where labour is in short supply, there is often an unwillingness to break from the normal farm routine to provide extra attention to a recumbent cow. This information will be available to the regular attending veterinarian to the farm and will influence the prognosis. On such farms, in the interests of the welfare of affected cows, one will advise immediate slaughter of many cows, while on other farms where TLC is available, they would be likely to recover.

Treatment

Where the prognosis is considered hopeless or where it is known that TLC is absent, all cows should be slaughtered humanely as soon as possible. In some countries, particularly the UK, such animals can be fit for human consumption if they are not suffering from septicaemia, excessive bruising or any other infectious disease. However, in the interests of welfare, slaughter must take place on the farm. This is perfectly legal in the UK as long as the cow is bled on the farm and transported as soon as possible to the nearest slaughterhouse and the carcass is accompanied by a veterinary certificate that complies with the Fresh Meat (Hygiene and Inspection) Regulations 1995. If the slaughterhouse is EC approved, the carcass must reach it within 30 minutes of being bled.

Treatment will of course depend on the diagnosis, but for the cow that has been recumbent for 24 hours or more a soft bed is essential. A box or barn with an earth floor or deep litter bedding would be ideal, but if the weather is reasonable the best place for recumbent cows is in a field. Cows can be transported to the field on a gate, on a buck rake or with a cattle net on a fore-end loader. Wherever the cow is moved it must have

continuous access to food and water. It is surprising how many stockworkers will forget to provide water to a cow recumbent for 24 hours or more.

If the hindlimbs are continuously abducted either due to bilateral obturator paralysis or injury from slipping on ice or concrete the application of hobbles (Save A Cow, Arnolds Ltd) or a soft rope to tie the hindlimbs approximately 50 cm apart will prevent further muscle damage. This will sometimes result in the cow rising immediately, the only factor causing the recency being the persistent hindlimb abduction.

If there is any doubt as to whether the cow may still be suffering from milk fever, 8–12 g of calcium should be administered intravenously. This situation could occur where farmers, treating their own cows, have administered subcutaneous CBG on two or more occasions within 24 hours, the calcium has not been absorbed completely and a state of hypocalcaemia still exists. Some cows with milk fever that recover will relapse so, if in doubt, intravenous calcium should be administered. A blood sample analysed for calcium levels would provide valuable information, if performed quickly, either as a cowside test or in the practice laboratory.

The most important element of treatment, once the cow is on a soft bed or in the field, is frequent turning so that she does not spend more than three hours in one position or on one side. Cows that are attempting to rise will frequently change their position and will move from side to side. Cows with an injury, whether it is a nerve paralysis or pressure syndrome, can often be turned to lie on the side opposite to which they are found, but at the next attempt to rise they fall back on to the side that is paralysed or injured.

The Bagshaw hoist, which attaches to the pin bones and is lifted using a fore-end loader or pulley blocks, is often advocated for treatment. This equipment will cause muscle damage and its continuous use on the same cow must be questioned on welfare grounds. However, it can be a useful instrument to aid diagnosis. Occasionally, a cow raised by the hoist will take weight on her hindlimbs, remain standing and slowly walk away.

In recent years interest has increased in various inflatable rubber bags (Bovijac, Alfred Cox; Henshaw Airlift, J.M. Henshaw; Downer Cow Cushion, Hamco Products). The reasoning behind the use of these air cushions is to allow improved blood circulation to the affected legs. Unfortunately, with most of the inflatable bags available, once inflated and the cow raised, she frequently struggles and falls off the side of the bag. Cow nets are available and a supportive harness (Downacow Harness, Alfred Murray) can be quite useful.

In Denmark, water flotation is being used. The recumbent cow is hauled into a drop-sided water tank

and the tank filled with warm water. The cow will then stand, aided by the water, and is left in the same position for up to seven hours a day. The system is called an Aqua Lift (Rasmussen, 1988).

The use of the Bagshaw hoist (apart from aiding diagnosis) and the various slings and inflatable bags should be questioned. If a cow cannot stand unaided there is little point in raising her to the standing position. Repeated use of the Bagshaw hoist will cause extensive muscle damage and must be discouraged. Until an inflatable bag has been designed that will prevent a raised cow falling off the side, these air bags have only limited use.

The Danish Aqua-lift would appear to be the most practical aid to the recumbent cow, but the capital cost of making the lift and providing transport for it may prevent its widespread adoption.

The only therapeutic agents now licensed for use in cattle which may be of benefit in treating downer cows are the corticosteroids and the NSAIDs with intravenous glucose as supporting therapy. However, there is little or no evidence that would suggest any therapeutic agent may have a beneficial effect and TLC remains the most likely effective treatment.

Prevention

Selecting bulls with known shorter gestation lengths and ease of calving scores can, in part, prevent calving paralysis. Feeding of dry cows should also be monitored and frequently rationed, particularly in seasons where grass is plentiful. Overfat cows (condition score 3.5 or over) more frequently develop dystokia due to relative fetal oversize. If a particular bull has been identified as causing dystokia, then all cows remaining that are pregnant to him should be considered for induced parturition using long-acting corticosteroids (see p. 687).

The pressure syndrome is a preventable problem. The majority of cases are a sequel to milk fever where treatment has been delayed or is inadequate. Intravenous therapy with 8–12 g of calcium as soon as possible after the cow becomes recumbent, accompanied by moving the cow into sternal recumbency and turning her so that she is lying on the side opposite to that in which she was found, will prevent the pressure syndrome occurring. If the cow is down on concrete she should be moved onto a soft bed or into a field. Many pressure syndrome cases are the result of subcutaneous calcium therapy that fails to be absorbed completely.

Fatty liver syndrome

In the 1970s and early 1980s the syndrome of fatty liver (FLS) or fat cow syndrome (FCS) was widely reported

in dairy cows at or around calving. Reports of its occurrence came from many countries, including the UK, USA, France, Hungary and the USSR. The syndrome appears to occur in high-producing dairy cattle where overfeeding in the dry period results in overfat cows at calving. Depressed appetite after calving and the consequent energy deficit result in a rapid weight loss and an accumulation of intracellular fat in the liver. The syndrome is associated with an increased incidence of metabolic, infectious and reproductive disorders such as milk fever (p. 781), ketosis (p. 793), mastitis (Chapter 23) and retained placenta (Chapter 34). Fat cow syndrome as described by Morrow (1976) is clinically the most extreme manifestation of the syndrome but is probably only the 'tip of the iceberg' and a much larger number of cows were affected by subclinical FLS, as described by Reid and Roberts (1982).

Occurrence

The FLS was thought to be widespread in UK dairy cows in the late 1970s and was probably related to gross overfeeding of cows during late pregnancy, particularly with the use of high levels of concentrate foods during the late dry period. However, 'steaming up' with concentrates is now out of favour and is rarely practised in the UK, which is probably why the clinical incidence of FLS has apparently declined in recent years. However, in seasons where grass is in abundance there is still a danger of cows becoming excessively fat if their diet is not restricted during the dry period and hence FLS can and still does occur. At worst 50–90 per cent of freshly calved cows can be affected with FLS, although on some farms the incidence was very low or even non-existent. Mortality up to 25 per cent has been reported in herds where severe FCS exists (see also p. 796).

Pathogenesis

As most dairy cows in early lactation are in negative energy balance they mobilize energy reserves of fat and muscle and consequently lose body weight and condition. The mobilization of body weight reserves involves the release into the blood of free fatty acids from fat depots and glucogenic amino acids from protein stores. The fatty acids are transported via the blood to various organs, e.g. the kidney, liver and muscle, where they are deposited as intracellular droplets of triglyceride. Thus at one to four weeks after calving there is an increased level of fat in the liver. There is a rise in liver fat levels occurring two to three weeks before calving. This fat mobilization before calving is probably brought about by the changes in hormonal status as the cow approaches calving. The extent of fat deposition in the liver and other organs after calving is probably

determined by a number of factors including high milk yield potential, body fatness or condition at calving and loss of body condition after calving. Excessively fat cows tend to have depressed appetites so the fat mobilization is exacerbated, resulting in even higher liver fat levels and increased weight loss.

Signs

The most common indication of the existence of FLS is a high incidence of peri- or postparturient disease, e.g. retained placenta, milk fever, mastitis and ketosis. Cows with FLS will subsequently prove to be less fertile. However, if FLS is suspected it should be noticed that a high proportion of the dry cows are excessively fat (in excess of body condition score 3.5) and many of the cows four weeks after calving are thin (body condition score less than 2).

Clinical pathology

Cows with FLS one week after calving will have significant alterations in their blood constituents. Free fatty acids, bilirubin and AST will all be increased and glucose, cholesterol, albumin, magnesium, insulin and white blood cell count (WBCC) will all be decreased. In cows with severe FCS the WBCC may fall to as low as $3 \times 10^9/l$.

Pathology

At post mortem, cows with FCS will have large deposits of fat around the heart, kidney, pelvis and in the omentum. The liver will be enlarged, with rounded edges and a pale yellow colour. Intracellular droplets of triglycerides will be found in liver cells, kidney, adrenal glands, skeletal muscle fibres and cardiac muscle. In the liver the triglyceride globules are deposited within the hepatocytic cytoplasm. The extent of deposition may be as high as 70 per cent of total hepatocyte volume.

It is important to realize that the findings described above may be seen in animals that have been deprived of food 24–48 hours before death. Therefore, post-mortem findings can only assist in the diagnosis of FCS or FLS when used in conjunction with the herd history and clinical pathology.

Diagnosis

The history of increased disease incidence just after calving followed by examination of body condition of dry cows and cows three to four weeks after calving will often give a strong indication of the presence of FLS. Confirmatory evidence is best obtained by liver biopsy of five or six cows immediately after calving. The liver

biopsy samples can then be assessed for fat level percentage. The technique of liver biopsy in cattle is relatively easy to perform and should be used by all cattle practitioners. Levels of fat, as assessed by staining sections of liver with toluidine blue or oil red 0, in excess of 20 per cent would indicate the presence of FLS. Levels in excess of 50 per cent fat would indicate severe FLS.

Blood biochemistry has been widely explored as a measure of fatty liver and various parameters have been explored, e.g. non-esterified fatty acids (NEFA), glucose, AST and glycerol, but these cannot, as yet, be interpreted with great confidence. In the USA another method of estimating liver fat levels is based on the buoyancy of needle biopsy samples in water or copper sulphate solutions.

Treatment

There is no proven treatment for either FCS or FLS. Various empirical treatments have been suggested but there is little evidence that any are of value. The logical approach would be to use the same treatments that are used for acetonaemia. Increasing the glucose supply by the administration of glucose, glycerol or propionate and a glucocorticoid followed by the stimulation of protein synthesis by the administration of an anabolic steroid would appear to be the most logical approach to treatment.

Prevention

Fatty liver is a sign of cows too fat at calving and losing excessive weight in early lactation. The main element of a prevention programme is to restrict the feeding of dry cows so that they calve in a body condition score of 2.5–3.0. The big reduction in the use of concentrates before calving in recent years has almost certainly reduced the number of cows suffering from FLS at calving. Cows in condition score 2.5–3.0 at calving certainly have appetites greater than fat cows and hence lose less weight in early lactation. However, dry cows can become fat on grass diets alone in northern Europe during the spring and early summer, when grass quality is at its best. At such times, therefore, grazing for dry cows should be restricted or supplemented with low quality fibre such as straw or hay. The rules for prevention of FLS are therefore the same as for acetonaemia (p. 796).

Introduction

The use of metabolic profiles in dairy cattle was pioneered by Payne *et al.* (1970) at the Compton Institute of Animal Health. The approach has been adapted and modified since then (Blowey, 1975; Kelly *et al.*, 1988; Whitaker, 2000) so that it is now widely used in many countries in European-type cows (for example in Italy, Bertoni & Cappa, 1984; in Chile, Wittwer *et al.*, 1987; in Germany, Mansfeld *et al.*, 1996; in Turkey, Sevinc & Aslan, 1998; in Belgium, Opsomer *et al.*, 2000). The approach has also produced useful information in low yielding cows in developing countries (Whitaker *et al.*, 1999) by drawing attention to potential constraints and by confirming that some were not present.

In Britain the system has been developed as a management aid for dairy farmers and their veterinary surgeons (Ward *et al.*, 1995; Kelly & Whitaker, 2000). It contributes information for decision making about nutrition in a more precise and detailed way and more quickly than by other, more conventional approaches. Traditionally forages are analysed, stocks of them measured, targets for productivity set, financial constraints considered – and a ration plan is produced from one of many perfectly satisfactory sets of software. Inevitably such a ration has limitations, starting with those of the reliability of forage analysis and of assessment of intakes. Furthermore, the ration may not be delivered in practice according to the theory of the plan. It may well be that the ration plan is for a cow producing 35 litres of milk at 4.0% butterfat and 3.3% protein, but it may actually be the only one like that in a group of cows, some of which may have just calved and others of which may be 100 days in to their lactations. If the ration is not adequate, a farmer and his advisers can detect this from individual milk yields, from milk constituents, from body weight and condition changes, from weak oestrous signs and from poor conception rates. All of these, with the exception of butterfat percentage, even if measured regularly and carefully, take weeks or months to alter enough for the presence of a problem

to be clear. And once it is clear, what actually is it? If the metabolic profile approach is used 'properly', then it can, within two weeks of a ration being started, identify that there is a problem, what it is and what is the best and/or the most economic solution.

The 'proper' use of metabolic profiles depends on care with the timing of blood tests, the selection of cows to be included and the collection and use of background information about the farm, feeding and feeding system and physical state and performance of the cows.

Timing of blood tests

In relation to feed changes

As changes in the diet of ruminants require changes in the character of rumen activity, blood samples for metabolic profiles should not be done until two weeks after a major change and activity has had time to adapt. Minor changes such as an increase in the quantity of an existing component or in access to the same ration do not require a wait of more than 7–10 days. Changes in forage type, such as turnout to grass, housing or the introduction of silage, require the full two weeks, as does the introduction of concentrates or of a new type of concentrates.

In relation to feeding

There can be changes in biochemical values in blood associated with feeding. These are most marked in cows receiving all their concentrate ration at milking time. In such cases two hours should be allowed to elapse after milking before blood sampling. In circumstances where the major part of the concentrate input is mixed with the forages and is available for most of each 24 hours, the timing of tests in relation to feeding is less critical. If lower yielding mid lactation cows are included (see later), their results can be used as a check to see whether there is an effect of feeding on the biochemical values in the blood samples. Cows should not be separated at milking time and confined for hours without access to food when waiting for blood sampling as this can also affect the results.

In relation to calving pattern and seasonal feeding changes

The cow in early lactation is the most important because what happens to her in the first few weeks after calving has the major influence on her subsequent productivity, including her future fertility efficiency. Therefore blood sampling for metabolic profiles should be carried out at the beginning of each new calving season,

with the first cows checked so that the majority can benefit from the information derived.

Of equal importance is the need to test as soon as possible (see previous section) after the introduction of a new ration, so that the judgement of the cows' biochemistry can be made available as quickly as possible, i.e. what the cows, the end users, think of the ration.

Therefore planning of metabolic profile tests needs to be done in advance and should take into account both expected calving pattern and feed changes. Without planning along these lines, time may be lost and productivity with it.

Selection of cows

The selection of appropriate cows for blood sampling is very important. This is because some of the metabolites looked at, particularly those relating to energy balance, can quickly return to the optimum range as cows adapt themselves, including their productivity, to a nutritional constraint. It is possible for cows to experience a significant energy deficit in the first 2–3 weeks of lactation because of intake problems, lose excessive body condition, perhaps modify their milk yield and have their subsequent fertility efficiency suppressed but yet still arrive at four weeks calved with all biochemical measurements within the optimum ranges. This is because the common appetite constraint of the new calved has worked its way out and there is plenty of food available for lower performance than anticipated. If blood were sampled at four weeks calved or longer, a farmer could see thin, underproducing cows with poor fertility but with nothing abnormal about their biochemistry. Thus the farmer would be entitled to feel the metabolic profile test was of no value. However, if those cows had been blood sampled at 14 days calved instead of 27, the blood results would have been quite different and would have identified the nutritional constraint on productivity.

Individual variations in biochemical values are such that single cows should not be tested. Groups of no less than five should be sampled. They should not be picked at random but rather should be typical, average cows of their stage of lactation. Cows with extremes of performance – either very high or very low – should not be selected. Cows with problems should also not be included because the type of analysis carried out is not designed to clarify individual problems. It is important to make all this clear to farmers in advance because they cannot be expected to appreciate the limitations of the analyses made. Experience in the Dairy Herd Health and Productivity Service (DHHPS) (Kelly & Whitaker, 2000) suggests that selecting cows for metabolic profiles may be best done by the veterinary

surgeon himself in advance of the test after looking at the calving and production records. If there is a specific concern, such as a poor conception rate, farmers may expect only cows which have failed to conceive to be sampled. This hardly ever delivers helpful information as any nutritional constraints have been compensated for by then and blood biochemical values are usually within optimum ranges. The best approach may be to include such cows as the mid lactation group (see later).

Early lactation group

The definition used for this group is most critical for the reasons given in the previous paragraph. Since the original Compton metabolic profile (Payne *et al.*, 1970), where a high yielding cow was used as the definition, the importance of this group has become increasingly apparent. The definition also has had to be changed to take into account changes in farm practice. The way cows are fed now – total mixed rations, increased out-of-parlour concentrate feeding – has reduced the time after calving by when they can adapt themselves to an unsatisfactory diet. To be sure of detecting the presence of an energy constraint in particular, blood sampling should be carried out between 10 and 20 days calved – less than 10 days and yield is still too far below peak for the test to be a realistic one for early lactation performance; more than 20 days and some cows will be thin, unproductive and subfertile but have compensated for their nutrition and they may have normal blood metabolite values.

Mid lactation group

Some cows which are past the period of peak yield, and so past the greatest period of potential nutritional stress, should always be included. They should be between 80 and 150 days calved so that they are still relatively high yielding. This group provides a within-herd comparison with the early lactation cows. Without this it is very difficult to distinguish between problems caused by constraints on intake of food or protein and energy content, to identify changes in biochemical values caused by mistiming of tests in relation to feeding or by oddities in the diet such as silage with a high butyric acid content and to make judgements on concentrate/forage usage within the herd.

Dry cow group

As the dry period is so important to the success of the following lactation, blood sampling to make sure nutrition is adequate is essential. However, the nature of the measurements which can be made means that primarily cows in the last 7–10 days of pregnancy should be

sampled. Cows tested with longer to go than that tend to have normal measurements of energy balance even though they can still get into difficulty. This is because the period of greatest risk is when the volume of the pregnant uterus increases to the point that it can seriously inhibit food intake. It follows that, in a seasonal calving herd, the first dry cows which come in to these last 7–10 days ought to be blood sampled, so that the information can be used for the benefit of the others still to come in to the maximum risk period.

Blood sampling a group of dry cows with a month or longer to go to calving at the same time can sometimes provide a useful within-herd comparison with respect to energy balance. It may also identify the presence of dietary protein inadequacy – specifically rumen degradable – in the early part of the dry period.

Background information

So that full value can be obtained by the farmer from the metabolic profile approach, information about the cows and the farm should accompany the blood samples to the laboratory. This should include cow identification; last calving date for milkers/expected for dry cows; bodyweight – by calculation from heart girth measurement with a weighband pulled to a constant 5kg tension is the best, because it is not affected by gutfill, and usually most practical, because no mechanical weighing device/crush is required; body condition score by a palpation method; current daily milk yield; expected current daily milk yield; lactation number; daily supplementary feed intakes; daily estimated forage intakes; analytical description of feeds and current herd milk solids percentages. It is useful to have information on herd size, breed, feeding systems and health and fertility. A note of what concerns the farmer has, if any, should also be made.

Interpretation of results at the farm

Circumstances where the diagnosis of a nutritional constraint from blood samples is clearly correct, but the cause is unclear from a distance and there could be many, are common. Therefore it is very important that a final interpretation of what is not working and what are the best and most economic solutions ought to be made at the farm with the information from the laboratory to hand. Farm advisory visits should be made as soon as the results are available and discussions held, including farm staff and any other advisers involved. Experience in the DHPPS suggests that such a team approach produces a more balanced strategy and is more beneficial than each party working in isolation.

Written advice

Any advice given should be recorded concisely in writing and copies given to all participants on the farm. This ensures that the agreed path is followed, keeps a record of it and ensures that the fee is for something tangible.

Metabolites measured

The number of metabolites which could be measured is great. For the sake of cost, not overcomplicating the picture and speed of turn round of results, the number is usually restricted. Metabolites measured should also be confined to those from which reliable, useful and practical information can be derived. Consequent actions will therefore be beneficial. It needs to be borne in mind that aspects of energy and protein nutrition are the most important and constitute, between them, at least 90 per cent of identified constraints (Kelly & Whitaker, 2000).

Chosen metabolites need to be stable in the blood samples after collection for two to three days while in transit to the laboratory. Methods of analysis need to be quick, accurate and automated. Each laboratory must use an outside agency as a continual check on quality control and so reliability of results.

Optimum values

What constitutes a 'normal', or rather optimum, value or range of values for a metabolite in blood is crucial. In the DHHPS (Kelly & Whitaker, 2000) we used originally the values proposed by Payne *et al.* (1970). These were based on population means from 2400 cows plus or minus two standard deviations. The DHHPS laboratory has been operating since 1978, with thousands of blood samples passing through every year, accompanied by information on stage of lactation, feeding, performance and responses to advice based on optimum values used; consequently some of the values have been modified. Account must also be taken of the fact that variation in some metabolites is skewed. For these we have carried out a lognormal transformation (Whitaker *et al.*, 1983) before arriving at an optimum range. For some metabolites, such as urea, the interest primarily is in low values and so in variation only one way from the optimum. Some controlled trials, where detailed measurements of weight and condition change have been made with blood sampling (e.g. Whitaker *et al.*, 1989, 1993), have confirmed the otherwise largely anecdotal evidence for what is optimum. These ranges are the ones quoted in the following pages.

Optimum values should nevertheless not be used too precisely. Small variations from optimum may not be

important, depending on the metabolite. Group means should be looked at and compared firstly and then the individual variations and the number of them within each group. Variations which might relate to performance, body weight, condition or stage of lactation need particular attention because they can provide important information on the practical causes of a constraint. Values within the optimum ranges can also be used, in conjunction with the background information, to give advice of economic importance on concentrate/forage usage (see following sections on interpretation).

Energy balance

β -Hydroxybutyrate (BHB)

In cows in milk the optimum level for β -hydroxybutyrate (BHB) in blood is below 1.0 mmol/litre. BHB reflects fat mobilization as an energy source and so higher values are associated with greater degrees of negative energy balance. Values below 0.6 mmol/litre represent a situation where cows are unlikely to be losing body condition. Between 0.6 and 1.0 a low and acceptable rate of fat mobilization may be taking place, depending on the stage of lactation. Above 1.0 mmol/litre health and productivity will be affected. Cows with ketosis will probably have values over 2.0 mmol/litre. In a small proportion of cows BHB results, if very high in early lactation, remain outside the optimum range after energy balance has been restored and body condition is being regained.

Dry cows in the last month of pregnancy should have BHB values below 0.6 mmol/litre because they should be restoring and maintaining energy resources.

BHB is stable in blood after collection for several days. Butyric acid from grass silage, directly absorbed across the rumen wall, has been blamed for increased blood values. In our experience since 1978 this is a rare problem. If it is present, all cows with access to that silage will have high BHB levels in blood. Including lower yielding mid lactation cows receiving the same basic diet, as a within-herd comparison, provides the most reliable means of ruling it out – if those cows have lower results than the early lactation animals which are eating the same silage.

Non-esterified fatty acid (NEFA or free fatty acid)

The optimum level of non-esterified fatty acid (NEFA) in cows in milk is below 0.7 mmol/litre and for dry cows within the last four weeks of pregnancy 0.4 or below. The reasons for the difference are the same as for BHB. NEFA is a more direct measure of fat mobilization than

BHB. It may rise more quickly and it often returns to within the optimum range quite quickly as well, even when negative energy balance is still present. Cows with ketosis have values in their blood above 1.5 mmol/litre.

NEFA is less stable in the blood sample after collection than BHB. It is reputed to start to rise after 48 hours, but we have not seen practical evidence of this in samples analysed four to five days after collection. Severe stress prior to blood sampling is also reputed to cause the level to rise, but this also has not apparently happened in the ten years that we have used this metabolite. Sampling groups of no fewer than five cows and including those in early and mid lactation as within-herd comparisons enable these potential problems to be set aside.

Glucose

Glucose was the first metabolite used in the Compton Metabolic Profile (Payne *et al.*, 1970). Because of the fundamental requirement for glucose in the tissues, homeostatic mechanisms are very strong and variations were not found to be great. Whole blood or serum tended to be used, neither of which are as accurate with respect to energy balance as the plasma content. Added to the difficulties was the fact that glycolytic enzymes start to break down glucose after sampling. So either analysis needed to be carried out very quickly or blood needed to be collected into a tube containing oxalate fluoride as an anticoagulant. This does not mix as easily as other anticoagulants and sample tubes have expiry dates which are easily overlooked. Glucose is also the most likely metabolite to change with delay in transit and it goes down. All this has meant that glucose acquired a reputation as not being very useful in assessing energy balance with certainty.

Our experience suggests that if blood is collected into tubes within their dates, mixing is thorough but gentle and analysis is carried out within four to five days of collection, plasma glucose is a sensitive measure of energy balance – even within the optimum range which is above 3.0 mmol/litre. Sampling groups within a herd, as for BHB and NEFA, allows a check for abnormalities not associated with nutrition.

There are some nutritional circumstances where the predominant finding in a metabolic profile is that plasma glucose levels are low but BHB and NEFA are within their optimum ranges. These appear to be associated often with a dietary shortage of fermentable metabolizable energy (FME), judging by the responses obtained to dietary adjustments.

Plasma glucose does increase sharply to over 5.0 mmol/litre in a cow which is severely stressed immediately prior to sampling.

Bile acids

Some laboratories include bile acid measurement in metabolic profiles as a means of assessing subclinical ill health, with reference in particular to heavy fat infiltration (lipidosis) into the liver in the peri-parturient period as a consequence of severe negative energy balance. There is not firm agreement on the value of this. West (1991) found bile acids to be significantly correlated with the degree of a variety of liver diseases including lipidosis, whereas Garry *et al.* (1994) found no correlation between bile acid level and liver fat content. Schrotter *et al.* (2000) found bile acid levels to be within the normal range in cows with subclinical disorders and chronic hepatopathy. In the DHHPs (Kelly & Whitaker, 2000) we have carried out this analysis on several hundred occasions alongside those for BHB, plasma glucose and NEFA and have found that it did not appear to add sufficiently to the information obtained to justify its regular inclusion.

Interpretation of results for energy balance: cows in milk

Raised BHB and/or NEFA values with or without low plasma glucose results indicate that cows are experiencing a dietary energy problem and not necessarily a dietary energy deficiency. The easy response is to recommend an increase in energy supply through more concentrates. This can be completely the wrong thing to do, which illustrates that identifying that there is a problem is the easy bit and only the start. Identifying the cause(s) and the practical solution(s) is the difficult bit. Using the type of background information described earlier and seeing what is actually happening at the farm are essential parts of the process.

There are a number of possible reasons for dietary energy problems in milking cows, all of which should be considered:

- The forage component of the diet is being expected to contribute more energy than is reasonable, i.e. not enough concentrates are being fed.
- Less concentrate is being fed than supposed because of misunderstanding or feeders are in need of recalibration.
- Too much concentrate is being fed, resulting in a concentrate to forage ratio in the rumen which is in excess of 3:1 on a dry matter basis. This causes underutilization of the energy which is in the diet. For this calculation grazing, silages, hay and straw only count as forages. Often the only way to arrive at a ratio is to add up the amount of dry matter being supplied as non-forages, calculate the theoretical total dry matter intake of the cow and assume the difference is the amount of forage dry

- matter being eaten. Another way of looking for this problem is from an expected forage ME calculation (see later). Rationing, which is expecting the forage component to provide less than the equivalent of the energy needs of maintenance (about 65 megajoules), is likely to be threatening this ratio. Loose dung provides supporting evidence.
- The concentrate amount offered each milking is too high – it is either not eaten or, if it is, causes transient rumen acidosis; 4kg per milking is a reasonable top limit.
 - Concentrates supplied contain too much readily soluble carbohydrate, causing rumen acidosis.
 - Single feeds of concentrates, unmixed with forages, supplied at times other than milking, may be too great to ensure even intakes between cows – 2kg per cow per feed is a reasonable limit.
 - Not enough conserved forage is being offered – ideally fresh forages should always be readily available to all cows at all times. Empty troughs militate against the cows who are most at risk. Between 5 and 10 per cent more food than the cows are going to eat should be supplied if possible/practical, with the surplus removed at least once daily.
 - Silage or silage concentrate mixtures can become stale, because troughs are not cleaned out often enough.
 - Loss of nutrients from silage due to secondary fermentation may occur – from exposure to air or water at the clamp face by the way it is handled or because rations are mixed too infrequently. Silages of high dry matter content are more at risk. The ration warm to the hand or with steam rising from it on a still day shows this as a problem.
 - Conserved forages may be unpalatable, in UK circumstances grass silages which are very wet or very dry are a risk. Modern forage analytical measures give some indications.
 - Access to conserved forages is restricted, e.g. by inadequate trough space and design, troughs not filled evenly, self-feed faces tightly compressed, severe electrified barriers, not enough ring feeders or the feeding facilities or the route to them are exposed to bad weather.
 - Different forages fed unmixed – grass silage available as an alternative to maize or whole crop, but not mixed with them, does not deliver the same potential nutritional benefits as a mixture.
 - Conserved forage is of low energy content – provided it is palatable this can usually be balanced by other components of the diet, if the problem is recognized. Laboratory analysis of forages can exaggerate the energy content, particularly the fermentable metabolizable energy in maize silage.
 - Grass silage can be very low in fibre – uncommon but can occur if of high quality, having been harvested very early in the spring. Mixing 0.5kg of chopped straw with it may be enough.
 - Access to grazing is restricted – strip grazing systems or paddocks not changed often enough; set stocking systems allowing the development of fibrous, less nutritious grass.
 - Buffer feeding to grazing may be inappropriate – poor quality forage used; timing of access; substitutes instead of supplements grazing; site of access inappropriate.
 - Too much digestible undegradable protein and not enough energy in a ration can occur.
 - Salt deficiency is common in some winters.
 - Water deprivation is easily overlooked – trough size, site, filling rate and cleanliness can all be constraining.
 - Inadequate dry cow nutrition and management can be unnoticed – changes in diet components at calving; failure to allow dry cows to realize their potential appetites in late pregnancy; fat mobilization and body condition loss before calving.
 - Lack of reasonable cow comfort and space can contribute considerably to energy problems for new calved cows and especially heifers.
- It is important to see the silage clamp, grazing fields and water troughs, to be there when food is put out to see what happens, both with reference to men and cows, and to check troughs and self-feed faces at other times when at the farm. What is said or believed to be happening is not always so!
- There are rare circumstances where BHB levels are raised and glucose levels are low which do not reflect an energy problem. Observation of the cows' body condition and their performance can support this, but looking at the results in the different groups should confirm it. If cows in the mid lactation group, producing much less milk, have got the same scale of out-of-range results as cows in early lactation producing a lot more, then some aberration of the timing of sampling in relation to feeding or of a direct effect of a diet constituent, such as butyric acid in silage, is likely to be responsible.

Expected forage ME

More specifically, it is useful to look at the way the rationing is set up for the individual cows and what contribution is being sought from the forage component – the expected forage metabolizable energy (ME) in megajoules. The energy the cow needs, the required ME (AFRC, 1993), is calculated from the cow's body weight, milk yield and milk quality. The energy supplied

as concentrates, the fed concentrate ME, i.e. not forages, is calculated from the information obtained from the farm on fed amounts and analysis, actual analysis if available or book values if not. The difference is the energy that the rationing assumes is supplied by the forages. Similar calculations can be made to assess the energy contribution of forages where systems not based on metabolizable energy are used.

$$\text{Expected forage ME} = \text{required ME} - \text{fed concentrate ME}$$

The amounts of concentrates eaten per cow per day are usually the most accurate information available on feeding – certainly more accurate than the amount of forage eaten. Where concentrates are mixed in with silage offered *ad lib*, individual concentrate intakes are less accurate and group means should be considered first, not least because it is these which will have been used to design the ration.

Where metabolite values have been disturbed because cows have been blood sampled too close to a feed, cows will have similar out-of-range levels, even though expected forage ME figures vary widely.

This calculation is of further use when assessing the economic aspects of concentrate/forage usage. Table 47.1 shows an example of a blood test in which all the energy measurements were within the optimum ranges, indicating that all these cows were having their energy needs met. Cows numbered 1–5 are within the second and third weeks of lactation, the period of greatest potential nutritional stress. Because they are in energy balance, they must be achieving from forages the figures shown in the expected forage ME column. If they can, then the rest of the herd can too. This means that cows 6–10, who are being asked to get less from forages, should have their concentrate input reduced so that

their expected forage ME figures are at least the same as those for cows 1–5 or perhaps even greater. So blood tests showing the presence of no nutritional constraint – often looked at by farmers as a waste of money – can be used to guide the important economic management of concentrate usage.

Some further points need to be considered, however. The cost of concentrates and forages may not, in every country, be such that lower use of concentrates is more economic. In addition, a reduction in concentrate input will mean that cows will look to increase forage intakes. So there has to be forage offered/available to them to do this or milk yields will suffer. There may be important implications for forage stocks too because they will be used more quickly. Also it is necessary to consider the protein content of the ration. A reduction in concentrates in this context is of energy supplied, but it may mean that effectively protein input is reduced as well and that could also reduce milk yield. The protein content of the reduced level of concentrate fed may need to be increased to avoid this. Blood urea levels may give some guidance. If they are relatively high, no increase in protein content may be necessary. This is likely to be so where this assessment is being made in cows at grass.

It is worth repeating that optimum levels of BHB, glucose and NEFA can be found in thin, underproducing cows in modern feeding systems after four weeks calved, who have adapted their performance and their metabolic state after experiencing serious energy constraints earlier in lactation.

Interpretation of results for energy balance: dry cows

The dry period needs to be one of maintenance and restoration of resources for cows, especially high-yield-

Table 47.1 Examples of individual cow results for assessing concentrate usage/forage contribution to energy needs.

| Cow | Days calved | BHB mmol/l | Glucose mmol/l | NEFA mmol/l | Expected forage ME (MJ) |
|-----|-------------|------------|----------------|-------------|-------------------------|
| 1 | 10 | 0.4 | 3.4 | 0.5 | 169 |
| 2 | | 0.6 | 3.2 | 0.2 | 175 |
| 3 | to | 0.3 | 3.5 | 0.3 | 135 |
| 4 | | 0.4 | 3.2 | 0.4 | 181 |
| 5 | 20 | 0.4 | 3.2 | 0.4 | 150 |
| 6 | 80 | 0.6 | 3.4 | 0.3 | 152 |
| 7 | | 0.7 | 3.3 | 0.4 | 101 |
| 8 | to | 0.3 | 3.4 | 0.2 | 131 |
| 9 | | 0.3 | 3.2 | 0.3 | 95 |
| 10 | 110 | 0.4 | 3.3 | 0.3 | 121 |

ing ones, to be able to realize their productivity and longevity potentials. Body condition change during the dry period and body condition score at calving – aspects of energy balance primarily – influence productivity and fertility in the following lactation (e.g. Domecq *et al.*, 1997; Markusfeld *et al.*, 1997). So identifying the presence of undesirable situations during the dry period is important. Body condition scoring, if done once a week, is sensitive enough until the last two weeks of pregnancy. Then blood sampling may be the only way to confirm that there is a problem.

The following is a dry cow management ‘best practice’ list against which current practice on a farm can be checked where a problem has been found.

From drying off

- (1) Look upon the dry period as a unique opportunity for rest and recreation for cows.
- (2) Provide a clean, comfortable environment in the first month of the dry period.
- (3) Manage cows so that they go dry at body condition score 2.5–3.0 on a scale of 1–5 and maintain it until calving (p. 10). This may mean reducing concentrate inputs in late pregnancy, which is where much overfatness develops. It may mean restricting the quality of forage available in the first month of the dry period to stop excessive increase in condition.
- (4) Confine overfat cows at drying off on a diet of straw balanced with adequate effective rumen degradable protein (ERDP) to maintain rumen function. The restriction should be of quality and not quantity of forage so that rumen fill is maintained as far as possible. Only 10–14 days on this regime is advisable and it must be stopped absolutely by the time of one month to go to calving.
- (5) Feed overthin cows at drying off generously enough for some condition to be restored.
- (6) Provide free access minerals during the first month of the dry period if they cannot be mixed in with the forage on offer, which is preferable.

For the last month of the dry period

- (7) Provide the best environment and forages on the farm.
- (8) Offer 24 hour access to fresh, quality forages in the last month of pregnancy. All of the forage types which are going to be fed in production should be included. Cows should be challenged to eat between 12 and 15 kg of dry matter each day so that they can eat more and get to maximum intakes more quickly after calving. If more than 0.5 kg of straw is included, total dry

matter intakes will be reduced. Expecting cows to ‘fill up’ even to 12 kg dry matter by providing free access to straw does not work. Failure to provide enough fresh, quality forage, in cows receiving concentrates, is the commonest cause of negative energy balance in late pregnancy.

- (9) Feed 2–3 kg of good quality concentrates/cow per day. This increases the energy density of the total food intake, compensating for the dropping appetite. It allows the rumen environment and lining to adapt fully to concentrates by the time cows are in milk. These processes take *at least* two weeks.
- (10) Ensure that these concentrates contain appropriate digestible undegradable protein (DUP) if enhanced milk protein production is desired.
- (11) Ensure that the forages contain adequate ERDP and if not compensate through the concentrates. Specialist dry cow concentrates are usually formulated assuming that cows, if getting grass silage, will be getting enough ERDP from that. This is not always the case. A ration with maize or whole crop cereal silage included is more at risk.
- (12) Ensure that appropriate minerals are incorporated in the concentrates or silages fed. Production ration minerals are satisfactory for most farms for most of the time and only need changing if cases of hypocalcaemia start. Free access at this stage is not satisfactory.
- (13) Include pregnant heifers in this close to calving group, unless to be kept separately in lactation – but even then provide the same ration.
- (14) Oversize calves come from overfeeding in the seventh or eighth month of pregnancy, extended gestation length (a function of the genetic make-up of the sire) or an underdeveloped heifer with a genetic potential to be a lot bigger. The rate of growth of the calf in the last month of pregnancy is at its greatest but it cannot be influenced by feeding in that month – either to increase or decrease the eventual size of the calf.
- (15) Provide the same fresh concentrates and forages in calving boxes/pens. Also ensure fresh water supplies.

Protein

Urea-nitrogen (ureaN)

If rumen function is satisfactory blood ureaN level is above 1.7 mmol/litre. In some laboratories urea rather than ureaN is measured. This makes no difference except that the values are higher by a multiplication

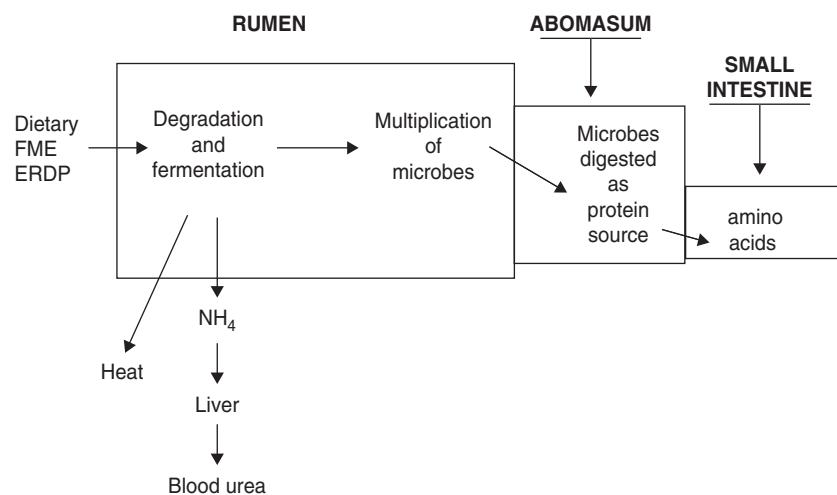

Fig. 47.1 Diagram of degradation and digestion of ERDP and FME by ruminants.

factor of 2.14. So the optimum for urea is above 3.6 mmol/litre.

Blood ureaN reflects the rate of arrival in the rumen of effective rumen degradable protein (ERDP) and the balance there with fermentable metabolizable energy (FME), as illustrated in Fig. 47.1. Low values are the most important from a practical, nutritional point of view but care needs to be exercised in distinguishing between values which are low because of low total food intake or because the diet does not contain adequate ERDP. This is one of the reasons for including mid lactation cows in a metabolic profile test as a within-herd comparison. If the new calved cows, which are the most likely to have appetite constraints, have low ureaN results and so do the mids, who should be able to eat readily, then the diet will be short of ERDP. If the mids have optimum ureaN results though, the diet should be adequate in ERDP but the new calved are not eating as much as they should. If diet intake is the predominant problem, some of the energy metabolites may be out of their ranges too. Obviously the approach to this is different – and importantly so – from a diagnosis of a dietary shortage of ERDP.

On farms where maize and grass silages are not mixed but are offered so that cows can make a choice, or where one silage is fed for 12 hours and the other for the next 12 hours, low blood ureaN may not always relate to an overall diet shortage of ERDP. The best solution then may be to promote mixing of the forages rather than a change in concentrates.

Where an ERDP shortage is diagnosed and more is to be supplied, cows will respond with increased milk yield within 24–48 hours. They will have improved

rumen function and so will look for more forage to eat. Therefore for the approach to work, more silage must be made available to them. However, account must be taken of the fact that forage stocks may be depleted more quickly than previously anticipated.

There is a further practical risk arising from the fact that the theoretical ration plan being followed often indicates that ERDP is adequate – the reason is probably a shortcoming in the laboratory analysis of forages. Feed advisers may therefore be reluctant to agree to more ERDP – partly because it is usually cheaper than the existing ration – and often suggest 'higher quality' protein, which is usually digestible rumen-undegradable protein (DUP). That, by definition, passes through the rumen, plays no part in rumen function and does not work where ERDP is short.

Low ureaN results in dry cows are quite common for the reasons indicated in the dry cow/energy section. As a dietary shortage of ERDP inhibits rumen function, reduces potential appetite and enforces a change in rumen function at calving, it is important to identify it.

The same high level of ureaN can reflect (i) an excess of ERDP and adequate FME, (ii) an excess of ERDP and inadequate FME or (iii) adequate ERDP but low FME. Only (ii) and (iii) need action and some other evidence of nutritional imbalance is desirable to make the diagnosis more certain – some energy metabolites outside their reference ranges for example. Where ureaN results are above 3.3 mol/litre and there is evidence of an energy constraint, it is worth increasing the level of FME in the diet. This may mean substituting energy sources not available in the rumen, such as pro-

tected fats, with wheat or barley for example, which are high in FME.

It is not advisable to try to correct an excess of ERDP in relation to FME (examples ii and iii) by reducing the amount of ERDP in the diet. This is because it may be impossible not to reduce the DUP supplied as well and so precipitate an unwelcome fall in milk yield. The supposition that high blood urea levels directly affect fertility remains controversial and unproven. Certainly many cows retain good fertility, or even have improvements, when turned onto grass in spring with high blood urea levels. It is possible that observed subfertility in cows with such high levels occurs primarily because of negative energy balance. Therefore care should be taken, if looking at metabolic profile results in herds with fertility problems, before drawing definitive conclusions.

Digestible undegradable protein (DUP)

Higher yielding cows cannot meet their total protein requirements from ERDP and the production in the rumen of microbial protein alone; DUP is required as well. This passes through the rumen unaffected and is digested in the abomasum and small intestine as an additional source to microbial protein. There is no way of directly assessing the dietary adequacy of DUP through metabolic profiles. However, if milk yield is below expectation and cows are maintaining good body condition in early lactation – and if ERDP supplies are adequate – increased dietary DUP should be tried. As with ERDP, the milk yield response should be within 24–48 hours and also as with ERDP cows will be looking for greater forage intakes. More must be made available and account taken of a greater rate of depletion of conserved forage stocks.

Before embarking on this approach a metabolic profile test to confirm satisfactory energy balance and adequate dietary ERDP is strongly advisable. As part of a dietary shortage of DUP is often a complaint that milk protein production is low and as energy constraints are the commonest cause of this, the check metabolic profile test is the first step in such a complaint. Farmers need to be advised as well that feeding more DUP, where there has been a dietary shortage, should result in an increase in milk and milk protein yield but not necessarily an increase in milk protein percentage.

Albumin

Albumin is a protein that is synthesized in the liver. The optimum level is over 30 g/litre. Low levels reflect poor

liver health or a poor supply of amino acids from the diet. Any effect from diet is long term. Low levels will only appear after prolonged and severe underfeeding of protein. If the cause is disease, the effect can be more immediate and may involve a raised globulin level as well.

Serum samples as opposed to plasma produce albumin results between 2 and 5 g/litre lower.

Total protein

Measurement of total protein is required to deduce globulin level. This is not directly measured and is the difference between albumin and total protein. As total protein consists of something based on diet and something based on disease and inflammation, it should not be shown on result sheets. If it is, people who are not aware of its content frequently draw exclusively dietary conclusions, which are incorrect.

Globulin

Globulins are produced in response to inflammation of the chronic type. The optimum level is below 50 g/litre. If it is higher, the individual cow concerned has a recent, acute or chronic inflammation problem. The globulin measurement is crude and not specific, consequently a raised value does not indicate with any accuracy the severity of the problem or how recently it took place. In some cases a cow may have some disease process clinically obvious, but the globulin has not risen at the time of blood sampling. The whole value of the measurement is to draw attention to the possibility of individual or herd disease problems and so stimulate discussion and investigation. The commonest individual complaints are mastitis, metritis or lameness. The most likely herd problem in the UK is infection with *Fasciola hepatica*, when albumin levels will be low as well (p. 276).

Minerals and trace elements

Magnesium

Blood magnesium levels should be between 0.8 and 1.3 mmol/litre. This reflects current dietary intake rather than body tissue resources from which magnesium is not readily available. Low blood levels can therefore be a matter requiring urgent action to avoid clinical hypomagnesaemia. A number of slightly low magnesium results may indicate subclinical hypomagnesaemia, which can affect appetite, performance and behaviour.

Because of the complex nature of the dietary factors which interfere with the absorption of magnesium from the diet, a check test 10–14 days after increased supplementation is advisable to make sure that it has worked.

Low dietary magnesium in the dry period may be involved in the incidence of hypocalcaemia, but low blood levels may not be detected until a few days before calving. Clinical hypomagnesaemia is rare in dry cows but it can occur and, if it does, is usually fatal. Under-feeding and exposure to severe adverse weather conditions are the predisposing factors.

Inorganic phosphate

Plasma values also reflect current dietary intake primarily. Optimum levels are between 1.4 and 2.4 mmol/litre. Unlike magnesium and calcium, however, low levels in diet and blood can be tolerated without harm to health and fertility for months (Brodison *et al.*, 1989). A check blood test, a few weeks after some low results occur, is advisable before embarking on potentially expensive and probably useless supplementation. Measurement of this mineral is usually carried out because of the widespread misconception that dietary deficiency is a common cause of poor fertility because of the aggressive marketing of supplements to meet this perceived need.

Hypophosphataemia can be a contributory cause of the downer cow syndrome (pp. 439, 797). However, misdiagnosis can take place because a blood sample taken after a cow has been recumbent and not eating for 24 hours may be low because of that only. Firm diagnosis can only be on response to treatment with phosphate.

Calcium

Homeostatic control of the level of calcium in the blood is so strong that variations are small and do not reflect dietary intake at all. Measurement of calcium should not therefore be carried out as part of a metabolic profile and should only be done as part of clinical diagnosis.

Sodium and potassium

Homeostatic control of sodium and potassium is also too strong to allow measurement in blood to be a reliable indicator of dietary intake.

Thyroxine (T_4)

Thyroxine provides an indication of the iodine status of the cow. The optimum level is above 22 nmol/litre (Whitaker, 1999). Low values have been associated with abortion and stillbirth. Weighing the thyroid gland of stillborn calves does not appear to be sensitive enough

to identify an iodine deficiency or the presence of goitrogens, although the iodine content of the gland may be. Histopathology of the thyroid gland should provide confirmation. Iodine deficiency has been associated with poor production as well.

Measurement of inorganic iodine in plasma is also widely practised. Caution is required over interpretation as the level is very sensitive to variation in daily iodine intake. A cow which has not eaten will have a low result primarily because of appetite.

Copper (see also p. 298)

Blood copper levels are not an accurate guide to body and liver status where most of it is found. So, while the optimum level is over 9.3 µmol/litre, clinical copper deficiency can be found with results above or below that. A number of individual results below that in a metabolic profile merit further, clinical enquiry because deficiency, if present, will affect health and productivity.

Recent reports of copper toxicity in cattle, perhaps associated with higher absorption rates from the use of chelates or proteinates in minerals or overzealous supplementation, suggest that blood levels over 20 µmol/litre should be followed up (p. 948).

Much more difficult is assessing the possible primary role of excessive molybdenum on fertility and secondarily on copper status (Phillippo *et al.*, 1987). Suttle (1993) suggested that this problem would not be present unless the forage offered contained more than 5 mg/kg molybdenum on a dry matter basis. Telfer *et al.* (1996) believe that forage values can be lower than this and the problem may still be present because of molybdenum in concentrates. They have developed a complex system of testing blood involving a ratio between plasma copper and serum caeruloplasmin, trichloroacetic acid precipitated copper and superoxide dismutase. This may be too arduous for many laboratories. If this problem is suspected – and forage analysis frequently encourages farmers to think it is – the most practical solution may be to administer for six months an intrararticular copper bolus to alternate cows as they go dry or calve and see what happens.

Glutathione peroxidase (GSHPx) (see p. 302)

The optimum level is over 50 units/g of haemoglobin or over 15 units/ml of red blood cells. As this is an enzyme containing selenium and as it has a half-life of some weeks, GSHPx values reflect historical selenium intake. Low values in early lactation cows, satisfactory ones in mid lactation and lower but still satisfactory ones in dry cows describe a dietary deficiency in the dry period, with production rations taking care of it. GSHPx values

can be dropping while selenium intake is rising and *vice versa*. Isolated groups of cattle sampled can therefore produce a deceptive picture. Clinical assessment of possibly related problems is necessary – such as muscular dystrophy, poor fertility in maiden heifers, retained placenta, stillbirth or mastitis in early lactation. Because of the relationship with vitamin E, measurement of this in blood may be advisable as well if a problem is suspected. Blood selenium itself can be measured, but the analysis is too expensive for routine use.

Manganese (see p. 305)

Estimation of blood levels is practised but the relevance of results is questionable. Since Wilson (1966) found no differences in conception rates between supposedly manganese deficient supplemented and unsupplemented herds no published evidence has appeared that this trace element is limiting on fertility. More recently, Gelfert and Staufenbiel (2000) found no evidence of effects on fertility in 70 dairy herds in Germany where, according to published values for the manganese content of hair and serum, deficiency should have existed.

Zinc (see p. 305)

Optimum values for zinc concentrations in blood are equivocal. In UK circumstances the likelihood of primary zinc deficiency is low. Furthermore, specially prepared sample tubes need to be used to avoid contamination from the glass or the cork.

Cobalt (see p. 295)

Levels of vitamin B₁₂ in blood below the reference value of 90 ng/litre are commonly found in productive, healthy and fertile cattle. It is probable therefore that what is usually measured is not biologically active or cattle can exist with lower levels than this without coming to harm. It may therefore be preferable to avoid altogether the expense of a laboratory analysis of doubtful practical value.

Metabolic profiles on milk

If the same rigorous ‘rules’ are applied to the selection of cows, timing of tests and the use of background information as for blood samples, using the more easily collected milk can provide useful information on energy balance and protein intakes. Failure to follow the ‘rules’ and failure always to check energy and protein together lead to erroneous conclusions. Milk urea can be readily

measured and is virtually the same as the level in blood. Methods of assessing energy balance through measurements in milk are available – β-hydroxybutyrate, acetooacetate, ketones. There are technical difficulties, for example because of volatility. The practical value is less clear at the time of writing and measurements may not be as sensitive as for metabolites in blood. Minerals and trace elements can also be measured in milk, but there is no reliable information on reference values. Furthermore, as milk is manufactured for the specific purpose of feeding a young animal, it contains concentrated amounts of many elements, bearing little or no relation to levels in blood, body or dietary intake.

Bulk milk measurements are generally unhelpful. Analysis for urea is widely practised and frequently misunderstood by farmers causing unnecessary concern. A number of milk purchasers have now given this up. The problem is largely because the result is an average for the herd and because of variations in urea in cattle which relate to intake rather than to diet content. Only if bulk milk urea is very low should there be any response and that should be a proper metabolic profile to determine the nature of the constraint.

Metabolic profiles in maiden heifers

In response to complaints of poor conception rates in heifers, blood samplings in housed animals often show diets to be inadequate in ERDP. Sometimes minerals and trace elements do not all fall into optimum ranges either. Anecdotally responses are achieved by correcting the ERDP query. So investigation of this type of complaint should not be confined to minerals and trace elements, which is where feed advisers and farmers often expect the problem to lie.

Metabolic profiles in suckler cows

In the DHPS metabolic profile samplings are often carried out in suckler herds on cows in late pregnancy and when new calved. While these sometimes suggest the presence of some mineral or trace element shortcomings, it is common to find evidence of considerable negative energy balance at these stages, using the same optimum blood values as in dairy cows, which may inhibit subsequent fertility. As with dairy cows, waiting to blood sample until inseminations are about to start is likely to miss identifying the presence of the most probable nutritional constraint. Equally, if sampling is not done until a problem of low pregnancy rates is apparent, the true cause may not be revealed by it. Then it may be better to wait until pregnant cows are available before the start of the next calving season.

Dietary shortages of ERDP are also common in housed suckler cows fed on low quality conserved forages, resulting in the waning of body reserves when they should be maintained.

A dangerous degree of hypomagnesaemia present in autumn and winter suckling cows is quite commonly revealed. Follow-up tests can assess the success of supplementation.

Summary

The metabolic profile approach in dairy cattle should be used as a way of 'asking the cows what they think of their nutrition'. If the timing of this question is planned for as soon as possible in each new feeding regime, any shortcomings can be quickly identified and corrected before major losses in productivity, including fertility, are inevitable. While the approach may well help in problem solving, continued use as a preplanned exercise in the DHHS since 1978 in Britain (Kelly & Whitaker, 2000) shows that its most valuable asset is as a means of providing more information to cow managers, more quickly and more precisely, than is possible by any other means.

| Diarrhoea | 850 | | |
| Salmonellosis | 850 | | |

The mouth and associated structures

Examination of the mouth, muzzle, mucous membranes, tongue and teeth should form a part of the normal clinical examination. Mouth lesions can be signs of systemic diseases such as foot-and-mouth disease, mucosal disease, bluetongue and various poisonings. Lesions of the muzzle and lips and occasional congestion of the oral mucosa can be a feature of photosensitization. Injuries occasionally occur and there are a number of infections and allergic diseases that produce lesions of the lips, tongue and jaws. Diseases of the gums and teeth are rare in cattle, although chronic fluorosis (see p. 949) where it occurs will cause mottling, discolouration or hypoplasia of the teeth, particularly in growing animals. Even problems associated with excess tooth wear are uncommon, presumably because the majority of cattle are slaughtered well before they reach 'old age'.

The main signs associated with mouth lesions are salivation, excess chewing movements, frequent protrusion of the tongue and licking of the lips and muzzle. Swellings of either jaw will indicate lesions of the jaw, the most common of which are abscesses, infections of the buccal mucosa, e.g. calf diphtheria, or lumpy jaw (actinomycosis). Submandibular swelling may indicate mouth lesions, e.g. wooden tongue (actinobacillosis), or be a sign of cardiac or liver dysfunction, e.g. liver fluke (p. 276) or severe hepatitis (p. 147).

Swelling of the submandibular and retropharyngeal lymph nodes may be the result of infections such as tuberculosis, actinobacillosis or lymphosarcomata. Swollen salivary glands do also occasionally occur due to tuberculosis infection or infections resulting from penetrating wounds.

Salivation

Ruminants normally produce large quantities of saliva, which acts as a buffer in the rumen to maintain the normal ruminal pH. Adult cattle normally produce 5–10 ml/100 kg body weight/minute. A 600 kg cow can therefore produce 60 ml/minute of saliva.

Excess salivation occurs as a result of many diseases:

- Foot-and-mouth disease (p. 700) and infectious bovine rhinotracheitis (p. 289).
- The various causes of stomatitis, e.g. wooden tongue (p. 823), calf diphtheria (p. 250), and teeth-related problems (p. 825).
- Pharyngeal paralysis, although rare in cattle, is a sign of rabies (p. 908), Aujeszky's disease (p. 907), botulism (p. 721) and occasionally tetanus (p. 733).
- Obstruction of the oesophagus, the most common of which is choke (p. 826).
- Eating plants or chemicals that are themselves irritant and cause inflammation in the mouth (Chapter 54).
- Certain chemicals such as copper, lead, mercury and arsenic also stimulate excess saliva production (Chapter 54).

Salivation can be controlled using atropine at a dose of 30 mg for adult cattle and can be used 20 minutes prior to anaesthesia. However, the use of atropine to control excess salivation is not to be recommended or considered necessary. The primary cause of the problem should be diagnosed and corrected.

Simple stomatitis

Inflammation of the oral mucosa is characterized by redness and excess salivation. There are a variety of causes, which include the following:

- Traumatic injuries from the use of balling and drenching guns, mouth gags and stomach tubes may occasionally be encountered.
- Foreign bodies, such as sticks and vegetable roots, may damage the roof of the mouth or be wedged between the teeth and the buccal mucosa.
- Injuries to the tongue may also occur, for example it may be accidentally amputated by sharp metal.

Stomatitis caused by chemicals is more common. Creosote, discarded engine oil, formalin, acids or caustic soda used for forage preservation, chemical dips or sprays are all found on most livestock farms and, if left unprotected from animals, the inquisitive cow may well consume small quantities, resulting in inflammation to the oral mucosa.

Inflammation or infection of the buccal mucosa is occasionally seen. Also, decaying cud may be found

wedged between the mucosa and the teeth; this produces a swelling on the side of the face. Removal of the offending material and treatment with a course of parenteral antibiotics (penicillin and streptomycin) results in recovery, although further accumulation of cud material may occur and this has to be removed daily until the lesion heals.

The treatment of these conditions is generally symptomatic. The foreign bodies are removed, antibiotics may be administered and corticosteroids or non-steroidal anti-inflammatory agents may help to reduce the painful effects of the inflammation. Most conditions recover quickly when removal of the offending material has occurred.

Necrotic stomatitis (calf diphtheria)

Fusobacterium necrophorus will be associated with necrotic lesions of the mouth, tongue and larynx. In calves the condition is extremely common, but it does occasionally occur in growing or adult cattle. A frequent site is the buccal mucosa and this may be a cause of decaying cud accumulating between the teeth and buccal mucosa as described above. The lesions are necrotic and often contain caseous material. Necrotic glossitis has been reported in feedlot cattle with the necrotic lesions present on the tongue. The aetiology is unknown but is probably infectious and may be viral. The signs are of excessive salivation, swollen cheeks when the buccal mucosa is affected and a foul smelling breath. Treatment with parenteral antibiotics or sulphonamides is generally very effective if given over a period of three to five days (see p. 250).

Papular stomatitis

Papular stomatitis is a virus condition producing vesicles that rupture and produce ulcerative lesions. It is a common condition in calves (see p. 252) but is of little economic significance. It is, however, a differential diagnosis of foot-and-mouth disease and lesions caused by mucosal disease, but there are not usually any signs of systemic disease and there is no excess salivation.

Mucosal disease

Erosions or shallow ulcerative lesions of the dental pad, the mucosa below the tongue, the roof of the mouth and occasionally the tongue occur as a sign of mucosal disease, which sporadically affects growing cattle around nine to 18 months of age. The lesions are similar to papular stomatitis, except that vesicles do not precede them. Diarrhoea and wasting are also present. Mucosal disease and bovine viral diarrhoea (BVD) are described in detail on p. 853.

Mycotic stomatitis

Mycotic stomatitis caused by *Monilia* spp. is thought to be a specific disease entity and is characterized by yellow necrotic lesions on the buccal mucosa, which erode, coalesce and become covered in a fibrinous necrotic membrane. It is likely that the fungal infection is secondary and it has been suggested that bluetongue virus (see p. 691) may cause the primary disease. Muzzle lesions similar to mycotic stomatitis also occur occasionally.

Phlegmonous stomatitis

Phlegmonous stomatitis and deep-sited cellulitis occur sporadically in adult cattle. It takes the form of an acute, deep-seated, diffuse, rapidly spreading inflammation of the oral mucosa, pharynx and surrounding structures. It may often follow injury to the mucosa by a foreign body. *Fusobacterium necrophorus*, streptococci and *Escherichia coli* have all been isolated from lesions.

The onset of signs is sudden, commencing with excessive watery salivation and lacrimation. The rectal temperature is raised to 40.5–41.5°C (105–107°F) and the heart rate and respiratory rate are increased. There is marked swelling of the face, mouth, muzzle and the submandibular area. There is a foul or fetid smell to the breath and the oral epithelium frequently peels off. In severe cases death may ensue within 24 hours.

Treatment is successful if commenced early and the condition usually responds to sulphonamides or a course of injections with penicillin and streptomycin.

Wooden tongue (*actinobacillosis*)

Wooden tongue is a well-defined disease producing stomatitis and glossitis, mainly in adult cattle. The causal agent is *Actinobacillus lignieresii*. The disease is found worldwide but the incidence varies considerably between countries. In the UK the incidence of the disease has declined considerably in recent years; whereas 25 years ago the annual incidence was of the order of 20–30 per 10000 cattle it has declined to less than 5 per 10000.

Aetiology and pathogenesis

The aerobic, Gram-negative coccobacillus *A. lignieresii* is the causative organism and it produces small abscesses commonly referred to as 'sulphur granules' in soft tissues. The bacteria do not survive outside the animal host for longer than five days but have frequently been isolated from the faeces of normal healthy animals. It is considered to be a normal inhabitant of the upper respiratory and alimentary tracts.

The organism does not normally invade healthy skin or mucosa but trauma to the mucosal surface from sharp objects such as sticks, dried thistles, straw or barley awns will allow entry of the organism. Although wooden tongue is the most common clinical manifestation of *A. lignieresii*, the organism will produce lesions elsewhere, e.g. the oesophageal groove, the rumen wall, and other soft tissues of the head and neck. It is frequently isolated from cervical and pharyngeal lymph nodes. The organism, once it has gained entry into tissues, produces small multiple swellings that develop into small abscesses 2–5 mm in diameter. The surrounding tissues swell as a result of the inflammation and the tongue may increase in size by 50 per cent.

Signs

Wooden tongue has a sudden onset, with excess salivation, difficult mastication and therefore reduced feed intake. There is considerable submandibular swelling and frequently swollen submandibular and retropharyngeal lymph nodes. The tongue will frequently protrude from the mouth. The tongue (particularly the dorsum) will be swollen, hard to the touch and on the surface will be seen round, discrete, yellow lesions 2–5 mm in diameter. These are abscesses situated just below the tongue epithelium. If left untreated the disease progresses so that eating becomes impossible and weight loss follows. Eventually death will occur due to starvation.

Treatment

If initiated early in the course of the disease, treatment is generally successful. However, if treatment is delayed beyond two weeks it is less likely to be so. Traditionally, treatment consisted of intravenous sodium iodide 7 g/100 kg body weight administered as a 10 per cent solution and repeated in 10–14 days. Oral treatment with sodium or potassium iodide is also effective.

Iodine treatment should continue until signs of iodism occur, such as dry scaly skin rather similar to dandruff. Sodium iodide should not be administered to heavily pregnant animals because of the risk of abortion (see pp. 261, 302).

Antibiotics are effective. Streptomycin at a dose rate of 10–15 mg/kg daily given intramuscularly for 10 days is effective in most cases. However, penicillin is less satisfactory. Some workers advocate the streptomycin should be injected into the lesion. Besides being extremely painful to the animal this does not appear to be necessary.

Animals that have been affected and untreated for two weeks or more and animals that do not recover within two weeks of treatment should be slaughtered.

Prevention

In most situations the disease of wooden tongue is sporadic. However, herd outbreaks have been known to occur, which may be the result of feeding hay or straw containing thistles, gorse or brambles. In any case affected cattle should be isolated to prevent spread of the infection and feeds such as those described above should not be offered. The reduction in UK incidence in recent years may well be related to a sharp decrease in the use of hay and a corresponding increase in silage as a method of grass conservation.

The jaw

A number of conditions affect the jaw of adult cattle, usually the lower jaw or mandible. Fractures of the symphysis (annual incidence 1 per 10000) are a result of falling on ice or slippery concrete and hitting the jaw on a hard surface. Fractures of the mandible usually result from accidental collision with a farm vehicle or occasionally a pathological fracture due to lumpy jaw (actinomycosis) or neoplasia. Jaw abscesses are seen in calves and growing cattle. In calves these are the sequel to untreated calf diphtheria but in growing cattle they may be caused by infections being introduced at the time of tooth eruption. Actinomycosis is a well-defined infection of the mandible, but only occurs rarely.

Fractures

Fractures of the symphysis are presented as an acute onset problem. Some swelling, occasionally blood-stained, of the lower lip will be noticed and some excess salivation. The animal continues to eat, but with obvious difficulty.

Examination of the jaw will reveal bruising of the lower lip and excess mobility of either side of the mandible. The front teeth may or may not be displaced, loose or even lost.

These animals will recover in about three weeks, provided they are isolated from the herd and food is cut and brought to the animal. Grazing or feeding from self-feed silage faces will prove difficult for affected animals. Abnormal positioning of the front teeth may be present after healing has completed.

Trauma-induced fractures of the mandible may be more difficult to manage. If there is no obvious displacement of bone at the fracture site and no dislocation, healing will take place in three weeks providing food is cut and brought to the animal. If there is severe displacement at the fracture site or dislocation is present, casualty slaughter is usually the wisest course of action.

Pathological fractures due to infection will not heal and immediate slaughter should be advised.

Abscesses of the jaw

Jaw abscesses present as round discrete swellings of the cheek and are quite common in calves and growing cattle. Their size varies but frequently they are about the size of a tennis ball (7.5cm or 3 inch diameter). Diagnosis is usually confirmed by paracentesis. Treatment by incising into the abscess, removing the pus and flushing with clean water should only be attempted if a soft area is apparent on the abscess surface. If palpation of the abscess reveals the external surface to be hard all over, treatment should be delayed until a softening and pitting of one area is noticeable. This is called pointing of the abscess. Abscesses that are opened and drained prematurely have a tendency to recur.

Retropharyngeal abscess

Abscesses of the retropharyngeal lymph nodes occur occasionally. These are presented as discrete round swellings the size of a tennis ball (7.5cm or 3 inch diameter) behind the vertical ramus of the mandible. The cause may be actinobacillosis or the result of infection entering a pharyngeal wound. Tuberculosis needs to be considered in countries where it is present. The treatment is the same as for jaw abscesses. There are a few differential diagnoses to consider. However, the author once encountered such a round hard swelling the size of a tennis ball in a Friesian cow. As the swelling was hard with no defined softening the farmer was advised to wait three weeks, by which time lancing the abscess should be possible. Three weeks later, as no softening had occurred and the cow was experiencing some difficulty with swallowing, the animal was anaesthetized and the pharynx explored, where a tennis ball was discovered!

Lumpy jaw (actinomycosis)

Lumpy jaw is a chronic infectious disease characterized by suppurative granulation of the bones of the head, particularly the mandible and maxilla. There is gross swelling, abscesses are present, fistulous tracts and extensive fibrosis all contribute to the granulomatous lesion. Its occurrence is quite rare in the UK (1–2 per 100000 annual incidence) but is said to be more common in the western and mid-western states of the USA. However, it is found at varying incidence levels worldwide where grazing cattle exist.

Aetiology and pathogenesis

The causative organism is *Actinomyces bovis*, a Gram-positive filamentous anaerobe, which is a normal inhabitant of the mucous membranes of the oral cavity, upper respiratory tract and digestive tract of most animals. The organism gains access to the soft tissues as a result of mucosal damage caused by sharp objects or erupting teeth. It generally affects cattle two to five years old.

The organism causes a low-grade inflammatory reaction. There follows a proliferation of connective tissue, invasion with leucocytes and the resulting formation of a walled tumour-like mass. The granuloma then invades the bones of the mandible or occasionally the maxilla. The hard, immovable, circumscribed lesion that results may reach a considerable size (15–25 cm in diameter) and will eventually interfere with mastication. The development of the lesion takes several weeks. Interconnecting abscesses and fistulae breaking to the exterior and discharging small quantities of pus are a frequent sequel. The pus may contain yellow granules that, on compression and staining, will reveal the Gram-positive filaments of *A. bovis*. The granulomatous lesion will continue to invade the soft tissues of the head and neck and the teeth are frequently displaced or become dislodged and the lower jaw may be displaced laterally. Pathological fracture of the mandible may occur (see p. 824).

Pathology

Rarefying osteitis, osteoporosis interspersed with granulomatous tissue and pockets of thin pus-containing, yellow, sand-like granules are the main pathological changes found in this condition. The soft tissues of the head, the oesophagus and oesophageal groove may also be involved. The lymph nodes are not involved.

Diagnosis

Diagnosis is straightforward and based on the clinical signs. Confirmation of diagnosis is made by staining the crushed yellow granules found in the pus and demonstrating the Gram-positive filamentous rods.

Treatment

Treatment with iodides as recommended for actinobacillosis is sometimes advocated (see p. 823). Injecting the swelling with penicillin is also occasionally recommended; however, because of the nature of lesions such treatment is unsatisfactory. Intramuscular injection of penicillin may assist, but once better casualty slaughter should be advised as lesions are likely to recur.

Teeth

Dental problems are rare in cattle. Fractures of the mandibular teeth occur occasionally and traumatic injuries can result in incisor teeth being displaced or lost. Excessive wear of the incisors indicates advancing age. Discoloration of the teeth may result from prolonged treatments with oxytetracyclines during the teeth development phase (see p. 1043). Discoloration and pitted enamel will occur as a sign of fluorosis (see p. 949).

Jaw abscesses may result from infection gaining access during tooth eruption.

Occasionally, heifers will experience problems with feed when teeth are erupting. This will be particularly noticeable if the forage is in the form of self-feed silage and the clamp well compacted.

Foreign bodies do occasionally become lodged between the teeth or between the teeth and the buccal mucosa.

Anatomy

Cattle have both temporary and permanent dentition. The upper front teeth are absent and the premaxilla is attached by a layer of fibrous tissue covered by a thick horny epithelium. There are 20 deciduous teeth with a dental formula of:

| | | | |
|----|----|----|----|
| 0 | 0 | 3 | 0 |
| I- | C- | P- | M- |
| 3 | 1 | 3 | 0 |

$$\times 2 = 20$$

In the permanent dentition the three pairs of premolars in each jaw are supplemented by three pairs of upper and lower molars:

| | | | |
|----|----|----|----|
| 0 | 0 | 3 | 3 |
| I- | C- | P- | M- |
| 3 | 1 | 3 | 3 |

$$\times 2 = 32$$

The front teeth, three incisors and one canine are all spatulate and arranged in a broad arch. The fixation of the teeth allows some dorsoventral movement within the alveoli. There is a large gap or diastema separating the front teeth from those of the cheek. The cheek teeth increase in size caudally and the lower premolars and molars are narrower than the upper ones.

The age of tooth eruption varies between *Bos taurus* and *Bos indicus* and also depends on breed, sex and state of nutrition. Examination of the permanent incisors is frequently used to give an indication of age.

The deciduous teeth have little use in age determination. Calves are frequently born with fully erupted incisors and all will be in place by one month of age.

The average age for tooth eruption in European-type cattle is shown in Table 48.1. However, the standard deviation is approximately 10 per cent of the average age. Thus for a given age of development, e.g. 2.5 years, 95 per cent of the population will be $2.5 \text{ years} \pm 0.5 \text{ years}$, i.e. 2–3 years.

The oesophagus

Emesis or vomiting (see p. 139)

Emesis (vomiting) is not a common sign in ruminants. Reverse peristalsis of the oesophagus is a normal physiological process in rumination.

Table 48.1 Average age for tooth eruption in European-type cattle (*Bos taurus*).

| Tooth | Deciduous | Permanent |
|--------------|-------------------------|-----------|
| 1st incisor | Before birth | 22 months |
| 2nd incisor | Before birth | 27 months |
| 3rd incisor | Before birth to 2 weeks | 37 Months |
| Canine | Before birth to 2 weeks | 44 months |
| 1st premolar | Birth to 3 weeks | 27 months |
| 2nd premolar | Birth to 3 weeks | 24 months |
| 3rd premolar | Birth to 3 weeks | 33 months |
| 1st molar | – | 6 months |
| 2nd molar | – | 12 months |
| 3rd molar | – | 24 months |

However, vomiting (when rumen contents are ejected from the mouth) does occasionally occur in actinobacillosis of the oesophageal groove or with painful conditions of the mouth caused by teeth erupting. The ejection of rumen contents is also frequently seen in the terminal stages of milk fever, the result of rumen pressure caused by tympany accompanying oesophageal relaxation that occurs with hypocalcaemia, not by reverse peristalsis. Grain overload (rumen acidosis), traumatic reticulitis, diaphragmatic hernia, vagal indigestion and abomasal impaction have all been reported to produce emesis, but in the author's experience vomiting is not normally associated with these conditions. Emesis as a herd problem has been reported to occur following the consumption of spoiled maize silage. In the UK poisoning with azalea or rhododendron species (see p. 943) is probably the most common cause of vomiting in cattle, although poisoning by lily of the valley (*Convallaria majalis*) and sneezeweed (*Helenium loopsii*) has been reported to cause vomiting in cattle in the USA.

Diseases of the oesophagus

Disorders of the oesophagus are relatively rare. Mucosal disease/BVD does produce shallow ulcerative lesions of the oesophagus (see p. 853). Malignant catarrh (see p. 935) also produces characteristic lesions of the oesophagus and occasionally oesophageal lesions may be found in calves suffering from calf diphtheria (see pp. 250, 822). Primary conditions of the oesophagus are:

- Traumatic lacerations
- Stenosis caused by pressure from outside the oesophagus
- Obstruction or choke
- Dilatation (see p. 139)

Oesophageal trauma

The usual cause of lacerations to the oesophagus is the result of careless use of a probang, stomach tube, or bolusing, which can sometimes cause rupture. As the probang is rarely used in cattle practice nowadays this problem is uncommon. If rupture of the oesophagus is suspected, then immediate slaughter should be recommended.

Oesophageal stenosis

Stenosis due to pressure outside the oesophagus can be caused by gross swelling of the mediastinal lymph nodes. This used to be a problem associated with tuberculosis, but more recently it has been reported to be associated with lymphomatosis. Oesophageal stenosis caused by swollen mediastinal lymph nodes resulting in chronic bloat in calves three to six months old is sometimes reported in calves recovering from pneumonia.

Choke

Oesophageal obstruction or choke is a relatively common problem in cattle. As cattle consume food rapidly, incomplete mastication is normal. Regurgitation and remastication of food boluses is relied upon to ensure food is ground into small particles. Apples, potato tubers or portions of root vegetables, such as turnips, fodder beet or mangolds, will all be swallowed in relatively large pieces, often without any mastication. The occurrence of choke therefore mirrors the fashions in feeding cattle. When potatoes are in excess and inexpensive they are used as cattle feed and when mangolds and turnips were widely used choke was common. The presentation of the root crops also affects the occurrence of choke. If large roots such as fodder beet or mangolds are fed whole then choke is uncommon, but if chopped they will attempt to swallow without mastication pieces of root that are too big to pass down the oesophagus. Strip-grazing root crops, such as stubble turnips, also rarely results in choke. Presumably cattle bite relatively small pieces at a time. This is probably why the most common causes of choke are apples and potatoes, which are the right size to obstruct the oesophagus, are difficult to masticate being round and slippery and are rarely chopped before being fed. If potatoes are being fed, ample bunker space is essential for all cows to eat simultaneously. If not, cows trying to barge through to reach the feed bunker may cause the cow eating inadvertently to swallow a whole potato it might otherwise chew.

Signs

Profuse salivation, followed by bloat, are the principal signs of choke because the obstructed oesophagus pre-

vents swallowing of saliva and eructation of rumen gas. Affected cows will look distressed, the head is extended forwards and frequent attempts to swallow are often evident. Excess chewing movements are frequently observed and coughing, due to saliva accumulation in the pharynx, may occur.

The extent of the rumen tympany is related to the length of time choke has been present and the nature of the object. A round object such as an apple or potato will completely obstruct the oesophagus and death from bloat may be a sequel. If the offending object is irregularly shaped, such as a root or a portion of a potato, some gas may escape past the obstruction and death from bloat will be avoided.

Diagnosis

Diagnosis is usually made on the basis of the signs of excess salivation, rumen tympany, forward extensions of the head and the history of the availability of offending feeds. The obstruction is usually at one of three sites:

- Alongside the larynx in the upper oesophagus
- At the entrance to the chest
- In the thoracic portion of the oesophagus.

The cervical sites are more commonly involved than the thoracic oesophagus and occasionally the obstruction will be between the laryngeal area and the entrance to the chest.

Usually the obstruction can be seen and palpated as a discrete swelling, although if it is present alongside the larynx confusion with the thyroid cartilage may occur. If in doubt or an obstruction in the thoracic oesophagus is suspected the passage of a stomach tube will aid the diagnosis. If the stomach tube reaches the rumen and the tympany is relieved, an obstruction, if it existed, will probably have been dislodged. The differential diagnosis should not present problems, although indigestion and tympany may be mistaken for bloat. Bronchitis, because of the cough and protruding tongue, may be, but should not be, confused with choke. Once the obstruction has been located, either by palpation or by stomach tube, diagnosis presents no problems except with rabies (p. 908). Excess salivation is the only sign both rabies and choke have in common so the possibility of rabies must be eliminated by assessing other signs before proceeding along the diagnostic pathway to choke.

Treatment

Before treatment commences, the animal will need to be restrained in a cattle crush or at least tied in a byre stanchion. A bulldog-type nose handler is used by an assistant further to restrain the animal and keep the head from moving. The first element of treatment is to assess the severity of the rumen tympany. If the animal

is in distress because of bloat, this is relieved by inserting a cannula into the rumen in the left sublumbar fossa, using a standard bovine trochar and cannula.

If the obstruction is in the cervical oesophagus a spasmolytic such as hyoscine *N*-butylbromide and dipyrone or butylscopolamine bromide and metamizole is administered by intravenous injection and five minutes allowed to elapse before attempting to move the obstruction. The spasmolytic will relax the smooth muscle of the oesophagus, which is in spasm and contracted firmly around the obstruction. Five minutes after the spasmolytic has been administered the operator, using his fingers in the jugular groove with an assistant holding the head forward, gradually pushes the obstruction up the oesophagus until it reaches the laryngeal area. Frequently, when at this position and the spasmolytic has taken effect, upward pressure with the fingers will cause the object to be ejected into the mouth. If this does not happen then a mouth gag has to be applied to keep the mouth open and a second assistant places his forearm into the mouth and pharynx and, simultaneously with the operator pushing the object upwards, will grasp it and be able to remove it. If the object is large and appears reluctant to move, this latter procedure can be carried out under anaesthesia. It is the author's experience that anaesthesia has not been required since spasmolytics have been available.

If the obstruction is in the thoracic oesophagus this will have been detected by the use of a stomach tube. The application of gentle pressure with the stomach tube will dislodge the obstruction and push it into the rumen. Again spasmolytic administration will enable the obstruction to be more readily moved. On occasions the obstruction will move on into the rumen without pressure following the spasmolytic injection. If the efforts described do not remove a thoracic oesophageal obstruction, a probang may be used. However, care must be exercised when using the probang, as the pressure applied must not be too severe for fear of lacerating the oesophagus. If the probang fails to dislodge the obstruction a rumenotomy may be considered and the object removed from the oesophagus manually via the rumen.

In preference to a rumenotomy and if it is certain that the obstruction is caused by vegetable matter, a rumen trochar may be sutured in place in the left sublumbar fossa to prevent bloat and the obstruction allowed to macerate. This may take two to four days but is usually effective.

Prevention

Choke can be prevented by the shredding or chopping of root vegetables into small pieces that will not cause obstruction. If potatoes are fed, ample feeding space is required and if they are offered at pasture they should

be placed in the field before the cows enter. Cows will follow a vehicle that is unloading food and will attempt to eat while on the move. If they attempt to eat potatoes or apples while on the move they are more likely to choke. It is rare for apples to be intentionally fed to cattle. However, when cattle graze orchards, windfall apples should be collected before allowing cattle access. This will not only prevent choke but also rumen acidosis (see p. 829) from overeating apples.

Upper alimentary squamous cell carcinoma (see also p. 946)

Occurrence

Squamous cell carcinoma of the upper alimentary tract occurs sporadically in cattle grazing bracken areas. The problem usually affects beef cows and has been reported in Scotland and North Wales. It occurs on farms with a high bracken cover but is less common than another bracken-induced disease, enzootic haematuria (see p. 947). Both conditions have been reported in the same animal. The disease generally occurs in animals over six years old. Almost invariably alimentary papillomata, in which papilloma virus can be demonstrated, occur in animals affected with bracken-induced squamous cell carcinoma. It is thought therefore that the disease is caused by a toxic factor present in bracken that activates papillomata in the alimentary tract to develop into squamous cell carcinomas.

Signs

The clinical signs can be divided into four main syndromes that are related to the site of the carcinoma, which can occur in the pharynx, oesophagus or rumen.

Oropharyngeal syndrome: The presence of the carcinoma in the oropharyngeal region will produce a chronic wasting condition of one to six months' duration. A cough may be present in the last two to four weeks of the disease and excess salivation and drooling will often be evident. Snoring may also be a feature and halitosis is frequent. Examination will reveal a tumour in the mouth or pharynx. Papillomas will also be present. The submandibular lymph nodes may be enlarged.

Oesophageal syndrome: If present in the oesophagus the carcinoma will produce signs similar to choke with partial or complete occlusion of the oesophagus. Halitosis, coughing and drooling may be present and gurgling sounds may be heard coming from the oesophagus. The passage of a stomach tube may prove difficult. The history will include a gradual weight loss over a period of one to three months. Papillomata may be present in the mouth or pharynx. A palpable mass in the oesophageal region will be present.

Ruminal tympany syndrome: Carcinoma of the reticuloruminous cardia or thoracic oesophagus will produce intermittent ruminal tympany following a period of one to six months of gradual weight loss. The passage of a stomach tube will prove difficult. Papillomata of the mouth and pharynx will usually be present and profuse diarrhoea is a common feature.

Wasting and diarrhoea syndrome: If the carcinoma is present in the dorsal pigmented area of the rumen symptoms of rumen indigestion will be present. The tumours in the rumen can reach 30–50 cm (12–20 inches) in diameter. A slow loss of weight over up to nine months is followed by diarrhoea, which contains much fibrous undigested material. Ruminal tympany is usually present and the abdomen is often pendulous. Papillomata are usually found in the mouth or pharynx.

Diagnosis

The diagnosis may at first be difficult, as the signs may resemble choke (p. 826) or rumen indigestion (see p. 829). However, the history of the slow weight loss, the presence of bracken and the occurrence in older beef cows will considerably aid the diagnosis. As papillomata are almost invariably found in the mouth or pharynx of affected animals a thorough examination of the mouth should be made if the other signs are present. Johne's disease (p. 857) may also be confused with this condition but the distinguishing feature is the consistency of the faeces. In Johne's disease the faeces are homogeneous, there being no signs of undigested fibrous material.

Treatment and prevention

There is no treatment and as the condition is invariably fatal affected animals should be slaughtered as soon as possible.

To prevent the condition, cattle should not have access to bracken. Where bracken exists on a farm cows will rarely eat the bracken if adequate food is available.

Diseases of the rumen

There are a number of diseases that affect the rumen, all of which cause inappetence, reduced milk yield and failure to thrive. An essential element in a thorough clinical examination of the bovine is to observe whether the rumen is tympanic by observing distension of the left sublumbar fossa, the animal is chewing its cud, eructating normally and normal rumen contractions are taking place. Rumen contractions can be detected by palpating with slight pressure in the left sublumbar fossa and detecting the rumen movements, which occur approximately every 30 seconds. Eructation will accompany every second rumen contraction.

Indigestion

Simple indigestion is to be suspected if the rumen contractions are weaker than normal, are less frequent and the clinical examination has revealed no other evidence of disease.

Simple indigestion is frequently seen in dairy cows when new feeds are suddenly introduced to the diet. Intakes of large quantities of very wet grass, frosted feeds, sour or spoiled feed, e.g. butyric or soil-contaminated silage, or the sudden introduction of large quantities of concentrate feeds may all predispose to the onset of indigestion. The accidental intake of small quantities of antibiotics, which disturb the rumen flora, will also precipitate indigestion, as is seen in feedlot beef cattle when rations containing monensin sodium are first introduced. Dairy cow concentrate rations containing as little as 0.005 mg/kg dry matter (DM) of lincomycin have been incriminated in causing severe indigestion of whole dairy herds with a consequent 50 per cent reduction in the herd milk production. The lincomycin contamination occurred at the compound mill where the milling equipment was used to produce dairy concentrate immediately following the production of a pig feed containing lincomycin.

Relatively minor changes in rumen pH are likely to cause atony of the rumen. The intake of any indigestible, stale or sour feeds will interrupt the process of rumen fermentation, which changes the pH resulting in rumen atony. The sudden introduction of new feeds to which the rumen is unaccustomed will have a similar effect.

The rumen is a versatile fermentation chamber and will accommodate a wide variety of feeds, e.g. 100 per cent cereal diets in feedlot beef production, extremely wet grass in some seasons and highly fibrous foods such as hay or straw. However, if changes to the diet are made the rumen flora have to adapt to the new feed and to prevent indigestion occurring, the changes should be gradual. Thus new food should be introduced in small quantities at first, with the intake being gradually increased daily.

Signs

The first clinical sign of simple indigestion will be reduced appetite and in dairy cattle a simultaneous milk yield reduction will be apparent. The reduction in feed intake may be as much as 50 per cent with no other obvious signs. The cow may be slightly depressed. Rectal temperature will be normal and heart rate raised slightly to around 80/minute. There may be mild diarrhoea and a mild rumen tympany may be present. In chronic cases of indigestion undigested fibre may be present in the faeces. Rumen contractions will be reduced in strength and frequency, often to as few as one contraction every 3 or 4 minutes.

Diagnosis

Diagnosis of simple indigestion will be based on the clinical examination and the elimination of any other disease. There is very little in the way of laboratory tests that can be useful. An increase or decrease in rumen pH may be a useful guide but tends not to be used in practice because of its impracticability. The history may be the most useful clinical indicator and may suggest a 'feed problem'. If only one cow in the herd is affected the history may not be helpful and the diagnosis more difficult. However, if the whole herd or a substantial part of the herd were suddenly affected with inappetence it would be quite logical to suspect a 'feed problem'.

Other diseases that may be readily confused with simple indigestion are displaced abomasum, traumatic reticulitis, lesions of the oesophageal groove, early milk fever and acetonaemia. A thorough clinical examination will eliminate these other diseases.

Treatment

Many animals suffering from indigestion will recover spontaneously in two to three days if they are removed from the offending diet and allowed access to good quality hay.

A large number of treatments for indigestion have been employed and were administered as drenches. Historically mixtures containing nux vomica, gentian, sodium bicarbonate, magnesium carbonate, etc. were frequently used and acted by altering the rumen pH and stimulating appetite and even providing vitamins and trace elements essential for rumen microbial synthesis. However regulations on the use of licensed medicines in food animals have resulted in all such preparations being withdrawn by the manufacturers.

If the rumen is atonic for more than 24 hours the administration of rumen inoculum obtained either from an abattoir or a healthy cow will aid recovery. Probiotics may also be helpful.

Prevention

The prevention of indigestion is not always straightforward. The avoidance of abrupt changes in feeds and of indigestible, sour or putrefied feeds is relatively easy. However, cows will break out into pastures where they should not be and will, if given the opportunity, consume foods of dubious quality in large enough quantities to be harmful. The frequency of occurrence of simple indigestion on a farm is likely to be inversely related to the quality of management that exists.

Rumen acidosis (grain overload, overeating syndrome, barley poisoning)

Wherever intensive livestock production is practised acute indigestion as a result of excessive intakes of

grain, beans or compound feed is common, either as a result of cattle gaining accidental access to grain stores or by the sudden introduction of unlimited supplies of grain to the diet. There are two distinct syndromes associated with overeating.

The most common is acute acidosis as the result of consuming excess carbohydrate, which rapidly ferments leading to lactic acidosis followed by acute dehydration and depression. Accidental access to compound feed stores by cattle, who will readily consume 15–20 kg of concentrate, is the most common scenario but the problem is also seen in feedlot beef cattle fed *ad libitum* cereal-based diets, particularly when the diet is first introduced. Excess intake of apples by cattle grazing orchards is also a common cause of rumen acidosis.

Alkalosis: A less common syndrome occurs as a result of excessive intake of highly fermentable proteinaceous feeds, e.g. soya bean, which results in excess ammonia production in the rumen leading to alkalosis with excitement and hyperaesthesia.

Pathogenesis

The rumen can be visualized as a continuous culture fermentation vat. The rumen microflora constitute the culture, which grows on the substrate or medium being provided by the feed the animal consumes. The rumen microflora form a balanced colony of bacteria and various protozoa. If the feed content changes the balance of the microflora will need to change, e.g. increase in intakes of highly fermentable carbohydrate will lead to streptococci and lactobacilli organisms predominating. With a normal balanced microflora the fermentation end products are the volatile fatty acids (acetic, propionic and butyric acids), which are absorbed from the rumen. Bacterial cell proteins for digestion and absorption in the lower intestine and water-soluble vitamins are also products of the fermentation process.

The streptococci and lactobacilli organisms that predominate when excess carbohydrate is ingested produce lactic acid as a fermentation end product. Lactic acid production increases the rumen osmotic pressure and fluid is drawn into the rumen from body tissues. The rumen pH also drops and the majority of Gram-negative bacteria and protozoa are destroyed. The pH may drop to 4.5. The lactic acid is converted to sodium lactate, which is absorbed directly from the rumen into the blood or is passed down the intestinal tract and absorbed from the abomasum or small intestine. The presence of sodium lactate in the small intestine produces an osmotic gradient and draws water into the small intestine, thus contributing to the diarrhoea. The sodium lactate in the blood reduces blood pH.

Chemical damage to the rumen mucosal epithelium results in bacterial and fungal organisms penetrating the rumen wall and in chronic acidosis will lead to the occurrence of liver abscesses, which are frequently seen in beef cattle raised on 100 per cent cereal diets.

Urine output will be decreased as a result of the dehydration and will also be acidic, containing high levels of lactate. The damage to the rumen epithelium leads to a chronic rumenitis, which in turn causes an increased incidence of bloat. This is often seen in feedlots as a cause of sudden death. Although the main signs of acidosis are the result of lactate absorption an additional component may be the absorption of endotoxins released from the destruction of large numbers of Gram-negative bacteria in the rumen.

Signs

The speed of onset and the severity of clinical signs will depend on the quantity and nature of the food consumed and whether the rumen is adapted to that particular feed. Newly introduced feeds may well prove fatal to animals that are not accustomed to the particular feed in quantities that other animals consume regularly. Also, feedlot animals that are apparently accustomed to cereal diets will sometimes overeat for no apparent reason. Feedlot cattle being fed cereal diets are probably in a continuous state of mild acidosis and a relatively small increase in intake will produce enough lactic acid to destroy the remaining Gram-negative bacteria and produce clinical signs of acidosis. Problems also arise should cattle on *ad libitum* feed run out of cereal and then are immediately introduced to the old level. Water deprivation can also produce a problem.

Clinical signs usually become apparent 12–36 hours after the engorgement. Incoordination and ataxia are the first signs to be noticed with the stockworker reporting the cattle as 'drunk'. The animals will be anorexic, they may appear to be blind and will rapidly become weak and depressed. The rumen will be distended producing abdominal pain, which causes the animal to grunt or grind its teeth and ruminal movements cease.

Dehydration becomes apparent within 24–48 hours and severe diarrhoea will be evident in animals that do not die immediately. The faeces will be a pale 'pasty' colour. Respiratory rate will be raised because of the acidosis, the rectal temperature depressed by 1–2°C (2–4°F), the heart rate is in excess of 180/minute and the pulse weak. Severe cases will become recumbent with the head resting on the shoulder, as in milk fever. Death will occur within 24–48 hours in acute cases.

In feedlot cattle that recover some animals fail to thrive even after apparent recovery and this can be due to chronic rumenitis, liver abscesses, or chronic laminitis (p. 420).

Alkalosis: The signs are not completely typical but they do involve muscle tremors, convulsions and slow shallow respiration. In the later stages there may be dyspnoea and hyperpnoea.

Clinical pathology

Affected animals are dehydrated and show haemoconcentration. Blood pH may also be depressed. The pH of rumen contents will be 4 or lower and urine pH around 5.

However, in practice, laboratory tests are rarely performed because of the necessity to institute treatment quickly and the diagnosis is rarely a problem. In order to assess blood pH, bicarbonate and total carbon dioxide levels need also to be measured.

At post mortem of acute cases the rumen will be distended, containing excess fluid with evidence of grain particles present. Rumen pH evaluation at post mortem is of no value unless done immediately after death because post-mortem changes will increase the pH. Chronic acidosis as a result of long-term cereal intake may be characterized by rumenitis, although to observe this the examination must be performed soon after death. Multiple liver abscesses may also be present in chronic acidosis.

Alkalosis: If the less common syndrome of alkalosis is present due to the ingestion of excess soya beans or similar high-protein feeds, the rumen pH may be alkaline and the urine and blood pH will also be raised. On occasions there is a paradoxical acidic urine.

Diagnosis

Diagnosis is not usually difficult and is frequently made on the history together with signs of incoordination and ataxia. In feedlot beef animals it is usual for several of the group to be affected, but with dairy cattle any number may be affected, depending on how many cows had accidental access to the grain store, which is the most common scenario. Cows grazing orchards will consume large quantities of apples, particularly after a storm, and again the history should be of considerable help in reaching a diagnosis.

Laboratory tests are not normally necessary and unless a result can be available within an hour or so are of no value in the practice situation because to be effective, treatment must be administered as quickly as possible. The prognosis for peracute recumbent cases is very poor, but for the less acute standing cases the prognosis is relatively good provided treatment is not delayed.

Treatment

In peracute recumbent cases the rumen should be emptied by rumenotomy (pp. 834, 1106) and the dehy-

Table 48.2 McSherry's solution.

| | |
|--------------------|---------|
| Sodium chloride | 4.95g |
| Sodium acetate | 7.50g |
| Potassium chloride | 0.75g |
| Calcium chloride | 0.30g |
| Magnesium chloride | 0.30g |
| Water | 1 litre |

dration and acidosis corrected using a balanced electrolyte, e.g. McSherry's solution (see Table 48.2), and 5 per cent sodium bicarbonate solution intravenously. Up to 60l of electrolyte solution will be required for an adult cow over a 24-hour period. Up to 300ml of 5 per cent sodium bicarbonate solution may also be administered, the quantity required depending on the degree of acidosis present and can be assessed by observing a slowing down of the respiratory rate during its administration, if given slowly. Supportive therapy should include intravenous calcium borogluconate (400ml of 30 per cent solution) and 400ml of 40 per cent dextrose solution.

For less acute cases that are still standing, the oral administration of magnesium hydroxide, magnesium carbonate or aluminium hydroxide at a dose rate of 1g/kg body weight mixed in 10l of warm water and administered by stomach tube will help restore rumen pH. The dehydration and acidosis is corrected using an electrolyte solution and sodium bicarbonate intravenously as for peracute cases. Intravenous administration of a vitamin B/vitamin C mixture is widely used in the UK with apparent success. Doses of 30–50ml intravenously are frequently used and are thought to aid detoxification of lactate in the liver.

Antihistamines are also considered to be of value by some clinicians. Calcium borogluconate and 40 per cent dextrose are also useful as supportive therapy when administered intravenously.

Alkalosis: Treatment of alkalosis resulting from soya bean or high-protein engorgement should consist of an electrolyte mixture containing excess chloride such as Ringer's solution. Volumes of 30–50l will be required over a 24-hour period, but no bicarbonate should be used. All concentrate feeds should be withdrawn from the diet and only hay or silage offered.

Prevention

Bulk storage of concentrates in large bins has reduced the incidence of acidosis in many dairy herds where accidental access of feed stores with concentrate stored in bags was once quite common.

In feedlots where concentrated food is fed *ad libitum*, often to the exclusion of long fibre, introduction to the concentrate must be gradual and the feed bunkers

should be of adequate size to allow all animals to feed together. The feeders should not be allowed to empty to avoid excessive intake by hungry animals once the feeders are refilled. Continuous access to the food will allow 'little and often' intakes of food. Ideally, some roughage should always be available even if it only represents 10 per cent of the DM intake. Roughage availability has been shown to reduce the incidence of liver abscesses in cereal-produced beef in the UK. It is also advisable that the grains should not be finely ground, which in itself encourages rapid fermentation. The grain should be cracked or rolled and more recently whole grain has been fed without seriously affecting the digestion of the cereal.

Rumen parakeratosis

Parakeratosis of the rumen epithelium is a common sequel to the feeding of 100 per cent concentrate diets to cattle. The disease is characterized by enlargement and hardening of the rumen mucosa papillae and may affect 100 per cent of animals reared on 100 per cent cereal diets. The disease syndrome also includes the associated lesions of liver abscesses and possibly laminitis. Parakeratosis may occur as a secondary stage of acute rumen acidosis.

Pathogenesis

The association between liver abscesses, lesions of the rumen mucosa and the feeding of 100 per cent concentrate diets to ruminants has long been recognized. The lower rumen pH associated with concentrate diets and the consequent increase in lactic acid production produces an inflammatory reaction of the rumen mucosa. This damage to the mucosa allows debris to adhere to the mucosa causing ulceration and infection and resulting in abscess formation in the rumen wall. The rumen papillae become enlarged and thickened and may clump together to form bundles in response to the inflammatory reaction. The papillae may contain excessive layers of keratinized epithelial cells, particles of food and bacteria. A sequel to the damage to the rumen mucosa is the presence of liver abscesses. Some workers also report that laminitis is a later sequel but, as laminitis has been found in the absence of rumen and liver lesions, the role of acidosis in the aetiology of laminitis is far from clear.

Signs

Rumen parakeratosis does not necessarily produce signs of disease, although it has been reported that the addition of 10 per cent hay or silage to the diet of 100 per cent cereal-fed cattle will improve appetite and weight gain. Some individual animals that are seriously affected with abscesses in the rumen wall and liver may show reduced appetite and reduced growth rate, par-

ticularly towards the end of the feeding period. Complications such as peritonitis, septicaemia or even endocarditis may occasionally be evident.

Diagnosis

The diagnosis in the live animal is extremely difficult because the reduced growth rate and inappetance are signs of many diseases. As it is a group problem the detection of the rumen wall lesions and liver abscesses at post mortem will be the best diagnostic indicator.

Treatment and prevention

The treatment of individual cases by the time they show inappetance and poor growth rates is unrewarding because of the severity of the damage to the rumen wall and liver. However, if the problem is suspected (by the post-mortem examination of some animals from the same farm at the abattoir) feeding 10–20 per cent of the diet in the form of long roughage will prevent deterioration and allow the animals to reach slaughter weight. Prevention depends on the inclusion of 10 per cent long fibre in the diet, although recent experience has shown that feeding whole grains will reduce if not eliminate the problem of rumen parakeratosis and liver abscesses.

Bloat (rumen tympany) (see also p. 234)

Bloat or rumen tympany is a disease easily recognized and feared by cattle farmers. Bloat refers to an excessive accumulation of gas in the rumen and, because of a failure to eructate, rumen distension occurs, frequently resulting in death. It is a major cause of death in cattle in all intensive livestock areas of the world.

There are two types of bloat, gaseous bloat or secondary rumen tympany and frothy bloat or primary rumen tympany.

Gaseous bloat (secondary rumen tympany): Any condition that causes an oesophageal obstruction or that interferes with eructation will produce gaseous bloat. The condition is generally sporadic in occurrence and is less common than frothy bloat. The following conditions will lead to gaseous bloat:

- Lesions of the oesophageal groove, e.g. vagus indigestion, abscessation or infection with *A. lignieresii* obstruct the groove and prevent eructation (pp. 826, 837).
- Physical obstruction of the groove with afterbirth has been reported (p. 836).
- Physical obstruction of the oesophagus with potatoes or other root vegetables causing choke will prevent eructation (p. 826).
- Pressure on the oesophagus by enlarged mediastinal or bronchial lymph nodes prevents gas escaping through the oesophagus. This is a common problem in

- growing cattle three to six months old, particularly those that have been affected with pneumonia (p. 239).
- Inability to eructate is also a feature of tetanus (p. 733) and milk fever (p. 781) and gaseous bloat is a frequent feature of these diseases.
 - Prolonged lateral recumbency as a result of disease or animals that are cast for prolonged surgery will frequently lead to gaseous bloat because of the inability of the rumen gas to escape. Cattle that inadvertently fall in dorsal recumbency into ditches will generally die of bloat if not retrieved in time.
 - Severe damage to the rumen epithelium following acute acidosis may lead to rumen atony and accumulation of gas (p. 829).
 - Excess cereal ingestion usually results in gaseous bloat (p. 829).

Frothy bloat (primary rumen tympany): Frothy bloat is much more common than gaseous bloat and usually affects several animals in the group at the same time. Although frothy bloat does occur in feedlot cattle it is more generally associated with pasture feeding. Pastures that are most commonly incriminated in the cause of frothy bloat usually contain high levels of leguminous plants, particularly clover or alfalfa.

Frothy bloat is extremely common in some countries, e.g. New Zealand (p. 127), due to the high content of clover in the sward. In these situations the problem is well recognized and anticipated so that prevention regimens are universally applied. In the UK, frothy bloat can appear suddenly without warning on lush spring or autumn pastures and up to 25 per cent of the herd may be suddenly affected. Some of these pastures may not contain a high clover content. The onset may be extremely sudden, often 4–6 hours after milking and return to the grazing areas. The only warning that the farmer experiences is the bellowing of several cows in extreme pain, and on reaching the field there may be several cows recumbent or even dead, with many others exhibiting rumen tympany to varying degrees of severity.

Pathogenesis

Bloat is the result of the inability to eliminate gas from the rumen by eructation. With gaseous bloat this is secondary to some other condition or disease.

With frothy bloat eructation is prevented by the accumulation of froth, which prevents gas escaping into the oesophagus. The production of froth or foam is a result of the raised viscosity of the rumen fluid and the small bubbles of gas, the natural product of rumen fermentation, cannot coalesce. Under certain conditions some naturally occurring plant substances, e.g. saponins, pectins, hemicellulose and certain proteins, will raise the viscosity of rumen fluid. There also appears to be an individual animal susceptibility. Succulent, high-protein plants, particularly the leguminous plants in the pre-

bloom stage, undoubtedly predispose to the occurrence of frothy bloat. Frothy bloat does also occur in feedlot cattle, particularly if fed on finely ground grain. This may be due to the gases being trapped by the fine particles of feed, but the rapid fermentation that follows the feeding of finely ground grain is undoubtedly a contributory factor. Adaptation to a particular feed is also important. As the rumen microflora adapts itself to the particular pasture or ration there is a tendency towards reduced susceptibility.

Signs

Rumen tympany, as evidenced by distension of the left sublumbar fossa, is well recognized by most stockworkers and should present no problems. With severe tympany the animal will be exhibiting signs of pain, e.g. kicking its ventral abdomen and bellowing. The bellowing can frequently be heard up to 500m ($\frac{1}{3}$ mile) away. In acute frothy bloat the disease progresses rapidly and the animal soon becomes recumbent and can die in 30–60 minutes from the onset of tympany.

Pathology

Post-mortem bloat in ruminants that die from other causes can be confusing to the diagnosis of the condition. If the animal is seen soon after death, death from bloat will be obvious because of the gross abdominal distension and at post-mortem examination oedema in the inguinal and ventral perineal region together with congestion and haemorrhage in the anterior parts of the carcass will be evident. The liver will be extremely pale due to compression and the rumen will be grossly distended and contain froth. The quantity of froth present declines after death. Rupture of the diaphragm and the abdominal musculature, particularly in the inguinal region, may also be apparent. Death from gaseous bloat is less common, but the absence of froth and the finding of a primary lesion should differentiate it from frothy bloat.

Diagnosis

The preliminary diagnosis presents no problems and is based on distension of the left sublumbar fossa. If only one animal is affected in the herd the bloat is probably a gaseous bloat but if several animals are affected to varying degrees and they are at pasture the diagnosis will certainly be frothy bloat. However, if there is any doubt the passage of a stomach tube will provide the answer. If the problem is one of gaseous bloat and the stomach tube reaches the rumen and possibly removes an obstruction on the way, the gas will escape through the stomach tube and the rumen will rapidly revert to its normal size. If gaseous bloat is confirmed and the bloat relieved, a full clinical examination should be performed to ascertain the cause of the failure to eructate.

If the bloat is due to froth little or no gas will escape via the stomach tube, which will itself become blocked with froth.

Treatment

The traditional treatment for bloat was the passing of a 5 mm diameter trochar and cannula into the rumen via the left sublumbar fossa. Many farmers possess such a trochar and cannula. However, this instrument is of little use because gaseous bloat can nearly always be relieved by stomach tube and only when this is not possible should a rumen trochar and cannula be used. For frothy bloat the cannula itself becomes blocked with froth and does little to relieve the tympany.

Treatment for all but the peracute cases necessitates the passing of a stomach tube and, if this reveals the bloat to be frothy, antifoaming agents that reduce the viscosity of the rumen contents and disperse the froth can be passed down the stomach tube. Vegetable oils such as linseed, peanut, corn or soya bean oil are all useful antifoaming agents. Traditionally, 500 ml of linseed oil to which is added 50 ml of turpentine was effectively used as a bloat drench, but this does tend to taint the milk. Oil mixed with detergent will disperse faster in the rumen ingesta.

Proprietary bloat drenches containing silicone or poloxalene are available (Table 48.3) and are equally effective. Within five minutes of administration of the antifoaming agent the animal will start to eructate and in most cases the tympany will be relieved within one hour. If tympany still exists after one hour, a further administration of an antifoaming agent by drench may be given. If tympany still exists one hour after the second drench the diagnosis should be reassessed and a stomach tube passed to ensure there is no oesophageal obstruction. Once the diagnosis of frothy bloat has been established in a group of affected animals the less acute cases can be treated by drenching alone.

In peracute cases where death is imminent and the animal is recumbent, it will be necessary to conduct an emergency rumenotomy (p. 1106). A 10–20 cm vertical incision is made in the mid point of the sublumbar fossa, using a sharp knife. On incising the rumen there will be an explosive release of rumen contents and marked relief for the cow. Following the release of the frothy rumen contents the wound is cleansed and sutured using the

standard surgical closure. Antibiotics are administered postoperatively and recovery is usually uneventful.

Chronic gaseous bloat in calves and feedlot animals is often treated by establishing a 10–15-cm length rumen fistula. Under local anaesthesia the skin and musculature of the sublumbar fossa are incised and the rumen exposed. The rumen is then incised and the rumen wall sutured to the skin. Alternatively, a prosthetic device may be sutured into the abdominal wall and the rumen, allowing gas to escape (see p. 827). This device may be removed two to three months later and the wound allowed to granulate, by which time the primary cause of the bloat will have corrected itself.

Prevention

To prevent further cases of frothy bloat occurring when a sudden acute outbreak is encountered at pasture the cattle should be removed immediately, provided with dry food such as hay or straw and all cows showing any degree of rumen tympany drenched with an antifoaming agent. The pasture should not be used for grazing for at least 10 days.

Where risk pastures exist, e.g. those containing high proportions of legumes, gradual access to the pasture should be practised, starting with 10 minutes a day and increasing by 10 minutes each day. Long fibre should be fed before access is allowed to the pasture. Strip-grazing to restrict intake can be practised, but is not favoured by stock farmers who currently prefer paddock grazing or set stocking. However, during high-risk periods in problem areas these methods alone will not be satisfactory. In New Zealand and Australia, where the risk from bloat can be exceedingly high, during the spring, when the pasture is fast growing, the only satisfactory method of control has been the daily administration of antifoaming agents by drench after milking. Oils may be given at doses of up to 240 ml/day in high-risk periods, although 60–120 ml/day would be more common. Poloxalene, a non-ionic surfactant, is frequently used at 10–20 g/head per day and up to 40 g/day in high-risk periods.

If strip grazing is practised, the antifoaming oils can be emulsified with water and sprayed on the grass daily. Addition to the water supply is sometimes used, but effectiveness does depend on adequate individual intake.

Poloxalene can be added to grain mixtures or compound feed or even mineral blocks. However, in grass-rich areas, grain is rarely fed to cattle, particularly in the bloat-risk season of fast grass growth, and mineral blocks suffer from variable individual intake. Daily drenching has therefore become the preferred method of bloat prevention. The rumen implantation of a slow-release device containing an antifoaming agent has been developed in New Zealand and Australia.

Table 48.3 Treatments available for frothy bloat in the UK.

| Name | Active ingredient | Manufacturer |
|---------------------|---------------------------|------------------------|
| Birp Bloat Guard | Dimethicone Poloxalene | Arnolds Agrimin Ltd |

The ultimate objective in bloat control is to develop pastures that have a low bloat-producing potential yet still possess the characteristics for high levels of production. The direction of development will be to develop strains of leguminous plants that have a low bloat-producing potential. To date some progress has been made in identifying the strains of red clover with the ability to produce less bloat, although it is recognized that sainfoin produces fewer tympany problems than clover. At the moment, pastures should not contain more than 50 per cent clover until such strains of clover are developed (p. 128).

Vagal indigestion

Vagal indigestion is a chronic condition of adult cattle with a slow insidious onset, but is still a differential diagnosis of rumen atony, simple indigestion or mild bloat. The incidence of vagal indigestion is now quite rare, the annual incidence being less than 1 in 10000, having decreased in recent years, probably mirroring the decline in the incidence of traumatic reticulitis.

Aetiology

Vagal indigestion is caused by interference with the function of the vagus nerve. The condition has been produced experimentally by severing the vagus (Xth cranial) nerve. The clinical syndromes vary slightly depending on the site of the nerve severance. In practice, the most common cause of nerve damage is the adhesions formed around the reticulum in advanced cases of traumatic reticulitis. The vagus nerve passes through the diaphragm in the region of the reticulum and is susceptible to damage in that area from the inflammation and infection that follow traumatic reticulitis. Other lesions that may damage the nerve would include actinobacillosis of the reticulum, infections of the mediastinal lymph nodes, e.g. tuberculosis, ruptured diaphragm or pleurisy. Sometimes cattle that survive surgery for abomasal torsion (p. 842) later develop signs of vagal indigestion. This could be the result of damage to the nerve caused by the torsion.

Because of the loss of function of the vagus nerve, ingesta are not transported from the rumen to the abomasum or from the abomasum through the pylorus, with the consequent result that the rumen and often the abomasum distend with fluid and ingesta producing abdominal distension.

Signs

The clinical signs are variable in that the abomasum is not always directly involved. Depending on the level at which the vagus nerve is damaged various syndromes can develop that are clinically classed as follows:

- (1) Pyloric obstruction and abomasal impaction;
- (2) Ruminal distension with atony;
- (3) Ruminal distension with hypermotility. In some cases combinations will occur.

Pyloric obstruction and abomasal impaction: If the abomasum is involved there is a pyloric stenosis, which prevents ingesta leaving the abomasum. The ingesta accumulates, the abomasum becomes distended and can be palpated in the abdominal flank. Later the rumen becomes atonic and distends with fluid and ingesta.

Ruminal distension with atony: This is due either to a primary effect of the paralysed vagus nerve on rumen function or it can occur following (1) from a backflow from the distended abomasum. The effect of this is to produce a characteristic shape to the abdomen. The left flank is distended and well rounded as in mild bloat and the right flank is distended in the lower regions of the abdomen, giving the right flank a pear-shape appearance. This shape is characteristic of vagal indigestion. In some cases of vagal indigestion where only the rumen is affected the organ will be grossly distended, containing large quantities of fluid. Rumen contractions are infrequent and no rumen sound will be audible. Faecal output is decreased and the faeces are frequently of a pale pasty consistency. Rectal temperature is normal, the heart rate may be normal but in some cases is markedly decreased to around 40/min. There is also dehydration, decreased milk yield and a gradual but progressive loss of body condition. Rectal examination will reveal a grossly distended rumen, reaching into the pelvic canal, and also the ventral rumen distended well over to the right side of the abdomen. The abomasum is not usually palpated per rectum. The fluid content of the rumen and the abomasum can be assessed by ballottement of the abdominal wall on both flanks.

Ruminal distension with hypermotility: There is slight ruminal tympany, and frequent and forceful rumen contractions. Recent body weight loss will be evident. Faeces are scant and pasty. Rectal palpation will reveal a gross distension of the dorsal sac of the rumen and the ventral sac will possess a U-shaped distension.

Clinical pathology

The experienced clinician will make his diagnosis on the clinical signs described and there are no laboratory tests that can be considered specific for vagal indigestion. The dehydration will increase the packed cell volume. If pyloric stenosis is present a metabolic alkalosis will be present with the effect of reducing serum chloride to 40–50 mmol/l. An elevation of rumen chloride concentration (above 30 mmol/l) indicates abomasal reflux into the rumen.

Diagnosis

Veterinary advice is usually sought by the stockworker because it is noticed that the cow has slowly developed an abdominal distension and it is considered that the animal may be affected with bloat. A thorough clinical examination must be performed to establish the differential diagnosis.

If the animal is passing small quantities of pale pasty faeces, the left flank is rounded and distended, the right flank distended in the lower half only and the distension is due to fluid accumulation in the rumen and abomasum, and if the rectal temperature is normal and heart rate normal or slightly depressed, then a diagnosis of vagal indigestion can be made. However, many cases are brought to the veterinarian's attention before all the signs have fully developed and perhaps the right flank distension is not obvious. The insidious onset will distinguish the condition from bloat as will the fluid-filled rumen. Abomasal impaction must be distinguished by ballottement, which will indicate firm abomasal contents in impaction and fluid contents in pyloric stenosis.

Accumulation of fluid within the peritoneal cavity from ascites, peritonitis (p. 849) or ruptured urinary bladder can be differentiated by paracentesis. Hydrops allantois or amnii (p. 1119) will also produce severe abdominal distension, but will be differentiated on rectal examination.

Treatment

The prognosis in vagal indigestion is generally poor to hopeless and in most cases immediate slaughter is advised. If treatment is embarked upon because of the value of the animal the dehydration and any chloride deficit should be corrected. As much as 40–50 l of Ringer's solution may be required over 24 hours and given intravenously. It must be remembered that oral fluid therapy must not be contemplated because of the fluid retention in the rumen.

Following rehydration an exploratory laparotomy and rumenotomy may be performed. Adhesions around the reticulum can be palpated. A rumenotomy partially to empty the rumen is then performed and the reticulum and oesophageal groove examined for tumours or other lesions. The author, on one occasion, found a complete afterbirth wedged in the oesophageal groove in a cow that had not eaten since calving 10 days previously and was showing signs of rumen atony and distension. Removal of the afterbirth led to an uneventful recovery.

Even if tumours, adhesions or oesophageal lesions are discovered the prognosis is still likely to be hopeless so surgery should only be contemplated in valuable animals and a poor prognosis given before surgery commences.

Cold cow syndrome

Another rumen indigestion syndrome that has been reported from different areas of the UK has been named the cold cow syndrome. This syndrome usually occurs in early spring in lactating cows when grazing ryegrass pastures. The onset is sudden but not related to change in pasture use. Both poor and lush pastures have been involved and the occurrence is not related to levels of fertilizer use. The morbidity is high and varies from 8 to 100 per cent of the herd, but mortality is nil. Milk yield may be depressed by up to 50 per cent but recovers within two days. The condition was first recognized in Northern Ireland in the late 1970s and in the southwest of England in 1982 and has been reported in several years since.

Aetiology

The aetiology is unknown but several suggestions have been made. These include unusually high levels of soluble carbohydrate found in grass being grazed by affected herds (Jack, 1985). Other suggestions have been the oestrogenic zearalenone or other metabolites of field microfungi or the presence of high levels of soluble proteins or a protein metabolite. Climatic conditions have been investigated and cases have occurred during periods of frost, cold wet weather and during warm dry springs. Large night/day fluctuations in atmospheric temperature of the order of 17–18°C (30–32°F) accompanied one series of outbreaks.

Clinical pathology

Blood samples from affected cows have been examined for a wide range of biochemical parameters but no abnormalities have been detected.

Signs

A sudden onset of ataxia and incoordination, with a few animals being weak and becoming recumbent, followed by a copious non-smelling acute diarrhoea are the principal clinical signs. The cows behave as though they are drunk. The cows are characteristically cold to the touch as though in a state of shock but rectal temperatures are normal. Appetite is much reduced if not absent and the milk yield falls by up to 50 per cent in the herd and in some individuals by up to 100 per cent. The duration of the disease is short as appetite and milk yield return to normal in two to three days. If cows regraze the same pastures later in the season no disease is seen.

Treatment and prevention

Because of the rapid recovery treatment appears unnecessary, except that the herd should be housed on dry food for 24 hours and then moved to new pasture.

Symptomatic treatment of recumbent cows may be required.

Until the aetiology of this condition is understood, preventative measures will not be possible.

The oesophageal groove

Lesions of the oesophageal groove will interfere with the normal rumen digestion process. Tumours or granulomatous lesions will occlude the oesophagus and prevent eructation and lead to a gaseous bloat or secondary rumen tympany. The same lesions may interfere with normal rumen contractions and cause signs of simple indigestion. Although not common (annual incidence 1 per 10 000 cattle) actinobacillosis of the oesophageal groove does occasionally occur. Some lesions of the oesophageal groove may be due to upper alimentary squamous cell carcinoma in bracken areas (see pp. 828, 946).

Signs

The presenting signs of actinobacillosis of the oesophageal groove will be inappetence, reduced milk yield and possibly mild tympany evidenced by distension of the left sublumbar fossa. The rumen contraction will be weak, occurring once every 1 or 2 minutes. Rectal temperature and heart rate will be normal. Examination of the faeces will reveal strands of undigested fibre. Although this latter finding is in itself only an indication of indigestion, and several lesions of the rumen or rumen wall or dental problems may lead to undigested fibre appearing in the faeces, the most common cause is likely to be actinobacillosis of the oesophageal groove.

Diagnosis

Only a tentative diagnosis can be made based on the clinical observations described above. Although diagnosis would be confirmed by performing an exploratory laparotomy and a biopsy of any oesophageal groove lesion discovered, this is unlikely to be performed in practice because of economic considerations.

Treatment

Although the prognosis in these cases must be guarded because of the uncertainty of the diagnosis, cows presenting the above described lesions are worthy of treatment. Treatment using antibiotics over a prolonged period of at least 10 days can be successful. The antibiotic of choice is streptomycin and a dose of 5–6 g daily for 10 days is effective in a proportion of cows exhibiting the above described signs.

Traumatic reticulitis (traumatic reticuloperitonitis, hardware disease, wire)

Traumatic reticulitis is a well-described disease affecting mainly adult cattle. Because of the rather undis-

cerning eating habits of the cow, it is quite common for cattle to ingest metallic objects with their food. Some abattoir surveys have demonstrated over 50 per cent of cattle reticula to contain foreign objects of metal, wood or stone. If pieces of metal wire or nails 5–10 cm long are ingested these will accumulate in the reticulum and when rumen contractions occur may penetrate the reticulum wall. The incidence of this disease varies considerably around the world. The incidence in the UK has declined in the last 30 years and the present annual incidence is around 5 cases per 10 000 cows. However, in some areas the disease is still extremely common and may reach an annual incidence of 100–200 per 10 000 cows.

This disease is probably related to standards of management that exist on the farm, e.g. rusty, poorly maintained, barbed wire fences are a frequent source of the offending wire. It is thought that the incidence has declined since string has replaced wire to secure bales of hay and straw and much barbed wire fencing has been replaced by electric fences. However, cases of this disease will still be encountered on untidy farms where nails, wire and other metallic objects are left lying around in fields and where they can be accidentally picked up by hay or silage making machinery.

Pathogenesis

Metal objects that are ingested invariably lodge in the floor of the reticulum due to their relative mass and the position of the reticulum. It is only short sharp objects that penetrate the reticulum wall and these are usually 5–10 cm long. The penetration occurs as a result of the ruminal and reticular contractions. On entering the wall of reticulum the wire will continue to penetrate until it reaches the peritoneum. Infection from the rumen then follows the wire and a localized peritonitis is produced, causing local abscess formation and adhesions. If the direction of the wire is forward the diaphragm and pericardium may be punctured, which produces a localized pleurisy and pericarditis (p. 731). If the direction of the wire is left or right of the forward direction the diaphragm may not be involved but extensive peritonitis (p. 849) could well develop, with adhesions containing a variety of abscesses being produced. If the peritonitis is extensive, adhesions between the reticulum and liver or spleen may be evident. Sequelae to traumatic reticulitis include localized or diffuse peritonitis, liver abscessation, splenitis, pleurisy and pericarditis. These sequelae may take several weeks to develop.

Signs

The condition is generally progressive and the clinical signs change as the disease progresses from the initial acute phase through a subacute to a chronic phase.

In the initial acute phase the cow is anorexic and milk production is reduced. The cow may exhibit an arched back and the abdomen is tucked up. A grunt may be heard when the animal walks, although on occasions there will be reluctance to move and also a reluctance to lie down.

Rectal temperature will be elevated to 39.1–40°C (102.5–104°F) and although the frequency of rumen contractions may be reduced they are often increased to three or four per minute. Respiratory movements will be shallow, increased in rate and mostly thoracic. Frequently, farmers mistakenly diagnose the condition as pneumonia. The heart rate will be raised to around 75–90/minute.

The acute phase may last three to five days and then the rectal temperature will fall to around 39°C (102°F) or sometimes to normal. The subacute phase will last several weeks, showing signs of mild indigestion. Rumen contractions will be weak and infrequent, there may be a mild tympany and undigested fibrous material may be evident in the faeces. Sometimes apparent recovery from the acute phase will occur and the animal will return to near normal production, but a relapse will occur several weeks later. This relapse is usually associated with the onset of pericarditis. The animal will be reluctant to move, may occasionally grunt but signs of cardiac insufficiency will predominate. A firm pronounced jugular pulse will be noticeable, together with oedema of the brisket and auscultation of the lungs may reveal signs of congestion or even pleurisy. Auscultation of the heart will sometimes be difficult, as the heart sounds will be muffled and difficult to hear. However, splashing and tinkling sounds over the heart region will confirm the presence of pericarditis (see p. 731).

Pathology:

During the acute phase there will be a measurable increase in circulating neutrophils with white cell counts rising to $30 \times 10^9/l$ (30000/ μl). Ketone bodies may be present in urine or milk indicating a secondary aceton-aemia. During the subacute phase, when peritonitis is developing, the white cell count may be subnormal.

At post mortem, the degree of peritonitis can be dramatic with adhesions between the reticulum, rumen, diaphragm, liver and spleen. Incising through the adhesions may reveal multiple abscesses. Abscesses may also be present in the liver. The pericarditis, when present, will also be dramatic with gross thickening of the pericardium and large quantities of pus present in the pericardial sac, so-called bread and butter heart. Pleurisy, and localized pneumonia and abscessation may also be present.

Diagnosis

The diagnosis of the acute phase is based on the signs described and discovered during the clinical examina-

tion. Cows with traumatic reticulitis can often be made to grunt by pressing down firmly on the withers, thus making the animal lower its back. However, this test is only an indication of peritonitis and not specific for traumatic reticulitis. Grunting can also be induced by applying sharp pressure just to the left of the xiphoid process using a clenched fist. This will specifically indicate pain in the region of the reticulum.

The most successful diagnostic test is known as the ‘reticular grunt’ or Williams test (Williams, 1975). This test uses knowledge of the cycle of reticulo-rumen contractions:

- (1) Contractions of the reticulum, followed by contraction of the rumen. There is no eructation at this stage.
- (2) Following relaxation of the reticulum and rumen, an independent contraction of the rumen occurs. This contraction is accompanied by eructation.
- (3) Relaxation of the reticulum and rumen completes the cycle. The ‘reticular grunt’ is based on the correlation of pain with contractions of the reticulum. Since the reticular contractions occur in conjunction with rumen contractions, the clinician should observe for signs of pain during or just before the non-eructating rumen contractions. These signs of pain will be a mild grunt, and shuffling of the forelegs. To help detect the grunt, observation of the left costal arch may reveal the animal holding its breath just before it grunts.

This test is specific for traumatic reticulitis, but is only effective in the acute phase of the disease.

Diagnosis of the subacute phase may prove extremely difficult, as the signs are often vague and only indicative of a non-specific indigestion. If such cases are encountered and a diagnosis of indigestion made, but a return to normal is not rapidly achieved, subacute traumatic reticulitis/peritonitis must be considered as a differential diagnosis.

The use of metal detectors has been advocated by some workers. However, because metal objects are frequently found in the reticulum a positive metal detector test will often be misleading.

Diagnosis of pericarditis is more straightforward. The jugular pulse and brisket oedema will lead the clinician to auscultate the heart in detail. Muffled heart sounds and splashing, fluid or tinkling sounds around the heart will confirm pericarditis.

Treatment

Various treatment regimens have been advocated for traumatic reticulitis and they can be classified into surgical and conservative.

If a diagnosis is made during the acute or subacute phase and there are no signs of pericarditis, the surgical

approach has much to commend it. In many cases the diagnosis is only tentative and the rumenotomy is exploratory to confirm diagnosis or establish another diagnosis. Under paravertebral anaesthesia, an 18-cm vertical incision is made in the sublumbar fossa, the rumen wall exteriorized and a 10–15-cm incision made into which a McLintock ring is fitted, thus temporarily fixing the rumen wall to the exterior and preventing peritoneal contamination with rumen contents. A scrubbed arm is inserted into the rumen and the reticulum located. Each crypt of the reticulum should be explored as the offending wire may have penetrated to the extent that very little is left protruding into the reticulum. Adhesions between the reticulum and diaphragm or abdominal floor can be detected by attempting to lift the reticular wall. Once located, the offending wire should be slowly withdrawn back through the reticular wall and removed from the rumen. The rumen incision is closed using Lembert sutures and the abdominal wall incision closed in the usual way (see p. 1106).

Five days of antibiotic treatment should follow the surgery to prevent the spread of the peritonitis initiated by the foreign body. This operation can be very satisfactory to conduct in practice and the majority of cases make an uneventful recovery.

The conservative treatment involves restricting the animal's movement by tying it in a byre stall with the front feet raised 35–40 cm higher than the hind feet for three weeks. Parenteral antibiotics will also be given for five to seven days, and in some countries a magnet will be inserted into the reticulum using a balling gun.

If pericarditis is evident immediate slaughter must be recommended, as there is little likelihood of recovery. On no account should a rumenotomy be considered because even if the wire is located, removing it may well cause the heart to stop and death during surgery will be the result.

Prevention

The main thrust of prevention must be to avoid leaving wire or nails lying around to be picked up by cattle during feeding. The use of metal detectors on forage harvesting equipment to prevent damage to the equipment has undoubtedly reduced the incidence of metal objects being found in cattle feeds. Some workers have advocated the routine use of magnets. These are inserted into all cattle on the farm. There is no real evidence that these have been successful.

Abomasum

Diseases of the bovine abomasum comprise an interesting group of conditions only really appreciated in comparatively recent years (Pinsent, 1978).

There are three important conditions that probably have a similar aetiology and epidemiology, yet produce widely differing clinical syndromes. These are left displacement of the abomasum (LDA), dilatation and torsion in the right flank (RDA) and ulceration. Impaction of the abomasum has also been reported. The three important conditions (LDA, RDA and ulceration) appear to be the result of intensive management of cattle and have not been recorded in wild ruminants. In fact their occurrence, particularly LDA, is almost entirely restricted to dairy cattle and rarely found in suckler beef cows. Diet undoubtedly has an important role in the aetiology of these diseases, with the use of concentrated cereal-based feeds and low-fibre diets generally being incriminated. In some countries the feeding of root crops that are heavily contaminated with soil, sand and gravel has also been incriminated. In the UK and USA, LDA is much more common than RDA or ulceration. However, reports from Scandinavia would indicate that RDA is much more frequently seen there than in the UK or USA and may be the result of much greater use of root feeds such as fodder beet.

Displacement of the abomasum to the left

Left displacement of the abomasum is by far the most common of the abomasal diseases encountered in cattle in the UK or USA. Its occurrence is almost entirely confined to dairy cattle, although it has very occasionally been seen in bulls, where it is probably secondary to some other condition. The author has, on one occasion only, diagnosed the condition in a Friesian bull and in that case the animal was suffering from severe endocarditis. It was likely that this particular LDA was a secondary condition brought about by the inappetence caused by the endocarditis. The overall incidence varies considerably between years and between seasons. In some years the annual incidence can be as high as 25–30 per 10000 and in others as low as 4–6 per 10000.

There appears, in the UK, to be a definite seasonal pattern to the incidence with the majority of cases occurring in late winter–early spring, i.e. January to April, the period of winter housing in the UK. However, it is now being seen throughout the year, although at lower numbers during grazing. In the USA, LDA is reported to be more common in the winter housing period. However, the problem is encountered in countries where spring calving predominates and the cows are at pasture during the susceptible period, e.g. Ireland, Australia and New Zealand, although the incidence varies considerably between farms. The author has experienced the condition in eight cows in a 110-cow herd in one year, all occurring from January to April; yet there are many farms that have never, knowingly, experienced the condition. Breed susceptibility

has been investigated and there has been no authoritative confirmation that there is a genetic predisposition. However, it is thought that the condition generally affects the higher yielding cows, mainly in early lactation, although occasionally during late pregnancy.

Aetiology and pathogenesis

The precise aetiology of LDA is not readily understood but the occurrence of the problem soon after, or occasionally just before, parturition would suggest that the presence of the gravid uterus or the process of parturition predisposes to the condition. Certainly it has been observed that in normal cows in late pregnancy the presence of the gravid uterus displaces the abomasum forwards and to the left, and after calving the organ returns to its normal position. To remain displaced after calving, the abomasum must have developed atony and the subsequent accumulation of gas. Atony of the abomasum is likely to be caused by one of four factors:

- (1) Feeding of rapidly fermentable concentrate feeds, which have a tendency towards the production of acidosis.
- (2) The accumulation of sand or gravel in the abomasum, which damages the abomasal mucosa.
- (3) Stress conditions or metabolic diseases that frequently occur around the time of parturition. Hypocalcaemia will itself cause atony of the abomasum.
- (4) The occurrence of systemic diseases that produce toxæmia, such as acute metritis.
- (5) A lack of a suitable quantity of long fibre roughage.

It is likely therefore that atony of the abomasum and the accumulation of gas within the organ is the prime factor in the pathogenesis of the condition. The mechanical effect of displacement by the gravid uterus may well have some involvement in originally displacing the abomasum. Once displaced to the left and the organ is located between the left abdominal wall and the rumen the atonic nature of the abomasum and the presence of gas will prevent the organ returning to its normal position.

Signs

The clinical signs of LDA can vary considerably, although in general the signs are similar to chronic acetonaemia. Mild cases are encountered that show little more than a slightly depressed appetite, rumination and milk yield. At the other extreme, acute cases can be encountered with complete inappetence, absence of rumination, loss of condition, scanty diarrhoea and grunting with some signs of mild colic. The most common clinical picture is one of refusal to eat concentrates, some reduction in milk yield and scanty soft or pasty faeces. Rectal temperature will be normal but the heart rate may be raised to

80–100/minute. Rumen movements will usually be absent or at least infrequent and in some cases palpation of the rumen in the left sublumbar fossa will be impossible because of the presence of the gas-filled abomasum between the left abdominal wall and the rumen. A Rothera's test on urine or milk will usually be positive and thus in many instances the cow will be presented as a suspected case of acetonaemia. In the more acute cases, which are more common in late pregnancy, distension of the left flank will be evident.

Diagnosis

The diagnosis of LDA is relatively easy, providing the clinician always keeps the condition in mind when making a clinical examination of dairy cows. Confirmation is based on auscultation, percussion and auscultation, or ballottement and auscultation of the left flank. The stethoscope is placed on the last intercostal space in line with the lower limit of the left sublumbar fossa and the penultimate rib is percussed by 'flicking' it with the finger. If a 'ping' or high-pitched resonant sound is heard, this is indicative of a gas-filled organ inside the abdominal wall. Should the first attempt fail to elicit the characteristic 'ping' the stethoscope is moved so that an area representing a 20 cm square forward and below the first stethoscope site is auscultated and the second to last and third last ribs percussed in the same way as described above. If a high-pitched resonant sound is heard over this area, confirmation of the diagnosis should depend on auscultation only and a short series of tinkling sounds reminiscent of raindrops falling on a metal roof will be heard.

The frequency of these tinkling sounds is quite variable and the clinician may have to auscultate for up to 10 minutes in some cases. Ballottement of the lower left flank at the same time as auscultation of the target area described above may frequently elicit the same tinkling sounds. The diagnosis, by auscultation of the tinkling sounds without recourse to ballottement, is to be favoured because ballottement may elicit splashing sounds from the rumen that can be difficult to distinguish from the high-pitched tinkling sounds diagnostic of LDA. However, a negative diagnosis can fairly quickly be achieved by using the percussion and auscultation technique over a 20 cm square area forward of and ventral to the lower limit of the left sublumbar fossa. Only when this technique produces a pinging noise should it be necessary to spend time in auscultation alone.

All cows that are presented with inappetence and have a normal rectal temperature, particularly in early lactation or late pregnancy, should be subjected to the percussion and auscultation technique to eliminate LDA as part of a normal clinical examination. If this is performed the clinician is unlikely to fail to diagnose LDA.

However, it must be said that a small number of cases are not diagnosed at the first examination and a diag-

nosis of acetonaemia or, occasionally, indigestion is made and the corresponding treatment administered. Such cases will show a temporary recovery but the signs will relapse two to five days later. It is essential when treating acetonaemia or indigestion that the farmer is instructed to seek further veterinary advice if the condition regresses. Many cases of LDA are diagnosed in cows that have been treated for acetonaemia two to five days previously, either by the farmer or a veterinarian.

Following a complete clinical examination the differential diagnosis of LDA is related to whether the high-pitched resonant sounds can be confused with anything else. Once heard, these sounds are never forgotten. However, similar sounds do occur in conditions of the rumen that produce rumen atony, a rumen mildly distended with gas accumulation, as is seen in vagal indigestion, actinobacillosis of the oesophageal groove, localized peritonitis or mild rumen tympany. However, if the tinkling sounds are heard spontaneously and not induced by ballottement, the likelihood of misdiagnosing these other conditions as LDA is slim. The author has on one occasion, having made a diagnosis of abomasal dilatation in the right side of the abdomen by recognizing the tinkling sounds, performed a laparotomy to discover the sounds were produced by a large subperitoneal abscess in the upper right abdomen.

Treatment (see also p. 1109)

The treatment for LDA falls into two categories, conservative or surgical.

Conservative measures include drug therapy and rolling. Drug therapy using calcium borogluconate solution, neostigmine and saline cathartics has been attempted with very little success. The usual conservative treatment is to roll the cow. The cow is cast, using the Reuff's method, on to its right side. The cow is then rolled into dorsal recumbency and kept in this position for 5 minutes. During this time the animal may be rocked to the left and right and the abdomen massaged vigorously to encourage the abomasum to rise into the ventral abdomen. The animal is then rolled over to a left side lateral recumbency and maintained in this position for a further 5 minutes, allowing time for the abomasum to return to its normal position. During this process, splashing and gurgling sounds can be heard coming from the abdomen as the abomasum moves. The animal is then allowed to rise. The left flank is then auscultated to ensure the abomasum is still not present in the LDA position.

One variation of this procedure reported to be successful by one UK practitioner (B. Jeffrey, pers. comm.) is to cast the cow into left-sided lateral recumbency and restrain the animal in this position for 30 minutes. The gas present in the abomasum allows the organ to 'float' back to its normal position.

It is essential if the LDA has been corrected by rolling that the animal is re-examined 48 hours later to ensure that a relapse has not occurred. In the experience of the author, and many others, relapse is to be expected in over 75 per cent of cases of LDA that have been corrected by the rolling technique. Quite frequently if relapse does occur, the signs may not be so severe as those present before the correction and the animal may well complete its lactation, albeit with a reduced total milk yield. In such cases, chronic LDA exists and ulceration of the abomasum with adhesions to the abdominal wall may well develop, thus shortening the productive lifetime of the animal.

The surgical approach to treatment consists of laparotomy, returning the abomasum to the right side of the abdomen and suture fixation of the organ to the abdominal wall. Many different surgical techniques have been described for this procedure but the one favoured by the author is the right flank approach with the animal standing. The animal is starved of water and food for 24 hours prior to surgery to reduce the size of the rumen. Using paravertebral anaesthesia, a 20-cm incision is made in the abdominal wall, starting at the lower limit of the right sublumbar fossa and extending vertically downwards. The left arm then enters the abdominal cavity and moves carefully down the right side of the abdomen, along the floor and up the left side with the hand always in contact with the peritoneum. The hand can then locate the distended abomasum situated high in the left flank between the rumen and the abdominal wall. The hand is then placed over the top of the abomasum and downward pressure exerted. Several attempts at downward pressure may be required to disperse the gas present in the organ. The organ is then pushed down and below the rumen. It is important that contact by the hand is maintained with the abomasum during this stage of the operation because if it is lost it may be difficult to find the abomasum without causing trauma to the small intestines.

When the organ has been brought across to the right side, the pylorus is located and brought to the abdominal wall incision. Using non-absorbable suture material, e.g. monofilament nylon, and a round-bodied needle a suture is placed in the greater curvature of the abomasum close to the pylorus and this is then sutured to the peritoneum and abdomen wall at the base of the incision. The abdominal wall incision is closed in the normal way and postoperative antibiotics administered. Appetite is stimulated by the administration of rumen-stimulant drenches and the animal allowed immediate access to good quality fodder and water. The author has used this technique for over 20 years and on one occasion only has correction not been possible. In this case adhesions were present between the abomasum and the left abdominal wall. A second incision was then made in the left sublumbar fossa, and the adhesions were

broken down revealing a perforated ulcer. The ulcer was excised, sutured using a purse string suture and the abomasum returned to the right flank where an assistant located and sutured it as described above. This right-sided approach has been used widely in the UK and is suitable for operating on the farm.

The right paramedian approach is also widely used. The animal is cast into dorsal recumbency and local anaesthesia administered for an incision posterior to the sternum and midway between the midline and the right subcutaneous abdominal vein. The abomasum is located, returned to its normal position and fixed using catgut or monofilament nylon sutures 2–3 cm from the margin of the incision. This technique does return the abomasum to its normal position, whereas in the former the fixation of the pylorus to the abdominal flank wound results in the abomasum being slightly out of position. In the author's opinion the abomasopexy should be performed with non-absorbable suture material as the few cases that have relapsed following abomasopexy were mostly sutured with catgut.

A modification of the right paramedian approach, the Sterner–Grymer closed suture technique, has been gaining popularity in recent years and with considerable success (Gordon, 2001). The cow is cast onto her right side and rolled into dorsal recumbency, as above, and the hind legs restrained. The abomasum is auscultated by percussion using a stethoscope and should be on the right of the midline. A DA Trochar and Cannula (Kruuse UK Ltd) is inserted firmly through the skin, muscle and peritoneum 10 cm caudal to the xiphoid process, 10 cm to the right of midline and into the abomasum, avoiding the right subcutaneous abdominal vein. The trochar is removed and a toggle attached to a suture (Kruuse UK Ltd) quickly inserted through the cannula. Minimal gas should be released when placing the first suture. The procedure is repeated with a second toggle inserted 5 cm cranial to the first, allowing as much gas as possible to escape from the abomasum to reduce tension on the sutures. The two toggle sutures are tied together and the cow rolled onto her left side and allowed to stand.

Another technique involves a left flank approach, pushing the abomasum back to the right side and then entering the rumen as in a rumenotomy to transfix the rumen to the floor of the abdomen by using a large needle and a long suture. The suture needle is passed vertically down through the rumen wall and abdominal wall to the exterior. The needle is removed from the suture and the procedure repeated with the other end of the suture material and the suture tied as a mattress suture on the exterior of the ventral abdomen. This produces an adhesion between the ventral rumen and the ventral abdomen that will prevent a recurrence of the LDA.

Prevention

Advice on prevention is difficult because the precise nature of the aetiology is unknown. Furthermore, most cases occur only sporadically and it is rare for farms to experience more than one or two cases in a season. If the incidence is higher on a particular farm, attention to the feeding regimens may prove worthwhile. Dry cows should be fed a diet of long fibre and very little concentrates. Dry-cow diets should always contain less than 30 per cent concentrate on a DM basis. Maize silage, which itself contains up to 50 per cent grain on a DM basis, should be restricted to no more than 15 kg/day during the dry period. The change in diets that occur at calving should be made as gradually as possible. Ideally, 2 kg daily of concentrates for the last two weeks of the dry period will help the rumen microflora adjust to the increased concentrate intake that occurs in early lactation. The approach to prevention of LDA is much the same as the approach to the prevention of acetonæmia.

Right-sided abomasal dilatation and torsion

Occurrence

Right-sided abomasal dilatation and torsion occurs much less frequently than LDA in the UK and USA, although it appears to be more common in Denmark. The annual incidence in the UK is of the order of 2–3 per 10 000. It normally occurs in early lactation and rarely in the dry cow, but although predominantly affecting dairy cows it has been reported in bulls, young animals, beef cows and feedlot cattle.

Pathogenesis

As with LDA, the aetiology of RDA is not fully understood but the pathogenesis is probably similar to that of LDA. Atony of the abomasum followed by the accumulation of feed, fluid and gas produces a grossly distended organ. The presence of gravel and sand in the abomasum has commonly been observed in affected animals, which may account for the higher incidence in Denmark, where large quantities of fodder beet are fed that often is contaminated with soil. Torsion is frequently a sequel to the dilatation and this is purely a mechanical effect of the increased weight and size of the dilated organ. The torsion can be in several directions, e.g. the organ may be rotated dorsally 90–180°, or counterclockwise up to 180° as viewed from the rear or the torsion may incorporate the omasum.

Signs

The onset of dilatation is insidious with inappetence, milk yield reduction and varying degrees of ketosis.

Rumination ceases and rumen contractions are weak and infrequent. Faecal quantity is reduced but its consistency is usually diarrhoeic, foul smelling and often contains occult blood. Rectal temperature is normal and heart rate raised to 80–100 beats/minute. Mild colic signs may also be evident and there is often a noticeable distension of the right flank. Once torsion occurs, the signs become peracute. Then there is a subnormal temperature, with a heart rate up to 160/minute, cold extremities and extreme dullness. These signs indicate severe shock and frequently colic may be observed. At this stage the animal is anorexic and the rectum will be empty except for some tar-like mucus.

Diagnosis

Diagnosis should not present any problems if the techniques of percussion and auscultation, ballottement and auscultation and auscultation alone are applied to the right flank in the same way as described for the diagnosis of LDA on the left flank. The same ‘ping’ and tinkling sounds if heard on the right flank will indicate an RDA. Determination of whether torsion exists will rely on the severity of the signs exhibited, e.g. the presence of a very fast heart rate, subnormal temperature, the signs of shock and the consistency of the rectal contents. Rectal palpation may also reveal the presence of a grossly dilated viscus in the right sublumbar region. Differential diagnosis of RDA plus torsion will include all causes of acute abdominal obstruction, particularly caecal dilatation and torsion, torsion of small intestines, intussusception and perforated abomasal ulcer. However, being able to palpate the organ on rectal palpation and hearing the characteristic high-pitched sounds should not cause problems in diagnosis.

Treatment

If torsion is not present there is often a temptation to try conservative treatments using antacids by mouth and spasmolytics, vitamins or antibiotics by injection. This is not to be recommended. Although some cases of dilatation do recover spontaneously, many do not. Many cases will remain dilated and a chronic state of abomasal dilatation develops where the animal loses weight and milk production, and eventually is culled as a ‘poor doer’. Often the dilatation progresses to torsion and surgery to correct abomasal torsion is much less successful than correcting dilatation without torsion. This is because of the severe shock that is induced in the animal by the torsion. The decision on whether to attempt surgery in cases of RDA plus torsion will depend on the degree of shock that exists. In severe cases casualty slaughter should be advised. Recently, successful treatment of dilatation without torsion has been reported using metoclopramide hydrochloride, although not licensed for this purpose.

However, in valuable animals and less severely affected cows, surgery can be successful (p. 1112). Intravenous drip therapy should be set up immediately using Ringer’s solution or isotonic sodium chloride. Cows with RDA plus torsion will be suffering from metabolic alkalosis and will be short of chloride ions. Sodium bicarbonate or sodium lactate should not be used. To restore normal hydration, 40–50 l of electrolyte are likely to be required over a 24-hour period.

Having set up the intravenous drip, surgery should commence immediately. Under paravertebral anaesthesia an incision is made in the right abdominal wall with the animal standing. If the animal cannot stand it is likely her condition is so severe that surgery would not succeed and casualty slaughter should be advised. On entering the abdomen and the abomasum located the first procedure is to deflate the organ using a wide bore (12G) needle and rubber tube. Having deflated the organ the direction of the torsion should be identified and an attempt made to correct the torsion without removing the fluid. If correction of the torsion is not possible then half of the fluid should be siphoned out of the abomasum. This will ease the recognition of the torsion direction and more readily allow repositioning of the abomasum. Abomasopexy is carried out as for LDA correction. The abdomen is closed in the normal way. If RDA exists without torsion the abomasum should be emptied of fluid by siphoning and then the organ opened and all debris, which may include straw or hairballs, stones or gravel, should be removed. The abomasum incision is then closed, the abomasum is returned to its normal position and the abdomen closed in the normal way. Abomasopexy is not normally required in this situation. Fluid therapy is continued until the animal has rehydrated and postoperative antibiotics are administered for five days. Following recovery diarrhoea will be present for two or three days.

Recovery rates of 75–80 per cent are reported by some workers in hospital situations and around 50 per cent when the omasum is involved in the torsion. Recovery rates for on-farm surgery are likely to be lower and this must be appreciated before embarking on surgery in preference to casualty slaughter. The likelihood of recovery will depend on the length of time that elapses from torsion occurring to operation and the level of shock that exists at the time operation commences.

Prevention

Measures to prevent RDA are the same as for LDA (p. 842) but as the condition is relatively rare, specific measures to prevent RDA are academic. If root vegetables are used in large quantities for fodder they should be washed before feeding to remove the soil contamination.

Abomasal ulceration

Ulceration in the form of small multiple ulcers occurs in the abomasal mucosal surface in a number of systemic diseases but these are rarely diagnosed, their presence being masked by the other signs present of the systemic disease.

However, a syndrome of peptic ulceration in adult cattle does occur sporadically and may result in perforation and peritonitis or haemorrhage, which can be mild and recurrent or acute and be a cause of death. The actual incidence of abomasal ulceration is probably much more common than generally realized as many cases are difficult to diagnose and may produce little harmful effect until perforation or haemorrhage occurs. The aetiology is uncertain, but feeding regimens involving a sudden introduction of concentrate feeds are likely to be implicated much the same as in the presumed aetiology of LDA and RDA. The author has experienced three sudden deaths in a herd of 120 dairy cattle that were caused by perforated abomasal ulcers. The abomasum contained large quantities of sand and gravel, which were the result of a depraved appetite. The cows were constantly eating soil, which was later confirmed to be due to hypocuprosis. The aetiology of peptic abomasal ulceration is therefore similar to LDA and RDA and is considered by some workers to be another manifestation of the same syndrome. Certainly, ulcers are found in the abomasum of both LDA and RDA.

The ulcers occur singly or occasionally in twos and threes and vary in size from 2 to 6 cm in diameter. Fungal hyphae are frequently found in the depths of the ulcers, which tend to extend into the submucosal layers until, in some cases, perforation occurs. If the perforation occurs at a point covered by omentum the ulcer may be sealed by omental adhesion. However, if the ulcer perforates at a point lateral to the omental covering, the abomasal contents spill into the peritoneal cavity and death soon follows. Another complication occurs when the ulcer erodes into a blood vessel producing haemorrhage. This may be only temporary and the blood vessel heals, but more often the haemorrhage does not stop and the animal dies from blood loss. This can be a cause of sudden death. The annual incidence for abomasal ulcers with haemorrhage would be in the order of 5–10 per 10000.

Diagnosis

The only occasion where the syndrome can be diagnosed with certainty is when haemorrhage occurs. A cow presented with inappetence, reduced milk yield and passing black tarry faeces, which contain large quantities of occult blood, will almost certainly be suffering from a haemorrhaging abomasal ulcer. Severe cases will be anaemic, the heart rate fast and loud and death can occur within 24 hours. The prognosis in such cases is extremely guarded for, although animals do appear to make a recovery, relapses are common.

The diagnosis of abomasal ulcers with perforation is difficult. The signs are of mild colic and pain in the right ventral abdomen. Confirmation will only come from an exploratory laparotomy. Abomasal ulcers may well be present in many apparently normal cows and undoubtedly many do heal, but the sudden onset of signs associated with acute haemorrhage or perforation would indicate that until such dramatic consequences occur the ulcers may not be harmful.

Treatment

Treatment is purely academic. Ulcers without perforation or haemorrhage are unlikely to be diagnosed. The prognosis in haemorrhaging ulcers is so uncertain that casualty slaughter should be advised. Perforated ulcers, if not sealed with omentum, are usually only discovered at post-mortem examination. Ulcers that have perforated and become sealed with omentum are unlikely to be diagnosed, except on exploratory laparotomy in a cow showing signs of right-sided anterior abdominal pain and when discovered they are probably best left undisturbed.

Prevention:

With the current state of knowledge on aetiology, the best advice on prevention is to follow that for LDA and RDA (p. 842).

Abomasal impaction

Impaction of the abomasum may occur occasionally but is certainly of no great significance in adult cattle. Its annual incidence would be less than 1 per 100 000 and appears to be more common in beef cows than dairy cows as a result of feeding poor quality fibrous material. Cases can be the result of lymphosarcoma (p. 693). The impaction occurs with the accumulation of large quantities of fibrous food, sand or gravel close to the pyloric outlet. The onset is insidious, with a gradual loss in milk production and inappetence. Progressively, rumen impaction occurs, rumination ceases and constipation sets in. Rectal temperature is normal but heart rate will exceed 100/min. At first there is little or no abdominal pain but progressively pain becomes evident in the anterior right ventral abdomen (as distinct from the left anterior abdomen in traumatic reticulitis). Pinching of the withers at this stage may elicit a painful grunt. It is unlikely that a positive diagnosis will be made without recourse to an exploratory laparotomy when an enlarged doughy abomasum will be palpated.

Pinsey (1977) was of the opinion that many cases of abomasal impaction reported in the past may well have been vagus indigestion as workers reported enlargement of the fundus of the abomasum, which contained dry rumen contents, and an accumulation of fluid within the rumen.

However, if such a case is encountered at exploratory laparotomy, abomasotomy and removal of the offending contents can be attempted.

Abomasal impaction in calves

Abomasal impaction does appear to be more common in calves than adult cattle. Calves from three weeks to three months can be affected, although six to ten weeks is the most common period. Depraved appetite, causing the calves to eat bedding and lick hair, is thought to be the cause. Finely ground grains made into pellets have also been incriminated in the aetiology, presumably the result of rapid fermentation. Coarse ration where the grain ingredients are rolled or cracked is preferred to pellets by many calf rearers because fewer 'digestive upsets' appear to occur.

Diagnosis

Affected calves usually have a brown, mild diarrhoea and normal rectal temperature. The most striking feature is the result of ballottement of the lower right abdomen, which will reveal loud splashing noises over a large area, usually indicating an enlarged abomasum containing excess fluid.

Treatment

Treatment using antacids such as magnesium hydroxide or magnesium carbonate or mild laxatives such as liquid paraffin or linseed oil may be helpful. In early cases surgical interference to empty the abomasum can be effective. It is interesting to note that the abomasum of veal calves slaughtered at 14–16 weeks old and reared solely on liquid milk substitute diets frequently contains one or several hairballs many up to 20cm in diameter without abomasal ulceration or any abnormal effects being noticed before slaughter.

Colic and acute intestinal obstruction

Colic signs are frequently reported in adult cattle. They may indicate a tympanic intestinal colic or they may signal some more serious problem. This section will discuss the differential diagnosis of colic signs and will describe in detail: tympanic intestinal colic, intussusception, caecal dilatation and torsion, prolapse of small intestine through a ruptured mesentery and torsion of small intestine around the root of the mesentery.

Occurrence

Colic is a sporadic condition affecting only individual animals, it being extremely rare for more than one animal to be affected at any one time. Signs of colic are reported quite frequently in all ages of cattle and under all types

of management, whether extensive or intensive. A thorough clinical examination will be required to differentiate the many problems that produce colic. By far the most common cause of colic is tympanic intestinal colic, which is very similar to the syndrome so frequently seen in the horse. Intussusception, caecal dilatation and prolapse of the small intestine through the mesentery are much less common and in the UK each would have an annual incidence of less than 1 per 10000.

Signs

The clinical signs of colic in cattle are firstly reduced appetite or even anorexia, reduced milk yield and a noticeable change in behaviour – kicking at the ventral abdomen, shifting weight from one hind foot to the other, licking at the flank or chest wall, frequently lying down and then standing and generally restless. The intensity of the signs exhibited will vary with the degree of pain. On some occasions the signs are quite mild, with only occasional kicking at the ventral abdomen, and may be missed by all but the most astute stockworker. The above signs are all indicative of pain, but not necessarily abdominal pain. Conditions that will produce similar signs include photosensitization (p. 884), particularly if the teats are affected, strangulated scrotal hernia, uterine torsion, urolithiasis (p. 263) and ureter obstruction.

Diagnosis

The diagnosis of the cause of the signs of colic will include a thorough clinical examination. The rectal temperature may be raised, the pulse will certainly be increased and the more acute the problem, the faster and weaker will be the pulse. Abdominal sounds may be present or absent. In intestinal obstruction the sounds will be absent. The mucous membranes will be injected in acute problems and the eyes sunken. Ballottement of the ventral abdomen should always be performed and may reveal splashing fluid sounds. A rectal examination should also be performed. In intestinal obstruction the rectum will be empty and sticky. Enlarged viscera or abnormal positioning of the viscera may be palpated on rectal palpation. A detailed description of the use of rectal palpation in the diagnosis of abdominal disorders has been recorded by Stober and Dirkson (1977).

In many cases of intestinal obstruction diagnosis may only be confirmed on exploratory laparotomy. Exploratory laparotomy as a diagnostic procedure as opposed to its use solely as a surgical treatment is to be recommended (Pinsent, 1978) where the attitude of the farmer and conditions conducive to surgery exist. Many farmers, with their increased education and training, will understand the value of an exploratory laparotomy if the problem is fully explained. Furthermore, exploratory laparotomy may well reveal the cause of acute intestinal obstruction and allow surgical correction and recovery

to take place, whereas if surgical intervention is unnecessarily delayed the likelihood of recovery is always reduced. The author has, on two occasions, performed an exploratory laparotomy where an unknown intestinal obstruction was thought to exist to find that on both occasions a thin fibrous strand or adhesion was present in the abdomen and a loop of small intestine had become entwined around the strand, thus causing the obstruction. Severing the strand released the bowel and in both cases the animal made an uneventful recovery.

Tympanic intestinal colic

Tympanic intestinal colic is by far the most common condition to produce colic signs. It can occur at any age and calves are presented with colic signs as frequently as adult animals. The signs are of sudden onset, but in lactating cows they are frequently observed at milking time and in calves during or just after feeding.

Diagnosis

As all the usual colic signs are present the clinical examination will reveal normal rectal temperature, raised heart rate (80–90/minute) and normal mucous membranes. Abdominal sounds will be present, sometimes at an increased intensity. Rectal examination will reveal faeces in the rectum and it is unlikely that any abnormality to the viscera will be palpated. It is important to ensure that the differential diagnoses mentioned above are not present. Uterine torsion will only be present in late pregnancy but photosensitization is fairly common (5–10 per 10000) and must be eliminated from the diagnosis by careful examination and palpation of any white areas of skin.

In the calf, abdominal palpation should be performed, as intussusception (p. 847) is relatively common and can sometimes be palpated. The diagnosis will be confirmed by response to treatment or spontaneous recovery within 24 hours.

Treatment

The most effective treatment is the intravenous administration of a spasmolytic such as hyoscine-*N*-butylbromide and dipyrone or butylscopolamine bromide and metamizole. Oral treatment with mild purgatives, such as linseed oil or liquid paraffin, has been used in the past but these are unnecessary and not as effective as spasmolytics and may well be contraindicated.

Torsion of intestines (red gut in calves)

Torsion of the intestines around the root of the mesentery is extremely rare in adult cattle (1 per 10000), but has been reported to occur spontaneously and the cause is unknown. It has also been reported to occur follow-

ing rolling of cows to correct uterine torsion or left displacement of the abomasum. The entire small intestine twists up to 360° around the root of the mesentery.

In calves, the condition is more common and is known as red gut and is associated with the feeding of milk substitutes. It appears to have increased in incidence in recent years and is more commonly seen in loose-housed, machine-fed, calf rearing systems, where the intake of milk is uncontrolled and can be quite excessive. Although the aetiology is uncertain, the pathogenesis is thought to be the rapid fermentation of lactose in the ileum, which leads to gas production and gross dilatation of the intestine, which then twists at the mesentery root. Affected calves are normally three to six weeks old and are presented showing severe colic signs with death following within 12 hours. It can also be a cause of sudden death. Diagnosis is rare in the live animal, mainly because of the rapid progression of the disease and it is not possible to differentiate it from tympanic intestinal colic.

At post mortem the findings are quite dramatic. The small intestines are grossly dilated with gas, are a bright-red colour and the whole of the intestinal mucosa is bright red. To detect the torsion, the post mortem must be performed with care because if the abdomen is fully opened and the intestine allowed to spill out, the torsion will untwist and therefore not be detectable.

In adult cows the presenting signs of intestinal torsion are those of severe colic. Rectal temperature may be raised, the pulse weak and fast, mucous membranes are injected and the eyes sunken. Rectal examination will usually reveal multiple gas-distended loops of small intestine in the right side of the abdomen and these may distend into the pelvic cavity. The site of the mesentery twist will normally be beyond reach, but tense strands of mesentery may be palpable.

Treatment

Immediate surgery is indicated. Laparotomy is performed under paravertebral anaesthesia in the right sublumbar fossa. Loops of distended bowel may protrude through the abdominal incision. The root of the mesentery will be located in the region of the left kidney and the direction of the twist should be determined. The torsion is corrected by manipulation of the intestines, some of which will need to be exteriorized to allow room in the abdomen to correct the twist. This surgery is certainly of a heroic nature, but nevertheless can succeed if the animal is not too severely shocked when the operation commences. Follow-up treatment with intravenous fluids and antibiotics should always be administered.

Prolapse of intestines through mesentery

This condition is usually only seen in adult cattle and is more common than torsion at the mesentery root. Its

annual incidence is still only approximately 1 per 10000. The acute nature of the signs is identical to torsion at the mesentery root and rectal palpation will reveal gas-distended loops of small intestine, which make it clinically indistinguishable. If untreated, death will occur within 12 hours.

Treatment (see p. 1113)

Immediate exploratory laparotomy will reveal the grossly gas-distended intestine, but it may be difficult to distinguish from torsion of the intestines. Palpation of the root of the mesentery must be performed first to distinguish the condition from torsion. One clue to the problem being one of prolapse of intestine through mesentery will be the presence of normal intestine. Palpation of the gas-distended intestine will reveal that it is protruding through a hole in the mesentery. The hole must first be enlarged and the intestines slowly fed back through the aperture, after which the mesenteric rupture is sutured. It must be emphasized that surgery should only be contemplated if the animal is not too severely shocked. As death can occur quickly with this condition, casualty slaughter is commonly advised.

Caecal dilatation and torsion

Caecal dilatation is a distinct clinical entity in adult cattle. Its occurrence is sporadic (approximately 1–2 per 10000) and usually occurs in early lactation, although the condition has been reported in bulls. The aetiology is thought to be related to high levels of volatile fatty acids in the caecum, which originate from the rumen or from fermentation of undigested starch in the caecum. The fatty acids cause atony of the caecum and the gas accumulates. Mild dilatation probably causes no signs, but severe dilatation will produce typical colic signs. However, many cases of caecal dilatation progress to caecal torsion. Strictly speaking this is not a torsion but due to the gross size of the dilated caecum and the large quantity of fluid it contains, the distal end falls forward producing a kink in the organ. Occasionally, the weight of the distended caecum produces a torsion at the mesentery root and the colon, caecum and small intestine are involved in a torsion rather similar to the torsion of the small intestines at the mesentery root.

Diagnosis

Diagnosis is based on the presence of the signs of colic, although sometimes the colic signs are quite mild. Ballottement of the right flank will elicit copious splashing and fluid sounds and the right flank may be noticeably distended. Rectal examination will reveal an empty rectum and if a reliable history is available the animal will not have passed any faeces for 24 hours or more.

Usually, the dilated caecum will be palpable at the entrance to the pelvic cavity and many even protrude into the pelvic cavity. If the caecum has 'kinked' rectal exploration of the abdominal cavity will be required to detect the dilated organ.

Treatment

Successful treatment using butylscopolamine bromide and metamizole (Buscopan) has been reported in cases of dilatation where torsion is absent. It would be wise to monitor the effect of treatment by rectal examination at 6-hourly intervals so that surgical intervention can be instigated if there is no response or torsion occurs. If medical treatment fails or torsion occurs, surgical intervention should always be considered in an animal that is not too shocked and where the condition has not been present for too long.

A right-flank laparotomy is performed and, on exploration, the grossly enlarged caecum can be detected. Palpation of the root of the mesentery should be carried out to try and determine whether torsion exists.

The first stage of the operation is to siphon off the fluid present in the caecum, thus reducing its volume to a manageable size. It is possible in some cases to siphon off 30–40 l of dark, foul-smelling fluid. When as much fluid and gas as possible have been removed a purse-string suture is used to repair the incision through which the siphon tube was inserted and an attempt is made to relocate the caecum back to its normal position. If the caecum is kinked or twisted, removal of the fluid may well allow the torsion to correct itself. The laparotomy is closed in the normal way. Postoperative treatment is usual with fluid therapy if dehydration is evident and antibiotics to prevent peritonitis developing. This can be a rewarding operation and most animals make an uneventful recovery.

Intussusception (see p. 1114)

Intussusception or telescoping of the bowel occurs in adult cattle and calves. The annual incidence in adult cattle is around 1 or 2 per 10000, but may be more common in calves. The condition is caused by strong peristaltic movements of the intestine and either the small intestine telescopes into small intestine or occasionally through the ileo-caecal valve into the caecum. In calves the condition is usually a sequel to profuse diarrhoea, but this appears not necessarily to be the case in adult cattle. Some workers have suggested that a tumour or inflammatory growth in the lumen of the affected part may be a causative factor in adult cattle.

Signs

When the intussusception first occurs there will be mild signs of colic. These signs frequently go unnoticed by

the stockworker or if they are seen they are discounted because they do not last for long and the animal makes an apparent recovery. Two to three days later the animal's milk production declines, inappetence sets in and the astute stockworker may notice the animal to be constipated. This is the most frequent time veterinary attention is sought.

Examination will reveal a normal rectal temperature, the heart rate raised to 80–120/minute and auscultation will reveal bowel stasis. A rectal examination will reveal an empty rectum or the presence of scanty bloodstained faeces or thickened mucus. On questioning, the stockworker may admit that colic signs were evident two to three days earlier.

Diagnosis

In many cases rectal palpation will reveal a hard, sausage-shaped mass in the right abdomen. The absence of any dilated organ and complete bowel stasis will indicate a strong likelihood that an intussusception is present, even if it cannot be palpated, although simple rumen indigestion may be difficult to differentiate. Palpation of the offending intussusception may be made easier if the floor of the abdomen is raised using a pole under the ventral abdomen and lifted by two persons. The course of this disease is not as acute as other causes of intestinal obstructions; thus if the clinician is not certain of the diagnosis, mild purgatives such as liquid paraffin or linseed oil may be administered orally and the case re-assessed 24 hours later. These will do no harm if an intussusception exists and, if the problem is one of indigestion, faeces will be passed within 24 hours. It is important to instruct the stockworker to isolate the animal in a clean pen for this period so that any faeces voided will be observed. One of many problems with loose-housing systems is that accurate history of whether an animal is eating forage, defecating or urinating is frequently unavailable.

If no faeces have been voided in the 24 hours of isolation an exploratory laparotomy must be contemplated.

Treatment

An exploratory laparotomy in the right sublumbar fossa should be carried out if the farmer is willing. Failing this, casualty slaughter should be performed. Exploration of the abdominal cavity will reveal the hard mass of the intussusception, although when it is exteriorized it may not be recognizable as such. It may appear more like a bloodstained tumour. Normal gut should be identified entering and leaving the mass, which should then be surgically removed and intestinal anastomosis performed. If the mass is recognizable as an intussusception, as may be the case if diagnosis was

prompt, on no account should an attempt be made to unravel the intussusception. Although this may well be possible, the offending length of gut must be considered to be diseased because it will certainly re-form as an intussusception within 24 hours of correction. Some workers have suggested that if intussusceptions are not removed surgically, but conservative treatment principles applied, the necrotic tissues of the intussusception will slough out in 10–14 days and the animal will recover. This approach to treatment is not to be recommended because, in the author's experience, animals that are not treated surgically will die.

The intestinal anastomosis does require some surgical skill but should not be beyond the majority of large animal surgeons. The technique has been performed quite satisfactorily on the farm.

Intussusception in calves

In calves intussusception is a sequel to acute diarrhoea. Signs of colic will be present in the initial stages of the disease, but frequently the animal is presented because it is not defecating or is collapsed. Occasionally, the intussusception can be palpated through the abdominal wall and if the calf is not in an advanced state of shock an exploratory laparotomy may be considered and the offending lesion removed surgically and intestinal anastomosis performed. Unfortunately, in calves the condition is most commonly encountered at post mortem.

Diaphragmatic hernia

Diaphragmatic hernia has occasionally been reported in cattle but the condition is rarely diagnosed and the incidence is probably less than 1 per 100 000 per year. Diaphragmatic hernia can be a congenital or acquired defect of the diaphragm with partial or complete entry of abdominal organs (usually the reticulum) into the thoracic cavity. Congenital defects usually manifest before the animal is 12 months old and acquired defects are usually a sequel to traumatic reticulitis or trauma in adult cattle.

The most commonly prolapsed organ seems to be the reticulum and the result is interference with the motility and function of the rumen and reticulum. Colic signs will be noticed at the time of the rupture but they do not persist. Signs similar to vagus indigestion may be apparent, although low-grade pain in the posterior thorax/anterior abdomen region, rather like traumatic reticulitis, has been noticed. Respiratory signs may be apparent due to reduced thoracic space. A definitive diagnosis is unlikely to be made without recourse to an exploratory laparotomy, although radiography may be useful.

Successful response to surgical correction has been reported, particularly in Indian buffalo, although this

is only likely to be successful with relatively small ruptures and in cases where the vagus nerve is not damaged. The cow is positioned in dorsal recumbency and the incision made in the xiphoid area. Having retrieved the reticulum from the thoracic cavity the hernia is repaired with monofilament nylon or by the use of a fine nylon mesh.

Fat necrosis (lipomatosis, peritoneal fat necrosis)

Lipomatosis or peritoneal fat necrosis occurs sporadically (annual incidence 1–5 per 100 000) in old cows with a suggested predisposition towards Channel Island and Aberdeen Angus breeds. Affected cows may not present any signs and the condition is detected at routine rectal examination. Advanced cases of the condition will show signs of weight loss, underperformance and inappetence. The diagnosis will be based on rectal palpation findings when large hard masses can be palpated in the abdominal cavity. Occasionally, fat in the pelvic canal will be affected and the canal will be almost completely occluded and it is nearly impossible to carry out rectal palpation because of lack of space.

There is no treatment and slaughter should be advised. On post mortem as much as 20–25 kg of hard necrotic fat may be present in the omentum and mesentery.

Peritonitis (see also p. 141)

Peritonitis is a local or general, acute or chronic, inflammation of the peritoneal cavity. Peritonitis usually occurs as an accompanying condition of other specific diseases, e.g. traumatic reticulo-peritonitis (p. 837) or metritis (pp. 519, 521). The most common cause of peritonitis is traumatic reticulitis followed by peritonitis as a sequel to metritis, dystokia or retained afterbirth. However, peritonitis may be a sequel to abdominal surgery, a ruptured abomasal or intestinal ulcer, penetration of the intestinal tract by foreign bodies, pancreatic necrosis, rupture of biliary or urinary tracts, an infected umbilicus in calves, rupture of the rectum, uterus or large intestine, tuberculosis, liver abscesses and chronic right- or left-sided displacement of the abomasum. Peritonitis can also be associated with septicaemic conditions such as anthrax and calf septicaemia.

Signs

The clinical signs include a raised rectal temperature, which is frequently in the range 39–40°C (102.5–104°F), respiration is frequently shallow and pulse and respiratory rates are increased. The back is moderately arched,

there is a reluctance to move and walking sometimes instigates grunting. Appetite and milk production are invariably depressed and rumination ceases.

Diagnosis

The diagnosis of peritonitis can be difficult and is based on the history and clinical findings. However, the condition should be suspected in all cows that are presented with the above clinical signs and a thorough examination may reveal which organ is responsible. Ballottement of the lower right flank may reveal splashing sounds, indicating the presence of fluid in the peritoneum, and also may cause the animal to grunt. For a more detailed description of the diagnosis of traumatic reticulo-peritonitis see p. 837. The history may also be helpful in arriving at a diagnosis, e.g. recent dystokia or abdominal surgery. If metritis is suspected, a rectal or vaginal examination will aid the diagnosis. Abdominal paracentesis should reveal the presence of peritoneal fluid, which will be foul smelling and contain a large number of white blood cells.

The severity and extent of the peritonitis are usually reflected in the severity of the clinical signs. If the peritonitis is generalized and acute, the animal groans on expiration. When only a limited area of the peritoneum is involved, as in traumatic reticulo-peritonitis, pain will only be evident when the exact location is percussed.

It is important to attempt to determine the cause of the peritonitis in order to give an accurate prognosis and to determine the line of treatment that should be followed.

Prognosis

Localized peritonitis has a favourable prognosis, providing the offending organ can be identified and corrective action taken. However, in acute generalized peritonitis the prognosis can be poor, particularly if the peritonitis is a sequel to abdominal surgery, dystokia or a ruptured abdominal viscus. The prognosis will be related to the severity of the clinical signs, the degree of depression, the weakness of the pulse and the extent of the signs of toxæmia.

Treatment

Treatment may first be directed to correction of the initial problem. However, the peritonitis itself will be treated with large doses of antibiotics administered intraperitoneally, intravenously and intramuscularly. An initial dose of 5 g of benzylpenicillin and 5 g of dihydrostreptomycin is administered into the peritoneum via the right sublumbar fossa, using a 2-inch 16-gauge needle followed immediately by 5 g of procaine penicillin G and 5 g of dihydrostreptomycin by intramuscu-

lar injection and every 12 hours for three to five days. Some workers have reported success using heparin by intramuscular injection at a dose of 50000iu twice daily for three days in addition to antibiotic therapy (Breukink, 1980). The author can report successful treatment using intraperitoneal injections of metronidazole (10g daily for 3–5 days). However, metronidazole cannot now be used on animals intended for human consumption.

Diarrhoea

Diarrhoea in adult cattle is a frequent sign and is present in many diseases. It may occur sporadically, affecting only individual animals, or it may be present in a large number if not the whole of the group. If the whole group is affected, one must consider the feed or the possible presence of a virus infection as in winter dysentery. Blood may be present, in which case dysentery is used to describe the sign. The diarrhoea may be very watery or even projectile as in redwater (pipe stem diarrhoea). The colour and odour may be distinctive. Dark, foul-smelling, liquid faeces would indicate the presence of occult blood and haemorrhage in the upper small intestine. Pale, pasty-coloured faeces may indicate rumen acidosis. Diarrhoea with air bubbles is frequently attributed to Johne's disease. Endotoxaemia from a coliform mastitis or metritis will produce dark, watery faeces. Infections with agents such as *Campylobacter* spp. or BVD/mucosal disease virus will also produce diarrhoea and *Salmonella* spp. often produce dysentery. Intestinal parasitism will produce diarrhoea of varying intensity depending on the severity of the problem, although this more commonly affects growing cattle than adults.

Non-inflammatory diseases, e.g. cardiac failure, lymphosarcoma and systemic amyloidosis, also produce diarrhoea by increasing intestinal secretion into the bowel lumen.

The clinician is frequently presented with an adult bovine where the only sign is an afebrile diarrhoea. Clinical examination may reveal sluggish rumen movements but no other signs of indigestion or of abomasal disease. Many of these cases will be the result of ingestion of toxic plants if the cattle are grazing or being fed conserved fodder and frequently the cause may be a small batch of soiled or spoiled silage.

Some cows with such acute diarrhoea die rapidly and post-mortem examination reveals a severe enteritis, frequently haemorrhagic, but the examination for infections or parasite counts proves unrewarding. One usually assumes that the cause of death is poisoning but frequently the toxic agent is not discovered. When presented with individual cows showing diarrhoea and no

systemic disease or other signs present, the cow must be removed from its present food source, isolated and given only dry feed, such as hay, to eat. Treatment with antibiotics such as streptomycin may be instituted, although the efficacy in these situations is not proven. Spasmolytics may help and oral therapy with gut sedatives such as chlorodyne or adsorbents such as kaolin are frequently used but again their efficacy is not proven. The addition of glycine/electrolytes to the drinking water has more recently been suggested, but in cases where severe dehydration is present intravenous administration of 20–40l of balanced electrolytes is indicated.

If the whole herd or group is affected, one must remember that lush spring grass will produce diarrhoea as will wet autumn grass in the UK. Wet grass silage will also produce fluid faeces. In some areas of the UK and in other countries molybdenum toxicity is common, e.g. on the so-called teart pastures of Somerset, and this will produce severe diarrhoea in the whole grazing herd but can be corrected by the administration of copper in the form of copper sulphate to the diets.

An infectious cause of a whole group of cattle to be affected with diarrhoea is winter dysentery (see p. 852); infection with *Salmonella typhimurium*, *S. montevideo* or *S. goldcoast* may spread rapidly through a herd but the animals will also be pyrexic.

Thus diarrhoea is a sign of many disease conditions of cattle but frequently enteritis will occur in individual animals and the cause will remain undetermined. There remains a challenge for the bovine practitioner.

Salmonellosis

Infection of adult cattle with a variety of *Salmonella* spp. is frequently encountered in cattle practice (see Chapter 15). In the UK as many as 100–200 herds per 10000 may suffer the disease each year where it affects a considerable proportion of the herd. The incidence of sporadic salmonellosis, where only one or two animals in the herd are affected, may be as high as 500–1000 per 10000 herds. These sporadic occurrences are usually abortions due to *S. dublin*. A variety of *Salmonella* spp. have been known to affect cattle but the two most prominent are *S. dublin* and *S. typhimurium*. *Salmonella newport*, *S. montevideo* and *S. goldcoast* are less frequently reported and sporadic outbreaks with other species occasionally occur. The most serious problems are associated with enteritis and septicaemia, but sporadic outbreaks of abortion with no concurrent septicaemia or enteritis are frequently encountered due to *S. dublin*. Epidemiologically, abortion appears different from the enteritis and septicaemia syndrome and will be dealt with separately (p. 582).

Epidemiology and aetiology

The aetiological agents *S. typhimurium* and *S. dublin* are those most frequently encountered although other species are reported sporadically. The epidemiology of *S. dublin* appears to differ from that of *S. typhimurium*. It has been known for some time that to establish *S. dublin* carrier status in the adult cow there needs to be damage to the liver and/or bile ducts. The most frequent cause of liver damage is liver fluke and in areas where liver fluke is endemic, the incidence of *S. dublin* enteritis is more common. The source of infection for *S. dublin* is therefore carrier cows, most of which are suffering liver damage from liver fluke and if liver fluke is endemic in a herd, *S. dublin* may spread rapidly. In areas where *S. dublin* infection is unusually high, the organism can frequently be isolated from rivers, streams and ditches. It is difficult to postulate the role this contamination has in the spread of the infection as one would expect the watercourses to be infected if carrier cows exist in the area.

The carrier status probably also exists with *S. typhimurium*, but this is much less common than with *S. dublin*. The majority of *S. typhimurium* outbreaks in adult cattle are of sudden onset and indicate a recent introduction of the infection into the herd. The most common source of infection is probably purchased contaminated compound feeds. These feeds often used to contain processed animal protein, which was frequently infected with *Salmonella* spp. Cross-infection to cereals also occurs when common storage bins and mixing equipment are used. Cross-contamination of animal feeds may also be caused by wild birds or rodents that may live in animal feed production premises. A further source of infection for *S. typhimurium* is rivers or streams. In many rural areas public sewerage facilities do not exist and septic tanks or cesspits are used. If these do not function satisfactorily, raw or part-treated sewage finds its way into rivers. Human infection has also been the cause of infection when cattle have grazed fields in which human defecation is known to have occurred or fields that are situated next to lay-bys on busy main roads.

On occasions cows have been shown to be excreting *S. typhimurium* but yet not show signs of disease, i.e. they are carrier cows. The presence of a carrier cow within a herd may go undetected and no problem exists with the rest of the herd. The reason why the infection does not spread in these situations is not clear. It may be that a minimum infective dose is required to establish disease or the immune system of the animals may be depressed with a virus infection spreading within the herd and this allows *Salmonella* infection to develop into disease.

Signs

The principal signs produced by *Salmonella* infections are acute enteritis and septicaemia with a sudden onset of severe diarrhoea or dysentery. Frequently, the mucous membrane lining of the small intestine is passed with the faeces and, occasionally, blood clots are present.

The rectal temperature is 40.5–41.5°C (105–107°F) and the cow is severely depressed. The severity of the signs varies considerably. If the disease occurs at or near parturition, septicaemia sets in and mortality may be as high as 20 per cent of affected animals, particularly with *S. dublin* infections. *Salmonella typhimurium* produces morbidity varying from 10 to 70 per cent of the herd however mortality is generally not high, although it will be higher if infection occurs at or around calving.

If infection with *S. typhimurium* or *S. dublin* occurs during late pregnancy, seriously affected animals will frequently abort. This is probably a result of the fever and septicaemia rather than the infection directly affecting the fetus or placenta. *Salmonella dublin* will cause abortion without enteritis and septicaemia being present but the epidemiology and pathogenesis is different. This will be discussed under *Salmonella dublin* abortion (see p. 582). Animals that abort following septicaemia and enteritis frequently develop acute septic metritis and peritonitis and frequently die.

Diagnosis

The diagnosis is confirmed by the isolation of *Salmonella* spp. from faeces of affected animals. The faeces of all cattle presented with acute enteritis accompanied with fever should be sampled and tested for *Salmonella* spp. by bacteriological isolation. Affected animals should be kept in isolation until the result is known.

Treatment

Antibiotics administered parenterally are used for the treatment of salmonellosis. Due to resistance to some antibiotics an *in vitro* antibiotic sensitivity test should be performed as soon as possible. Resistance to penicillin, streptomycin, the tetracyclines and ampicillin is widespread with *S. typhimurium*. Neomycin and framycetin are frequently effective and resistance to chloramphenicol and gentamicin is rare. The combination of trimethoprim and sulphadiazine is also frequently used. There is always some controversy regarding the use of antibiotics in treating salmonellosis in adult cattle. Septicaemic cases and complications following abortion should always be treated with antibiotics. However, in a herd outbreak, some animals will be less severely affected than others and will recover spontaneously without the use of antibiotics. Antibiotic therapy will need to be administered for three to five days.

Oral rehydration therapy is indicated where dehydration is evident and if the dehydration is severe, intravenous administration of 30 l of balanced electrolyte solution will prove to be a valuable support to antibiotic therapy. Recovery time can be quite variable. Cattle with mild enteritis will recover within two days, whereas severe septicaemic cases may take one to two weeks to recover their previous appetite and will not normally return to previous levels of milk production.

Control

Once the diagnosis has been confirmed, it is important to limit the spread within the herd. Isolation of affected animals will help but by the time cows are identified with enteritis, *Salmonella* organisms will be isolated from any site on the farm frequented by the cattle. Vaccination of non-affected animals should be considered. In the UK the live vaccine prepared from an avirulent strain of *S. dublin* is no longer available. A dead vaccine prepared from formalin-killed cells of *S. dublin* and *S. typhimurium* (Bovivac S, Intervet Ltd) is available and has been used to control outbreaks of *S. dublin* or *S. typhimurium*. The whole herd should be vaccinated with two doses 21 days apart and booster injections administered two to three weeks before calving to boost the passive immunity available to the calves. If exotic *Salmonella* species are identified consideration should be given to the use of autogenous vaccines using the same protocol as stated above. Control measures should also include monitoring the environment, including the wildlife, and husbandry measures put in place to reduce the risk of spreading infection. Cattle slurry should only be applied on land to be ploughed or on grass for conservation at least three to four months before the grass is cut.

If *S. dublin* is identified as the causal organism, a representative number of faeces samples (usually six to twelve) should be examined for the presence of liver fluke ova and if positive the herd should receive appropriate anthelmintic therapy.

It is essential when salmonellosis occurs on a farm that the utmost care should be taken regarding personal hygiene. All the staff should be made aware of the zoonotic implications and should not consume farm milk during the course of an outbreak. In the UK, *Salmonella* isolation must be reported to the relevant departments of agriculture, who monitor the infection nationally. Very little action is taken against the farmer unless there is a perceived human health risk, e.g. fresh milk is being used for yoghurt, cream or cottage cheese production, in which case the public health authorities may insist on pasteurization of the milk prior to processing. The question is frequently asked: should recovered cases be kept and will they become permanent carriers? Practice experience would indicate that in the

majority of outbreaks of *S. typhimurium* the problem rarely recurs. It is only very occasionally that a herd may become chronically infected and sporadic cases will continue to occur. More usually the infection is confined to the calves in endemically infected herds. In the case of *S. dublin* enteritis the main thrust in control following vaccination is to control liver fluke in the herd. If this is successfully achieved, enteritis caused by *S. dublin* will be infrequent.

Attempts to identify carrier cows within endemically infected herds are sometimes recommended. This is achieved by faeces sampling the entire herd and culturing the samples for *Salmonella* spp. Unfortunately, *Salmonella* spp. are excreted intermittently in carrier cows and animals need to be sampled on several occasions, probably as many as six or seven, to be reasonably certain all carrier cows are identified. This procedure has proved to be neither practical nor necessary in most outbreaks.

Prevention

To prevent infection with *S. typhimurium* may be difficult because of the frequency in which it is found in animal feeds. Contamination of feed can also be caused by rodents and birds. However, legislation has been implemented in the UK to supervise all protein processing plants and to ensure the protein material is sterilized. In recent years infections entering the herd via purchased feeds have become less frequent.

Preventing infection spreading from the human population to cattle can be achieved to some extent by the supply of clean wholesome water for cattle to drink. For the effective control of a variety of infections cattle should not be allowed to drink from natural watercourses. Effective fencing of fields may also be required, particularly alongside main roads and lay-bys to prevent humans using grazing fields as a lavatory.

Winter dysentery

As the name implies, winter dysentery occurs during the period of winter housing and affects cattle of all ages. It is obviously an extremely infectious disease because when it enters a herd it rapidly spreads through all animals in the herd. Also, once infected and the animals have recovered, the herd will not usually experience the problem for four or five years, thus indicating development of a herd immunity.

Moreover, once one herd in an area becomes infected, it appears to spread rapidly to other herds nearby. Perhaps this is a disease that can be spread by veterinary surgeons! However, it is interesting that there has been very little mention of its occurrence in the UK during the last 15–20 years, whereas during the late 1950s and early 1960s it was frequently encountered. It has been reported to be present in several

countries in Europe and the northern States of the USA and Canada have experienced large outbreaks in past years. Although the morbidity is almost 100 per cent, mortality is normally absent. Milk production, however, may be reduced by up to 50 per cent and take up to two weeks to recover and so it is of economic importance.

Aetiology

Campylobacter fetus var. *jejuni* was once thought to be the causative organism. But the speed of spread, the short incubation period of around three days and the inability to reproduce the disease using cultures of *C. jejuni* lead one to suspect the aetiological agent is a virus, which to date has not been identified. However, coronaviruses have been encountered in several outbreaks and are now often considered to be involved in the causation of some outbreaks.

Signs

The main sign is of a severe, watery, dark brown diarrhoea with a foul-smelling odour. The faeces may be tinged with blood. The diarrhoea is sometimes described as explosive or projectile. At first only one or two cows in the herd are affected, but within three or four days several cows will show signs and within two weeks all the older cattle on the farm will have become affected. The rectal temperature is usually normal and appetite is reduced in only a small number of more severely affected animals. However, milk yield may be reduced by up to 50 per cent and such animals may show signs of abdominal pain, e.g. colic, arched back or a 'hunched up' appearance may be apparent. The course of the disease in most cows is two to three days.

Diagnosis

The severity and speed of spread of the disease present no real problems in diagnosis except with the initial cases, which may be misdiagnosed as a poisoning (Chapter 54) or non-specific enteritis. Once several cows are affected and the disease is occurring during the housed period, diagnosis is based on the clinical signs present.

Bovine virus diarrhoea would involve fewer animals, which would have pyrexia and characteristic oral lesions. Coccidiosis (see p. 282) normally affects younger animals, but this can be differentiated by the presence of tenesmus and the identification of oocysts in the faeces.

Treatment

Most affected cattle recover spontaneously in two to three days and treatments do not speed recovery.

However, a proportion of the cases are more severely affected and some may become weak enough to become recumbent. Severely dehydrated animals will require intravenous administration of 20–30 l of balanced electrolytes and electrolytes added to the drinking water should prove advantageous. Oral astringents, such as 50 ml of 5 per cent copper sulphate administered every 12 hours, may prove effective. Morphine and chloroform (chlorodyne) reduce intestinal motility and absorbents such as kaolin or bismuth salts have also been recommended. Oral sulphonamides have been reported to be useful by some practitioners.

Prevention

This is an extremely infectious disease and when it occurs in an area cattle or unnecessary personnel should not enter the farm. Veterinary surgeons should take the utmost care in thoroughly disinfecting their boots and protective clothing before entering and leaving farms when this infection is present locally.

Bovine virus diarrhoea/mucosal disease

Bovine virus diarrhoea and mucosal disease are both diseases caused by bovine virus diarrhoea virus (BVDV), which is similar to the viruses causing Border disease in sheep and swine fever in pigs. These three viruses are together classified as pestiviruses within the Flaviviridae. It is worth noting that all three pestiviruses can cross the placenta and damage the fetus.

In 1946, veterinary workers at Cornell demonstrated that a virus was the cause of a transmissible bovine diarrhoea and thereby named BVDV. The virus has since been identified worldwide as a most serious cause of cattle disease, particularly reproductive disease.

Aetiology (Figs 48.1 and 48.2)

Infection with BVD virus is generally a mild or even subclinical event, except on two occasions, i.e. infection of the pregnant animal and in mixed infections, e.g. with other respiratory viruses such as respiratory syncytial virus (RSV), infectious bovine rhinotracheitis virus (IBR) or parainfluenza virus (PI₃). Recently a more virulent BVDV type 2 has been reported in North America.

Many isolates of BVDV occur but all appear to cross-react with convalescent BVDV sera. There are two distinct biological forms of the virus called biotypes, distinguishable in tissue culture, cytopathic and non-cytopathic. This distinction is important in the pathogenesis and understanding of mucosal disease. Cytopathic virus in tissue culture causes severe damage to the cells and complete destruction within 48–72 hours. The non-cytopathic virus causes no cell damage

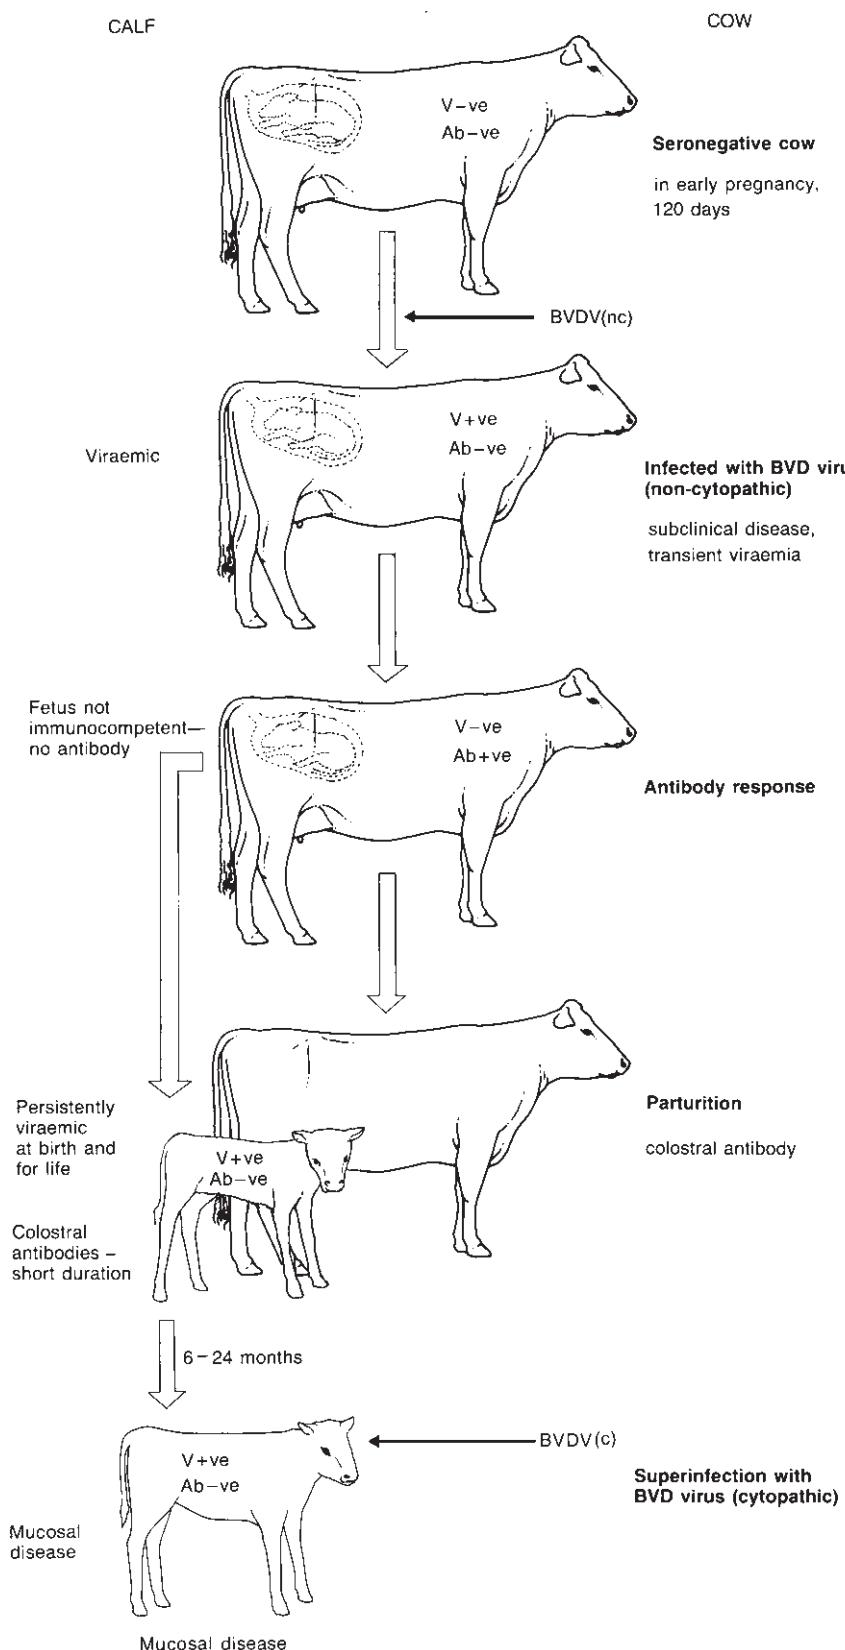

Fig. 48.1 Hypothesis for the aetiology of mucosal disease. V, BVD virus; Ab, antibody to BVD virus; nc, non-cytopathic; c, cytopathic (after Brownlie, 1985).

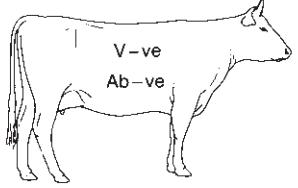

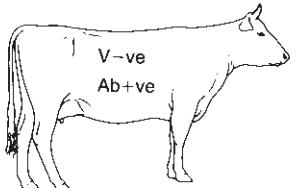

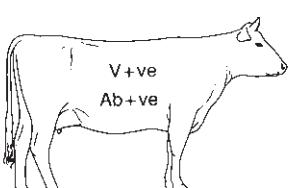

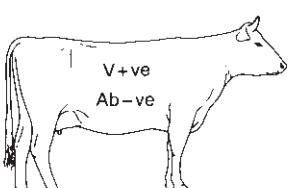

| Category | Animal | Status | Result of exposure to BVD virus | Final antibody status |
|----------|--|---|--|-----------------------|
| 1 |  | No previous exposure to BVD virus | Transient mild infection | + ve |
| 2 |  | Previous exposure to BVD virus from 120 days gestation onwards | Immune | + ve |
| 3 |  | (a) Acute viraemia presently sero-converting (b) Persistently viraemic; occasionally these animals may have low levels of antibody | Will become immune May later succumb to mucosal disease | + ve ± ve |
| 4 |  | (a) Acute viraemia (b) Persistently infected with BVD virus | Will become immune May later succumb to mucosal disease | + ve - ve |

Fig. 48.2 Combinations of BVD virus and antibody in cattle and their significance (after Brownlie, 1985).

and is identified by staining with fluorescein-labelled BVDV antisera.

Non-cytopathic virus is the major biotype that causes disease, whereas cytopathic virus, isolated from field cases of mucosal disease, is usually only found as a superinfection of a pre-existing non-cytopathic virus infection. Bovine virus diarrhoea virus is shed in nasopharyngeal secretions and urine and perhaps by aerosol droplets. Faeces are a poor source of virus.

Pathogenesis

Postnatal infection of the young or growing animal with non-cytopathic virus is usually a subclinical event. In most herds where the virus is present there is no disease-related problem. However, infection of the seronegative pregnant cow prior to 120 days of gestation, before the immune system of the fetus has become fully developed, can result in disease. When the virus has crossed the placenta, the fetus becomes infected

and may result in abortion, mummification or early fetal death. If the fetus survives until neonatal life, it may have developed a state of immune tolerance and then the virus will persist for life. The fetus at birth will be virus positive, but seronegative to the persisting virus. Infection after 120 days will still cause damage to the fetus, but it does not become immunotolerant and viraemic. Such damage would include cerebellar hypoplasia resulting in ataxic calves (see p. 900).

Infertility: Infection of the cow in early pregnancy will cause infertility due to embryo or early fetal death. Evidence of this has been seen in North America, where an infected bull was used on two groups of heifers. One group was seropositive and the other seronegative. The seropositive heifers conceived normally (about 70 per cent pregnancy rate) but the seronegative heifers suffered infertility (in the region of 33 per cent pregnancy rate) that lasted several weeks. These heifers eventually conceived when they had seroconverted some six to eight weeks after the initial infection.

Mixed infections: Bovine virus diarrhoea virus is immunosuppressive. Although infection of calves with BVD virus alone is generally subclinical if RSV, IBR or P13 viruses are also present the pneumonia will be more severe than infection with respiratory viruses alone (see Chapter 17).

Mucosal disease: Mucosal disease occurs as a result of a calf that was born viraemic and seronegative becoming superinfected with cytopathic virus. Mucosal disease is generally sporadic in nature affecting young cattle six to 18 months old. It is usual to find only one, two or three cases occurring on any one farm at the same time; however, larger outbreaks can occur. The disease is characterized by weight loss, severe diarrhoea and inevitably death. Death from mucosal disease usually occurs two to three weeks after infection with cytopathic virus.

Signs

The first signs to appear are anorexia accompanied by reddening and erosions around the dental pad, along the gingival border and under the tongue. These are followed by reddening and erosion around the muzzle. The erosions are shallow, varying sizes and shapes and frequently coalesce. These are to be distinguished from ulcers following vesicular damage, e.g. in foot-and-mouth disease (p. 693) or vesicular stomatitis (p. 710), which are deeper than mucosal disease erosions. Diarrhoea then follows and sometimes lameness may be apparent due to heat and reddening on the coronary band and erosions present in the interdigital space. Because of the sudden onset, diarrhoea is often the first sign that is noticed although salivation is frequently present. The animals are occasionally pyrexic. Weight loss is rapid and death inevitably occurs five to ten days later. Acute infections in adult cows can lead to diarrhoea and agalactia.

Necropsy

The post-mortem findings are usually strongly suggestive of mucosal disease. Oval erosions or shallow ulceration may be seen in the buccal cavity, oesophagus, abomasum, the small intestine beneath the Peyer's patches and in the colon. Oedema and erythema in the intestinal epithelium may also be a feature. The prime sites are the oesophagus, small intestine and abomasum. Care must be exercised in opening the small intestine, which must be opened at the mesenteric attachment in order not to incise through the lesions. Tissue culture can be used to grow virus from all the lesions, as well as from mesenteric lymph nodes, spleen, thymus and tonsil.

Diagnosis

The diagnosis of mucosal disease will be based on the clinical signs and laboratory tests. Pyrexia, diarrhoea, erosions in the mouth and on the muzzle and recent weight loss in an animal six to 18 months old should be highly suggestive of mucosal disease. In the live animal, clotted and EDTA blood samples and a nasopharyngeal swab should be taken and must be submitted to the laboratory within 24 hours for both virus isolation and for BVDV antibodies. It is also helpful to submit fresh spleen, mediastinal lymph node, thymus and small intestinal tissue (particularly with Peyer's patch tissue) for virus isolation. Bulk milk antibody levels can be ascertained.

Differential diagnosis

The main features of mucosal disease are mucosal erosions, diarrhoea and death. Foot-and-mouth disease (p. 693), malignant catarrh (p. 953) and rinderpest (p. 707) are the principal differential diagnoses. With foot-and-mouth disease, morbidity is 100 per cent and vesicles precede the mucosal ulcerations. With malignant catarrh, corneal opacity is a feature; there is also gastroenteritis and enlarged lymph nodes. Lymph node enlargement is not a feature of mucosal disease. Rinderpest has vesicles preceding the erosions, morbidity is high and intestinal oedema and lymph node enlargement are common. *Salmonella* (pp. 225, 850) enteritis should not present a problem with differential diagnosis as it generally affects either young calves or adult animals and there are no mouth lesions. Acorn poisoning can look similar on post mortem, but biochemistry and histology of the kidney should distinguish it from mucosal disease (see p. 951). Other poisoning events may also be considered as a differential diagnosis, but the characteristic oval erosions are generally absent.

Treatment

There is no effective treatment for mucosal disease. If the disease is suspected all efforts should be towards a diagnosis so that effective control measures may be instituted.

Control

When a positive diagnosis has been made, the dam of the affected animal and all the animals in the same group as the affected animal should be blood sampled and the blood cultured for the presence of virus. Persistently viraemic cows invariably give rise to viraemic calves so all dams of viraemic offspring need to be identified. If infection is a recent introduction then several calves in the same age group as the affected one may

also be persistently viraemic. Most of these are likely to succumb to mucosal disease at some time in the future.

When testing for BVDV, one should be aware of the possibility of sampling a calf that is only acutely infected and not persistently viraemic. To differentiate this possibility all virus-positive animals should be retested at an interval of six weeks. Persistently viraemic calves should be slaughtered. In the USA and elsewhere vaccines prepared from attenuated cytopathic virus are available, but it is believed that these have occasionally caused disease. Inactivated BVD vaccines are now available in the UK for injection in cows prior to pregnancy (p. 1011) and in calves for respiratory disease control (p. 1007).

It is important to recall that surveys have suggested that 1 per cent of adult animals in the national herd are persistently viraemic. The retention of viraemic animals in the herd is one strategy used to maintain herd immunity. However, there is always a risk that susceptible cows in early pregnancy can become infected. Therefore, once persistently viraemic animals have been identified they should be slaughtered unless they can, with certainty, be kept away from cows in early pregnancy. All newly introduced animals should be isolated and screened for the presence of antibody and virus before mixing with the herd. Persistently viraemic animals should not be kept.

Control of BVD at herd level

Surveys have indicated that upwards of 60 per cent of UK cattle are seropositive to BVD infection and that economic loss can be caused from infertility when seronegative animals are introduced into a seropositive herd. This can be a common scenario with the introduction of replacement heifers, whether home-bred or purchased. Diagnosis of the seropositive status of the herd can be achieved by testing bulk milk for antibody levels. Recently, inactivated BVDV vaccines have become available in the UK. The vaccines have proven excellent efficacy in preventing the fetus becoming infected if cows are vaccinated before they enter the breeding programme. Recent reports would suggest that significant improvements in fertility can follow the use of vaccination. Therefore vaccination of replacement animals before entering an infected herd is to be recommended. Booster vaccination at yearly intervals will probably be required so in time the whole herd will require vaccination annually. The best control policy should be a combination of vaccinating breeding animals and eradicating all persistently infected animals.

Special regard should be given to bulls as they can transmit BVDV in semen. Any veterinary inspection of bulls must include a blood test to ensure freedom from BVDV. Furthermore, any advice about the use of

'sweeper' bulls on breeding animals must include a caution about the possibility of introducing BVDV into the herd.

Johne's disease (paratuberculosis)

Johne's disease is a chronic, infectious enteritis that results in progressive wasting and eventual death. The disease has been reported worldwide wherever ruminants exist and the causal organism is the acid-fast bacterium *Mycobacterium johnei* (*paratuberculosis*). This is now often called *Mycobacterium avium* var. *paratuberculosis* (MAP). The prevalence of Johne's disease varies between countries and within countries.

There appear to be endemically infected farms on which the incidence can be as high as two or three confirmed cases every year, yet in the same district there will be many farms that do not experience the disease, except occasionally in a purchased animal. In some areas of the UK the incidence has declined considerably over the last 30 years, although the incidence in a number of northern European countries appears to be increasing. Recently concern has been expressed at the similarity of Johne's disease and Crohn's disease in humans. The possibility exists that some cases of Crohn's disease may be caused by *M. johnei*.

Pathogenesis

Infection with *M. johnei* occurs in young calves usually from their dams or contact with faeces of carrier cows. There follows a long incubation period of two to six years during which lesions develop in the small intestine and the animals intermittently excrete the organism in the faeces. Not all infected animals progress to the disease state. Where the disease does develop, the organisms multiply and cause extensive lesions in the small intestine that produce overt clinical disease.

Signs

The usual presenting signs are profuse diarrhoea accompanied by gradual weight loss. Frequently, the stress of calving initiates the onset of signs and affected cows are presented two to four weeks after calving. Rectal temperature, appetite and ruminal contractions remain normal. Submandibular oedema is sometimes present. In advanced cases the weight loss leads to emaciation and the diarrhoea remains profuse often with bubbles in the faeces.

Necropsy

The main pathological features are thickening of the lower part of the small intestine, the ileo-caecal valve

and sometimes the colon. The mucosal surface has a corrugated appearance. The organism may be present on the mucosal surface or tissue sections of the intestinal wall may reveal both intracellular and extracellular organisms.

Diagnosis

Any debilitating disease that results in emaciation may be confused with Johne's disease. However, the profuse diarrhoea, frequently containing bubbles, will distinguish the condition from weight loss caused by liver fluke (p. 276), liver disease, chronic traumatic reticulo-peritonitis (p. 837) or malnutrition. Johne's disease should always be considered as a possible diagnosis when a cow, four years old or more, and recently calved is presented with weight loss and chronic diarrhoea. The history of the prevalence of the disease on the farm will also be helpful. Diagnosis is best confirmed by the demonstration of clumps of acid-fast bacteria in smears of faeces stained with Ziehl–Nielsen stain. As excretion can be intermittent, repeat testing is sometimes necessary. The faeces sample is best taken from the rectum using a gloved hand, scraping faeces from the rectal mucosal surface. Failure to detect the organism in faecal smears does not rule out the possibility of Johne's disease. PCR tests are now also used for the antigen, but with the same provisos mentioned above. However, the organism can usually be detected at post mortem in stained impression smears of the mucosal surface of the terminal ileum or in histological sections of the same area of ileum.

An ELISA test is now available which has a high sensitivity and specificity in animals with clinical disease, although the sensitivity is reduced in animals infected but not showing clinical signs. PCR tests can be used on milk and are a valuable herd screening test.

In some countries, Johnin is used as a diagnostic test and can be administered intradermally or intravenously. Injected intradermally, Johnin produces an oedematous swelling at the site of injection in some cattle that are infected with Johne's disease. When injected intravenously, Johnin will initiate a rectal temperature rise of at least 0.8°C (1.5°F) 4–8 hours after injection. However, as with the complement fixation test, the use of Johnin as an accurate diagnostic indicator is not to be regarded as reliable.

If a definite diagnosis is required, the organism can be cultured from faeces, portions of terminal ileum or mesenteric lymph nodes, but positive results will not be available for six to eight weeks.

Treatment

Treatment of Johne's disease is not to be recommended, as the clinical signs are only evident in the terminal

stages of the disease. Antibiotics effective against Gram-negative bacteria, e.g. streptomycin, have been used but without any long-term success. A short remission of the diarrhoea is sometimes possible following a seven-day course of streptomycin and may be considered if for some reason it is not practical to cull the affected animal immediately. If dehydration is evident, rehydration with intravenous fluid therapy may allow the animal to be sent for human consumption.

Control

As infection with the Johne's disease organism occurs in calfhood the main plank in any control programme is to separate the calves from their dams immediately after birth and rear them completely separate from the adult herd. They should not be allowed access to faeces from adult cows at any time during the growing period and all drinking water should be from uncontaminated sources, namely mains water.

In the UK and elsewhere a live vaccine (p. 1012) is available for use in endemically affected herds. The vaccine used is licensed by the Department of the Environment, Food and Rural Affairs (DEFRA) and can only be used on farms where a positive diagnosis has been made from faeces or post-mortem material. Calves are separated from their dams at birth and the vaccine administered subcutaneously in the brisket area in the first seven days of life. A fibro-caseous nodule 2–5 cm in diameter is produced at the injection site and this remains for life.

Vaccinated animals will produce positive reactions to both the avian and bovine tuberculin administered during tuberculosis testing. Usually, the avian reaction is greater than the bovine so differentiation from tuberculosis is possible if the comparative intradermal tuberculosis test is used.

Vaccination in endemic herds has met with considerable success in reducing the incidence of disease in them, but not necessarily infection. However, to be successful separation of the calves from the adults and good hygiene is necessary in addition to vaccination.

Tenesmus

Tenesmus or ineffectual straining to defecate is commonly a sign of disorders of the pelvic cavity, the rectum and some diseases of the alimentary canal.

Tenesmus can be produced by profuse watery diarrhoea or dysentery, constipation, parturition, prolapsed vagina or rectum, vaginitis, urethral calculi, cystitis, lipomatosis of the pelvic cavity and coccidiosis. Tenesmus is also an important sign of ragwort poisoning. Manual examination of the rectum or vagina will produce tenes-

mus, which will be all the more severe if diarrhoea is present. Rectal or vaginal lacerations as the result of sticks or broom handles being inserted into the vagina or rectum by sadistic individuals will also cause tenesmus. In practice, the most commonly encountered reason for tenesmus is a cow that continues to strain after calving. This can be due to a second calf in the pelvic canal, a retained afterbirth or lacerations to the vaginal wall. The most effective treatment in these situations is to remove the calf if one is present or administer a local epidural anaesthetic.

A thorough examination is essential in cattle exhibiting tenesmus. Vaginal examination should be carried out using a vaginascope to prevent further damage, although frequently signs of vaginal damage may be apparent by separating the vulval lips. A rectal examination will normally be necessary, particularly if constipation is suspected, but a gloved well-lubricated arm should be used because this procedure may exacerbate the condition. Every effort must be made to identify the cause of the tenesmus so that corrective therapy can then be applied.

Diseases of the rectum and anus

Rectal prolapse

Rectal prolapse is less common in cattle than in other species. However, it may occur as a result of prolonged tenesmus associated with vaginal lesions, or coccidiosis, and it has been associated with laurel poisoning. The condition appears to be more common in the Hereford than other cattle breeds.

Treatment

The rectum, if not excessively swollen, can be replaced under epidural anaesthesia and a pursestring suture using umbilical tape inserted around the anal ring.

In recurrent cases a submucosal resection may be required.

Rectal tears

Rectal lacerations are occasionally produced during rectal examinations. They may also be produced by sticks or poles being inserted into the rectum by sadistic individuals. If the tear is completely through the rectal wall repair via a laparotomy may be possible, although it is not easy to reach the pelvic cavity from a laparotomy incision. Also, to succeed the repair must be effected immediately the laceration occurs, otherwise

faecal material will have entered the pelvic and abdominal cavities. The judicious clinician will advise immediate casualty slaughter in such cases.

Recto-vaginal fistula

Recto-vaginal fistulae are invariably the result of severe dystokia, usually in first-calving heifers. Tearing of the vulva can sometimes involve the anus or occasionally a foot of the fetus punctures the roof of the vagina and the floor of the rectum and a fistula results. These normally heal and the animal thereafter defecates via the vagina. Attempts at surgical repair are sometimes recommended because pneumovagina or vaginal contamination with faeces produces infertility. Although conception will not occur in cows so affected if natural service is used, it may be successful using artificial insemination because the semen is deposited in the anterior cervix or the body of the uterus, thus bypassing the vaginal damage.

Acute exudative pneumonia

Aetiology

This is thought in many cases to be a primary bacterial condition and usually *Arcanobacterium* (*Actinomycetes*, *Corynebacterium*) *pyogenes* (Gram-positive rods) can be isolated, or in some cases *Mannheimia* (*Pasteurella*) *haemolytica* and *P. multocida* (Gram-negative short rods) (Pirie, 1979).

Epidemiology

This condition is not uncommon and is usually seen as respiratory disease in individual animals. It can be present in cattle of any age, particularly when there has been chronic pneumonia in the housing period. It can be seen in dairy-bred cattle as well as in suckler animals, both indoors and at grass. Individual cases usually occur but outbreaks can follow some form of stress. The condition is one of sudden onset and is mainly differentiated from acute viral pneumonia by the fact that it usually affects individual animals.

Signs

The animal shows signs of suddenly going off its feed and is dull. There is an oculo-nasal discharge which may be mucoid or mucopurulent. The temperature is usually 40–41°C (104–107°F), respiratory rate is between 20 and 60/minute, usually with hyperpnoea. There is often some coughing but this is not pronounced. On auscultation there are usually squeaks, humming and wheez-

ing often at inspiration, particularly the latter. Cranioventrally, there may be moist sounds and there may be pleuritic rub (sandpaper-like) sounds in a few cases.

Necropsy

At post mortem there are dark areas of consolidation in the ventral parts of the apical and cardiac, and in some animals, the thoracic lobes. The areas of pneumonia may be small and scattered, but in more severe cases there are large areas of consolidation and, in some animals, abscess formation. Microscopically, there is exudation and vascular congestion with the bronchioles and alveoli showing infiltration with neutrophils and macrophages (Pirie, 1979).

Diagnosis

Diagnosis depends on the history of usually only a single animal being involved with pyrexia and respiratory signs normally being evident.

Differential diagnoses involve chronic pneumonia but normally the animals are less ill and several are affected. Inhalation pneumonia usually results in a very dull animal and also there is often a history of drenching.

Treatment and control

When treating, the affected animal should be isolated. Antibiotic therapy with oxytetracycline, penicillin and streptomycin, ampicillin, amoxycillin, cephalosporins, sulphadimidine, and trimethoprim and sulphadiazine for three to five days is usually successful. Most cases respond well to therapy, but a few cases relapse and some ultimately develop chronic suppurative pneumonia.

Prevention is by trying to ensure adequate ventilation when housed and to avoid chilling.

Aspiration pneumonia

Aetiology

This is also known as inhalation pneumonia and although not a common condition, it still occurs too

frequently. Obtaining an adequate history is important and often the stockworker may realize what has happened, but will be reluctant to admit it or even that the animal has been drenched. Obstruction or paralysis of the larynx, pharynx or oesophagus may produce the problem, as with parturient paresis, or the rupture of a pharyngeal abscess or the products of laryngeal diphtheria. The signs will depend on the nature of the fluid introduced, the quantity and the bacteria introduced. If a large quantity is administered into the lungs, then instantaneous death may occur. If the substance given is soluble, then absorption into the body is rapid because of the highly vascular nature of the lungs, and few, if any signs will occur. Less soluble products will result in a varying degree of toxæmia and respiratory signs, which are often fatal, after between one and three days.

Signs

In the peracute form death occurs rapidly after drenching. However, in the acute form only one animal is usually affected and there is a history of drenching. Signs develop rapidly and include a varying degree of dullness and inappetence, a cough and tachypnoea. The temperature is usually elevated to about 40°C (104°F) and on auscultation there are areas of dullness present, normally in the cranio-ventral parts of the lungs, and moist bubbling and crackles may be heard in the area. There is often also a pleuritic rub sound and some degree of thoracic pain. If the condition progresses, the signs of dullness and anorexia become more pronounced, and there may be a fetid odour to the breath.

In the subacute form there are few signs present except for episodes of coughing and tachypnoea following the introduction of the fluid. Some animals will survive the immediate episode and become chronic cases. These will show ill-thrift and intermittent bouts of respiratory problems.

Necropsy

At post mortem there is often an acute exudative or gangrenous pneumonia of the ventral parts of the apical, cardiac and usually also the diaphragmatic lobes. In some animals there is extensive suppurative necrosis.

Diagnosis

Diagnosis is helped if a true history is obtained and is indicative that the condition is present. Usually only a single animal is affected and the signs are of sudden onset. The respiratory signs are severe and there is usually a leucopenia and neutrophilia present.

Differential diagnoses include septicaemia, which has fewer respiratory signs, enteritis but then diarrhoea is present, and acute exudative pneumonia, but in this case there is no history of drenching and usually the animal is less dull.

Treatment and control

If there is to be a hope of effective therapy, it must be administered as soon as possible after the drenching incident. The use of antibiotics or a sulphonamide is indicated and it is best to give the first dose intravenously. Thus oxytetracycline, amoxycillin, ampicillin, sulphadimidine, sulphamethoxypyridazine or sulphapyrazole can be used. In exceptional circumstances where allowed chloramphenicol might be indicated. Therapy should be continued in most cases for about five days. In addition, fluid therapy may be required. The animal should be encouraged to eat and drink. It should be kept on its own in a well-bedded, airy pen.

Control is by ensuring that all drenching and dosing is undertaken slowly, allowing the animal time to swallow.

Bovine farmer's lung

Aetiology

This is a form of chronic atypical interstitial pneumonia. The condition appears to be a chronic reaction to certain fungi found in badly made hay, such as *Microsporum faeni*.

Epidemiology

The problem is quite common during the winter in housed cattle fed poor quality mouldy hay or straw. More cases occur in the wetter western parts of Britain and in other countries with high rainfall. Where much rain falls in the summer months, hay may need to be baled at very high moisture contents. This allows overheating to occur and thermophilic microflora then predominate. Disease is often only seen in adult cattle and in some cases the farmer will also have farmer's lung. In Britain this is defined as an industrial injury and is considered to be due to the inhalation of dust from mouldy hay or other mouldy vegetable produce. It results in a defect in gas exchange due to a reaction in the peripheral parts of the bronchopulmonary system. In cattle the condition is usually a herd problem but occasionally a farmer will consider that there is sudden onset in one animal. In such cases the examination of other animals will show varying lesser degrees of the problem.

Signs

The acute signs follow housing and there is often a sudden onset of dullness, a fall in milk yield and a decreased appetite. The animal shows respiratory signs, normally including some respiratory distress, and coughing. On auscultation there are crackles over the cranio-ventral parts of the lung. Although some cases are pyrexic, most animals will have a normal rectal temperature.

In the chronic form there is progressive weight loss and coughing, often with the production of green mucus, which tends to occur with each winter but resolves during the summer months with outside grazing. Occasionally, such animals will develop a sudden crisis following a stress such as calving, a sudden heavy exposure to the antigen, unaccustomed exercise or due to congestive heart failure. Usually there is obvious tachypnoea and hyperpnoea but no pyrexia or thoracic pain or alteration in the resonance of the thorax. Auscultation may produce harsh crackles over the cranio-ventral aspects of the lung and in some cases there are widespread whistles, squeaks and wheezing. It is uncommon for animals to die of the condition unless there are complications.

Necropsy

At necropsy all lung lobes may be affected and there is often overinflation of the peripheral acini. Small grey-green foci tend to be present in the lobules. Histologically, the alveolar walls show interstitial infiltration with plasma cells, lymphocytes and macrophages. Another change is bronchitis obliterans and also epithelial granulomata can occur.

Diagnosis

Diagnosis depends on a history of occurrence in wet areas and feeding poor quality mouldy hay in winter. The problem improves in the summer. Signs include loss of weight with the respiratory disease. An intradermal skin test with *Micropolyspora faeni* produces a reaction 4–6 hours after injection. On serological examination precipitating antibodies to *Micropolyspora faeni* are found but they may also be seen in unaffected cattle within the same herd.

Treatment and control

The use of long-acting corticosteroids may help reduce signs. Where mouldy hay or straw has to be fed or used for bedding then it must be shaken out outside before being offered to the animals. As human problems can arise, a face mask should be worn.

Control involves improving hay-making, which may mean the use of hay additives to upgrade hay quality. Otherwise, the provision of silage might be useful but this does normally mean investment in new machinery for producing the conserved roughage.

Bovine tuberculosis

Aetiology

This is infection with *Mycobacterium bovis* (Gram-positive, acid-fast rods).

Epidemiology

At one time the condition was very common in many countries. However, following tuberculin testing, pasteurization of milk and adequate meat inspection the disease is uncommon in most countries today, but is still seen periodically mainly in dairy herds. In most cases infection breaks out in the growing heifers or younger cows. The condition is still prevalent in south-west England, but is now being increasingly seen in other areas including the south Midlands, north-west England and Wales. In many regions infection has reappeared and is associated with the finding of tuberculosis in the European badger (*Meles meles*). However, in many cases infection can follow the purchase of a carrier without overt signs. Infection of deer with *M. bovis* can also spread disease and in New Zealand a problem occurs with the brush-tailed possum (*Trichosurus vulpecula*). The organism is killed by sunlight, but is resistant to desiccation and can survive in a wide range of acids and alkalis. It is also able to remain viable for long periods in soil that is moist and warm. In cattle faeces, *M. bovis* can survive for as little as a week or as long as eight weeks. Man can occasionally be infected and the disease can occur in goats and pigs, and very occasionally in horses and sheep. Very occasionally cattle can be infected with *Mycobacterium tuberculosis*, usually because people tending or in close contact with the cattle are infected.

When infection is by inhalation, a lesion often occurs at the point of entry and the local lymph node. When ingestion is the route of entry, alimentary lesions are rare but lesions may be present in the tonsils, pharyngeal or mesenteric lymph nodes. Lesions may then disseminate from the primary areas to others.

When the badger is involved, most infection is thought to be by ingestion, but a higher infection level is necessary to establish alimentary than respiratory infection. In most cases the lesions are respiratory and are thought to be due to the inhalation of ruminal gases.

The organism can be present in sputum, milk, faeces, urine, vaginal and uterine discharges and any discharg-

ing lesions. Entry is usually by inhalation (especially if housed) or ingestion (when outside or badgers are the source of infection). Drinking infected milk can infect the calf. Signs can occur in very young calves (under a month old). Intercurrent disease in the herd such as BVD may exacerbate the problem (Monies, 2000). Once in a herd, infection probably spreads from cow to cow by inhalation. However, spread from cows to calves may be via the milk. Occasionally, intrauterine infection has resulted from a coital transfer.

Signs

Various body systems can be infected. Often signs are few and usually are confined to the respiratory tract. There is a soft, productive, chronic cough occurring once or twice at a time. It can be elicited by pressure on the pharynx. If the condition continues there is a marked increase in the depth and rate of respirations as well as dyspnoea. In advanced cases, areas of dullness in the chest are heard on auscultation or percussion. In other cases there are squeaks and whistles. A snoring respiration can occur.

The alimentary form is unusual. There are few signs but occasional diarrhoea occurs. Bloat can arise through enlargement of the mediastinal and bronchial lymph nodes. Bone can be infected and meningitis occurs in calves.

Mammary involvement these days tends to be rare but results in udder induration and the supramammary lymph nodes are enlarged. The udder form can be a serious potential source of spread to humans. The uterine form is also uncommon. Swelling of various lymph nodes can occasionally be seen, and abortion may sometimes occur.

A generalized form can occur with signs following calving. There is a progressive loss of condition with a variable appetite. There may be a variable rectal temperature but usually it is only about 39.7°C (103.7°F). The animals are more docile than normal but still bright and alert.

Necropsy

A focus of infection occurs within a week of bacteria entering the cow and, after the third week, calcification can occur. Depending on the route of entry, and where the condition becomes generalized, one or several lymph nodes may contain tuberculous granulomas. In the respiratory system it is the mediastinal or bronchial lymph nodes that are involved, possibly with abscesses in the lungs. The pus is thick, cheese-like and yellow or orange in colour. Sometimes the pleura and peritoneum contain nodules.

In practice, an attempt is made to determine whether

infection is active and if cases are 'open' and therefore likely to infect other animals. Active infection is designated by lung infection with limited encapsulation and hyperaemia. This categorization is now thought to be erroneous and it is considered that most lesions are potentially infective. Other organs often show small, transparent, shot-like lesions and these may also be present in the lymph nodes. Tuberculous cystitis and metritis tend to be open cases. Closed infection is seen as discrete lesions enclosed within well-developed capsules. The enclosed pus tends to be caseous and yellow or orange in colour. In tuberculin reactors the apparent absence of gross lesions of tuberculosis – so-called non-visible lesion (NVL) reactors – does not necessarily indicate that the animal is uninfected.

Diagnosis

Diagnosis depends on the history of an area where tuberculosis occurs in cattle, badgers or other wildlife. The signs often result in chronic respiratory lesions with loss of condition and a soft, productive, single cough. The comparative tuberculin test is useful. It uses avian (0.5 mg/ml) and bovine tuberculin purified protein derivative (1.0 mg/ml) injected into the neck skin. There is a greater skin thickness increase in bovine than avian tuberculin. Interpretation depends on whether there is no history of reactions, one or more reactions without confirmation at post-mortem examination or a herd with a recent history of reactions confirmed post mortem.

Johne's disease (p. 857), skin tuberculosis (p. 886) or avian tuberculosis can result in false positive bovine tuberculin reactions but usually the avian reaction increases more than the bovine. False negatives occur following protracted infection, desensitization following tuberculin testing, early cases of infection, old cows and those animals recently calved.

The single intradermal test is used in many countries. Its main disadvantage is that it will give reactions to avian tuberculosis, skin tuberculosis or Johne's disease. A short thermal test can be used by injecting tuberculin subcutaneously and measuring the animal's temperature every 2 hours. A rise in temperature of 1°C (1.8°F) is considered significant. Intravenous tuberculin also results in a temperature rise. The Stormont test has been used to detect disease in infected cattle. Various serological tests have been used and recently the enzyme-linked immunosorbent assay (ELISA) test has shown promise. A gamma interferon test can be used to determine infected cattle.

Differential diagnosis

Differential diagnosis includes enzootic bovine leucosis (Chapter 43b) but this can be detected by serology.

Chronic lung abscesses can cause problems in diagnosis. Traumatic reticulitis (p. 837) may produce similar signs but there is usually a history of an acute attack. Chronic pericarditis (p. 731) can present problems but will result in a jugular pulse and muffled heart sounds and endocarditis (p. 726) cases usually produce a murmur. Contagious bovine pleuropneumonia (p. 868) can cause problems but can be differentiated by a complement fixation test. Lymph node enlargement due to actinobacillosis (p. 823) may be difficult to detect but can be done with a tuberculin test.

Treatment and control

Treatment is not usually undertaken because of the chronic nature of the disease and its potential zoonotic effects. Control in many countries, including North America and Europe, is by tuberculin testing and slaughter of reactors. Hygiene standards need to be upgraded and efficient meat inspection and tracing back to the farm of origin is useful. Research work on vaccine production is being undertaken and may be directed towards vaccination of wildlife such as badgers and possums.

Chronic suppurative pneumonia

Aetiology

Various initial causes may result in one or more pathological conditions such as bronchopneumonia, bronchiectasis and pulmonary abscesses. These are often encompassed by the term chronic suppurative pneumonia.

Epidemiology

Most cases occur in adult cattle rather than those still growing. It is, however, a very common cause of respiratory signs in the individual animal. Often there has been an outbreak of acute pneumonia in the history. Although most cases seem to progress slowly over a period of weeks or months, the odd case will appear to be of sudden onset, due to a rapid exacerbation of a suppurative area in the chest.

Signs

Severe signs of disease include a sudden marked loss of condition with dullness, obvious thoracic pain, pyrexia (40.5°C ; 105°F). In some animals there is halitosis due to a necrotizing bronchopneumonia and pleurisy. Death in these animals often occurs within a few days.

More usually the animal becomes progressively duller and thinner, with a fall in milk yield and intermittent pyrexia, up to 40°C (104°F). A cough is usually present with the production of mucus and there is a variable degree of tachypnoea. Thoracic pain may be obvious by an abduction of the elbows and reluctance to move, but in other cases it is only discernible on ballottement. On auscultation there are usually whistles, squeaks and wheezing sounds in the cranio-ventral part of the chest and there are often areas of dullness.

Necropsy

If the main lesion at post mortem is a bronchopneumonia, there is usually marked consolidation of the cranio-ventral parts of the lung, with exudate filling the bronchi and bronchioles. On histological examination, inflammatory cells pass the alveoli and bronchi. When the main problem is a bronchiectasis, often bronchi in the cranial and middle lobes, with dilated air passageways, contain mucus and fibrous tissue. In severe cases the histological sections show complete destruction of the alveolar tissue. When lung abscesses are the main feature, these are usually found in the ventral lung border. Necrotic tissues and pus-containing structures are found within a fibrous capsular wall.

Diagnosis

Diagnosis is based on a history of a chronic loss of condition with respiratory disease in a single animal with signs such as pyrexia, thoracic pain and cough.

Differential diagnosis needs to include acute pneumonia (p. 860), which may be in a single animal or several animals; salmonellosis (p. 850; Chapter 15), but at this age there is usually diarrhoea; infectious bovine rhinotracheitis (IBR) (p. 289) infection, but this usually results in a marked conjunctivitis. Inhalation pneumonia (p. 860) on the other hand has a specific history and tuberculosis (p. 862) will probably have a history of herd infection, whereas malignant catarrhal fever will involve ocular lesions and enlarged lymph nodes, etc.

Treatment and control

Often therapy is of limited use. Any treatment may need to be prolonged for 10 days to two weeks or more. Antibiotic therapy with amoxycillin, ampicillin, oxytetracycline, penicillin and streptomycin, sulphadimidine, or trimethoprim and sulphadiazine may be helpful. Most cases that respond are likely to break down again and so infected animals should be slaughtered when convenient.

Control involves culling animals that have had previous bouts of respiratory disease and ensuring all cases are treated early and thoroughly.

Peracute pleuropneumonia

A respiratory problem was described in the 1990s in Great Britain which appeared to be a relatively well-defined syndrome and which at post-mortem examination showed a pleuropneumonia (Harwood *et al.*, 1995). While it looked like contagious bovine pleuropneumonia, the history and epidemiology were not right and *Mycoplasma mycoides* subspecies *mycoides* was not isolated.

Aetiology

Routine bacteriology of lungs when positive routinely isolated *Mannheimia (Pasteurella) haemolytica*, usually of serotype Al. *Arcanobacterium (Actinomyces) pyogenes* has been isolated from the necrotic areas within the lung. No further consistent bacterial or viral synergism has been recognized.

Occurrence

All problems appear to have involved adult animals and calf respiratory problems on the farms did not appear to be unusual or of high incidence. Usually one or a small number of animals are affected and most of these die. The remainder of the herd do not appear to show any signs of disease. Animals in the immediate post calving period were most commonly infected. There was a history of purchase of cows and/or heifers within the last 12 months on all farms and in several there were imports from Europe as well as from the United Kingdom. There was no history of recent transport or movement of the affected animals.

Signs

Severe respiratory problems are seen with dyspnoea, hyperpnoea and tachypnoea. Most animals will die or are humanely destroyed regardless of any antibiotic regime. There are variable lung signs, including pleural rubs, etc.

Pathology

The thoracic cavity contains severe changes with very obvious fibrinous or fibrous pleurisy. There are strong attachments between the thoracic wall and the lungs; pleural deposits can often be 1cm thick. There are large amounts of pleural effusion and pulmonary oedema. The lungs show marbling with severe interlobular oedema, with parenchymal congestion and consolidation.

Diagnosis

Small numbers are affected with severe disease, which is often fatal. There is no apparent precipitating factor except for calving. Post-mortem examination allows diagnosis.

Differential diagnosis

Contagious bovine pleuropneumonia (CBPP) is an obvious differential and in many countries, as in Britain, CBPP is notifiable and so it will be necessary to report cases to the authorities (see p. 873).

Treatment

Large doses of antibiotics, often with non-steroidal anti-inflammatory agents, can help in a few cases.

Control

At present there is no real advice to offer in herds which for any reason have to buy in animals.

Diffuse fibrosing alveolitis

Aetiology

The cause is unknown but many cases occur in animals with chronic bovine farmer's lung and have precipitating antibodies to *Micropolyspora faeni*. However, it is probable that there are other precipitating causes as some cattle do not possess antibodies to this organism.

Epidemiology

The condition affects individual animals and is uncommon although more frequently seen in herds with a history of bovine farmer's lung. Both dairy and suckler cows are affected and cases can occur indoors or outside, particularly in animals older than six years. The condition is usually a progressive problem and may actually start following a stress such as calving. The condition has normally been present for weeks or months before advice is sought and the animal will have lost condition with coughing or respiratory signs when subjected to mild exercise. Congestive heart failure occurs in about 12 per cent of cases.

Signs

Affected cattle are bright and do not have a raised temperature or pulse rate. The appetite is good but there is a progressive loss of condition. The respiratory signs tend to be quite severe, with a persistent cough always

present as well as tachypnoea and hyperpnoea present even in the resting animal. On auscultation of the chest, rhonchi (whistles, squeaks, wheezing) are heard over both lungs and crackling sounds in the cranio-ventral chest. There is no thoracic pain.

Depression and inappetence only occur in the late stages of the condition with congestive heart failure resulting in subcutaneous oedema and an increased heart and respiratory rate. The liver may be palpably enlarged and there may be diarrhoea.

Necropsy

At necropsy alveolar changes predominate but there may be bronchitis with excessive thick mucus in the bronchi. There is thickening and fibrosis of the alveolar walls. Histologically, large numbers of mononuclear cells are seen in the alveolar air spaces. There may be hyperplasia of type 2 pneumocytes or metaplasia of the alveolar epithelium so that it contains ciliated and mucus-secreting cells. Pulmonary hypertension can occur and this results in right-sided heart failure.

Diagnosis

Diagnosis depends on the history, i.e. a single animal, with gradual loss of condition with respiratory signs present at rest, coughing, no thoracic pain or fever and a bright animal.

Treatment

As the cause is unknown, little can be done to alleviate the problem. However, corticosteroids can reduce the cellular changes in the lung. Casualty slaughter of the animal should be undertaken before the loss of condition is too severe.

Dusty feed rhinotracheitis

Aetiology

Particles of different sizes meet varying fates in the respiratory system following inspiration (see Table 49.1). Most of the particles will be in the nasal passages or the trachea, bronchi and bronchioles. The condition results from the introduction of dry, fine-particled feed, or very dusty bedding.

The introduction of a dusty dry feed to animals indoors causes the problem. The signs occur most frequently in the hour or two following feeding. Removal of the feed causes recovery in a few days. The condition occurs most commonly when the relative humidity is low.

Table 49.1 The fate of various-sized particles entering the respiratory system.

| Particle size (μm) | Fate |
|---------------------------------|--|
| >10 | Removed in nasal passages |
| 2–10 | Deposited at varying levels in respiratory tract, but above alveoli. The smaller the particle, the further down the respiratory airways it is deposited. Removed by mucociliary action |
| 1–2 | Deposited in alveoli |
| 0.5–1 | Exhaled with air |
| <0.5 | Deposited in alveoli due to diffusion forces |

Signs

Following feeding or bedding, there is the sudden onset of coughing. The cough tends to be dry and can be single or paroxysmal. Several cattle are normally affected. The animals are otherwise bright and alert; they eat well and there are no abnormal lower respiratory sounds. Respirations are normal in rate and extent, and temperature is normal. There is conjunctivitis and usually a copious ocular and nasal discharge, which is mucoid but sometimes slightly purulent.

Treatment and control

Treatment involves replacing the feed or bedding used. Otherwise dampen down the feed before giving it, or molasses can be added to it. In the case of bedding, new bales should be opened up outside before the cattle are bedded.

Control is by not feeding dusty hay. If the feed is found to be dusty then 5 per cent molasses should be added to it. Dusty bedding should not be used. As the particles affecting the animals can affect humans, it is advisable for workers to wear face masks.

Fog fever

Aetiology

This is a form of atypical interstitial pneumonia. Although not fully authenticated, the condition is considered to be a toxicosis following the ingestion of large quantities of L-tryptophan.

Epidemiology

The condition is seen in cattle over two years old, particularly those in suckler herds, and affects several cattle to a varying degree at the same time. Often the cattle

have been receiving little nutrition and are put onto a more lush pasture in the autumn (September to November). The field may have been top-dressed with a nitrogenous fertilizer. The condition is normally seen within two weeks of entry to the new pasture. The Hereford and Hereford-cross breeds seem to be particularly susceptible.

It is thought that L-tryptophan in the grass is ingested and metabolized in the rumen to indole acetic acid (IAA), which is decarboxylated by *Lactobacillus* spp. to produce 3-methyl indole (3MI). This metabolite can enter the blood and is usually acted upon by the mixed function oxidase system to produce indoles and other metabolites in the urine. 3-Methyl indole can cause the destruction of pulmonary cells such as type 1 pneumocytes and monociliated bronchiolar secretory cells, resulting in various pathological changes. Mortality in severely affected animals can be high (up to 75 per cent) but usually only a small number (5 per cent) are so involved.

Signs

Several animals will show signs but the degree will vary widely and often the farmer only notices one to be ill at the start. The cattle tend to be much quieter and more approachable than normal and to have a sleepy or tranquil expression. The respiratory signs are usually of distress but vary in degree. Coughing is normally little heard.

In the severe form there is the sudden onset of dyspnoea with a loud respiratory grunt, mouth breathing, and often the animal froths at the mouth. Auscultation reveals little considering the severity of the illness, but it may produce soft, moist sounds and a few crackles. Death can occur as the result of excitement. Less severely affected animals show tachypnoea (rate 50–80/minute) with hyperpnoea and usually there is no dyspnoea. The rectal temperature tends to be normal and the animal is again quiet and tranquil. Coughing is only heard occasionally and in some recovering animals a subcutaneous emphysema may develop. Auscultation may reveal harsh sounds.

Necropsy

Dead animals have haemorrhages in the larynx, tracheal and bronchial mucosae. The lungs tend to be swollen, heavy and dark red in colour. The cut surface glistens, is smooth and has a red appearance. Emphysema may be present in the interlobular septa and pleura. Histological examination reveals severe congestion and oedema of the pulmonary tissue, hyaline membrane formation, severe interstitial emphysema and moderate epithelial hyperplasia of type 2 pneumocytes.

Cattle slaughtered in the later stages do not usually show haemorrhages of the respiratory mucosa. There is an overall pale pink colour with variable amounts of interstitial emphysema.

Diagnosis

Diagnosis involves the history of a group condition, mainly in suckler animals moved to a lush pasture in autumn. The signs help, particularly the acute respiratory signs with little to hear on auscultation, no cough and the animals being more tranquil than usual. Post-mortem findings indicate the condition, with pulmonary oedema and emphysema.

Differential diagnoses include husk (p. 272), but a cough is present and there would be a history of no vaccination. Pneumonic pasteurellosis (p. 286) would produce pyrexia and a mucopurulent discharge. Nitrate poisoning (p. 950) would produce some signs but the blood would tend to be brownish and the urine contain methaemoglobin. Infectious bovine rhinotracheitis (p. 289) would usually involve pyrexia and a loud explosive cough. Thrombosis of the caudal vena cava (see below) would usually involve a single animal and eventually haemoptysis would occur. *Brassica* spp. (p. 941) poisoning would have a different history of feeding and would usually be later in the autumn.

Treatment and control

Treatment is to remove the cattle from the incriminated pasture. Most other treatment tends to be empirical. Interference with a severely distressed animal may result in its death. Atropine at 1 g/450 kg (990 lb) body weight intravenously acts as a bronchodilator and corticosteroids may be useful. Flunixin meglumine has been beneficial in experimentally produced acute bovine pulmonary emphysema and in the field.

Control means that if animals are hungry when they enter a new pasture in the autumn, restrict their feed by only allowing grazing for short periods during the first two weeks. This should be for about 2 hours on the first day, increasing by an hour a day so that the cattle can be left out for the whole day after about 12 days. Otherwise the area can be strip-grazed or initially grazed with a less susceptible species such as sheep. If monensin sodium is given at the rate of 200 mg/head per day before and after entering the pasture, this can stop problems.

Thrombosis of the caudal vena cava

Aetiology

The cause is a septic focus, usually in the liver, resulting in a septic thrombus in the caudal vena cava, from

which there is the haematogenous spread of infection to the lungs.

Epidemiology

This is an uncommon condition affecting single animals over one year old, although many cases occur in the growing animal. A few cases of thrombosis of the cranial vena cava have been recorded with similar signs. Most cases result from a liver abscess. This causes a localized phlebitis, usually in the area of the vena cava, adjacent to the liver. Septic emboli pass to the lungs where they can produce chronic suppurative pneumonia and multiple lung abscesses, or they can cause pulmonary arterial lesions. Endarteritis, arteritis and thromboembolism occur, resulting in aneurysms of the pulmonary artery, which then rupture causing haemorrhage in the bronchi and alveoli. Usually, there is a history of sudden onset of respiratory disease, although in some cases there is a history of chronic loss of weight and coughing. A few cases show obstruction of the hepatic venous return with chronic venous congestion of the liver, its enlargement and no access to the collateral venous drainage. Bacteriological examination often reveals little because of previous therapy. However, some cases reveal staphylococci, *A. pyogenes* and *Fusobacterium necrophorum* spp.

Signs

Peracute signs result in an animal dying suddenly with no premonitory signs but usually there is a pool of blood in front of it. In the acute case, cattle with the condition show respiratory disease for a few days or some months, with tachypnoea and shallow breathing. The animal develops haemoptysis and frothy blood can be found in the nasal passages and mouth. There are often blood stains around the animal and in many cases there is melaena. There is a variable amount of thoracic pain with abduction of the elbows. On auscultation there is a widespread whistle, with wheezing sounds.

The chronic form involves animals developing congestive cardiac failure and ascites with an enlarged liver, which may be palpated on the right sublumbar fossa. This often occurs some time before haemoptysis is present.

Once animals start to show haemoptysis then death will ensue, usually within a week or two but occasionally it may take up to 40 days.

Necropsy

Following death, often one or more abscesses are found in the liver, and usually the caudal vena cava thrombosis is in the area of the liver. Multiple septic emboli are

normally present within the pulmonary artery. In the lung itself there is usually embolic suppurative pneumonia, intrapulmonary haemorrhage, often concentric and globular in shape, and multiple red areas where blood has been aspirated. When there is obstruction of the hepatic veins then there is marked hepatomegaly and ascites.

Diagnosis

Diagnosis involves the history of loss of condition and respiratory signs in a single animal. The signs help, particularly haemoptysis with thoracic pain, and are almost pathognomonic. Post-mortem findings are relatively diagnostic with thrombosis of the vena cava, emboli in the pulmonary artery and intrapulmonary haemorrhage. Haematological examination shows the packed cell volume is often low (11.0–22.5 per cent).

Differential diagnosis includes an accident, but signs would be highly unlikely unless there is an immediate history of trauma. Tuberculosis (p. 863) could also give rise to some of the signs but is usually much slower and the tuberculin test would reveal this.

Treatment and control

There is no effective therapy. Cattle can be casualty slaughtered if necessary after a course of four or five days' antibiotic therapy using a broad-spectrum compound and then leaving the required withdrawal time.

Control is not possible, but any septic focus should be treated adequately as soon as it occurs. Make sure that all changes in feeding are undertaken slowly so as to avoid the possibility of acidosis (p. 829).

Contagious bovine pleuropneumonia (CBPP)

Mycoplasma mycoides is the cause of contagious bovine pleuropneumonia (CBPP), which now that rinderpest has been controlled, is the cattle disease of greatest economic importance on the continent of Africa. CBPP affects only cattle and the water buffalo (*Bubalis bubalis*). Claude Bourgelat, the great French veterinary surgeon and founder of the Lyons Veterinary School, was the first person to differentiate rinderpest from CBPP (in the eighteenth century). It was thought the disease was introduced into Europe from Asia in the seventeenth century and that the wars of the eighteenth and nineteenth centuries resulted in its spread throughout the continent. From Europe it was taken to the rest of the world; South America is the only continent that has never experienced the disease.

New techniques (PCR, DNA fingerprinting, ELISA, among others) in manipulating mycoplasmas have led to new thinking about the phylogeny of the group. Where there were individual species, the organisms now have been grouped into 'clusters'. Economically the *Mycoplasma mycoides* cluster is the most important, containing as it does, *Mycoplasma mycoides* subspecies *mycoides*, small colony type (*M. mycoides*), the large colony type that infects goats and to a lesser extent sheep and *M. mycoides capri*, another of the agents that causes contagious caprine pleuropneumonia.

It has been possible to trace the introduction of the infection into many countries. Indeed, in some cases the identity of the infected animal is known! There is, however, some dispute about the entry of the disease into Africa. French workers believe that the infection was introduced when *Bos indicus* crossed into the continent from Asia; it did not get to southern Africa in this way and there is evidence that it did not exist in East Africa before the invasion of General Napier into Ethiopia in 1868.

The Dutch Ambassador to the Cape Colony, with the intention of improving the local stock, imported a bull from his country in 1853. The infection was rapidly disseminated by trek oxen, particularly to the Transvaal where in the space of two years it killed more than 100 000 animals. From South Africa the infection was taken to Namibia, Zimbabwe and Botswana. From Namibia it was taken to Angola and from there to Zambia and the Congo. By 1940, with the exception of Namibia and Angola, the southern African countries had eradicated the infection. The development of an efficient vaccine at Muguga (the T₁ broth vaccine) and Joint Project 16 (a research project to improve knowledge of epidemiology, diagnostic techniques and the vaccine) resulted in CBPP being brought under control throughout west, central and east Africa by 1970.

The failure of African governments to invest in veterinary services over the subsequent years has resulted, as was seen with rinderpest, in a resurgence of the disease throughout the continent; by 1995 most countries of Africa south of the Sahara reported the disease (Fig. 49.1). It is said that the vaccine no longer works.

Aetiology

Two types of *M. mycoides* subspecies *mycoides* are recognized: the small colony type (SC) which causes CBPP in cattle and the large colony type which occurs in goats and rarely in sheep. They cannot be differentiated in culture, biochemical or immunological tests; however, they can be separated by PCR. They have a different pathogenicity in cattle, because only the SC types causes CBPP. *M. mycoides* is a micro-organism that lacks a cell wall and will grow under aerobic or anaer-

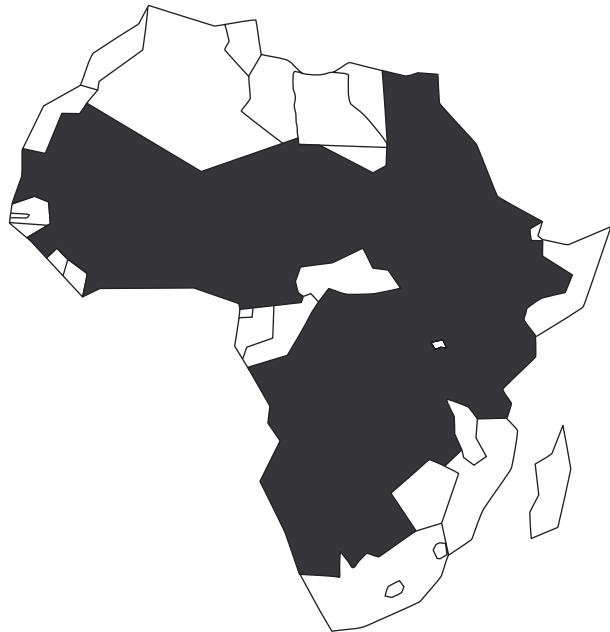

Fig. 49.1 In 1995 most countries in Africa south of the Sahara Desert reported CBPP.

obic conditions. The organism requires a complex medium for growth, containing serum and yeast extract, and growth is slow taking up to 72 hours to reach a maximum. In broth cultures a swirling mucoid mist is produced from the galactan which is attached to the cell membrane.

Epidemiology

Only cattle and water buffalo are susceptible to CBPP; the African buffalo has been infected under experimental conditions, but that same study found that natural transmission did not occur. There is some debate as to whether *Bos taurus* or *Bos indicus* is the more susceptible to infection with *M. mycoides*. An understanding of the epidemiology has been bedevilled by an inability to reproduce the disease in cattle other than by the cumbersome 'in contact' method, in which cattle are artificially infected by having a culture inoculated directly into the bronchi and then these artificially infected animals are mixed with healthy susceptible animals. Normal transmission is by droplet infection from actively infected animals to susceptible animals in close proximity. However, indirect transmission has been demonstrated under experimental conditions.

A second factor that hinders the understanding of this disease is the potentiation of myths and statements of fact that have no basis in experimentation, e.g. 'There

is a prolonged incubation period'; 'lungers break down and the animal again becomes infective'. There is no evidence for either of these statements but they are held to be true. In all the vaccine trials carried out at the East African Veterinary Research Institute, Muguga, Kenya, control animals put in contact with diseased animals showed signs of infection (either clinical or serological) at about six weeks (plus or minus 10 days). Under field conditions it may be that the animal has avoided infection for a long period of time. Work at Muguga failed to reactivate disease in recovered animals: stress, corticosteroid treatment and even removal of the spleen were unsuccessful. Until proven otherwise, it is the actively diseased or the animal incubating the disease which must be considered as the main risk to susceptible animals.

CBPP is a disease of the older animal and calves rarely show pneumonic disease. Infection in young animals normally results in lesions in the joints. In consequence, calves play little or no role in the spread of disease.

Although there is no experimental evidence to confirm the observation, it is generally believed that it is the weight of infection in a herd that determines the clinical picture. Under natural conditions, there might be a single animal infected in a herd and this animal will show only mild signs which may well pass unnoticed. Nevertheless, the animal infects several more animals and they in turn yet more. In this way the weight of infection builds within a herd until widespread clinical disease is seen. This picture may explain the long incubation periods referred to in the literature.

When the infection is introduced into a susceptible herd there can be a great variation in response, from a severe, massive, acute outbreak of disease involving up to 60 per cent of the animals in the herd with 40–50 per cent of the affected animals dying, to a much less severe problem, involving less than half of the herd with few animals severely affected and a low mortality. Recovered animals are resistant to further infection. In many of these recovered animals sequestra may be seen: a sequestrum is a piece of diseased lung that has become separated from neighbouring healthy tissue and surrounded by a fibrous capsule. In a closed herd, in which no action is taken, it is not uncommon for the disease to die out. Recently there has been a move towards treating clinically sick animals. The effects of this treatment on sequestrum formation are not known but it is thought that it might prevent the animals from developing a proper sequestrum and so prolong the period in which the animal can pass on the infection.

Pathogenesis

If little is known of the epidemiology of CBPP, even less is known of the pathogenesis of the disease. When

infection passes down the respiratory passages there is a bronchiolitis and alveolitis leading to pneumonia and pleurisy. It is thought that the galactan plays a part in attaching the organism to the mucous membrane and so preventing the body defences from eliminating the organism. Some workers believe that hypersensitivity or autoimmune reactions are responsible for the lesions and there is some evidence for this. It is hoped that by use of modern molecular techniques this will be resolved. It has also been suggested that there is a diffusible toxin which stimulates the formation of the fibrous capsule around the necrotic tissue. Some workers believe that the galactan acts as an endotoxin and causes systemic reactions similar to those seen in infection by Gram-negative bacteria; this is not proven. Until recently it was believed that only one lung was affected, which would support the suggestion of an autoimmune phenomenon. However, in recent outbreaks lesions have been seen, in a very few animals, in both lungs. This may be the result of antibiotic treatment. As can be seen from the foregoing, much needs to be done to give a clear understanding of the pathogenesis of CBPP.

Clinical signs

At least these are clearly understood! In the hyperacute form the animal may be found dead, without premonitory signs, but this is not common. The acute disease is characterized by fever, lethargy, loss of appetite and pneumonic signs. The animal stands with elbows abducted and the neck stretched out, the mouth open and the tongue protruding (Fig. 49.2). From time to time it may emit a soft, moist cough. The pleurisy causes severe pain and the animal will grunt if the chest is

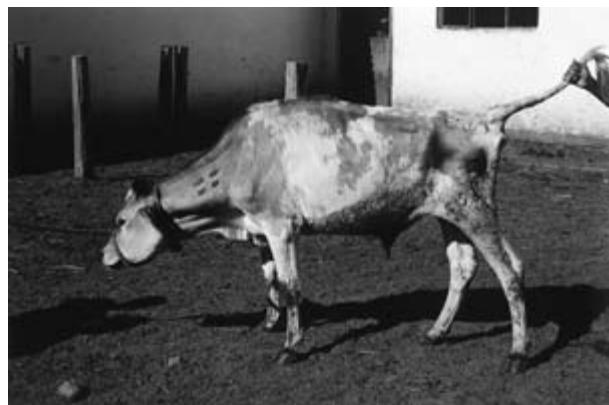

Fig. 49.2 Animal showing signs of acute CBPP – The animal stands with elbows abducted and the neck stretched out, the mouth open and the tongue protruding.

touched. Because the chest is so painful it is uncommon for an animal with the acute disease to lie down and it will remain on its feet until almost the end. Filthy mucus runs from the nostrils and saliva may drool from the mouth. Pregnant cows may abort and the fetal fluids contain vast numbers of mycoplasmas. Despite the size and nature of the lung lesions, it is often difficult to identify the site of the lesions by percussion or auscultation. Although there may be massive kidney infarcts present it is rare for an animal to show signs of renal disease. If the animal survives the signs grow progressively less pronounced, the nasal discharge may well become purulent, the animal will lose a considerable amount of flesh and become emaciated. The larger the lesions, the slower the recovery.

There is a great variety of clinical manifestation from this dramatic picture down to almost no clinical signs at all. What determines the size of the lesions and hence the clinical picture is not known. In any outbreak it is possible to see acute, subacute and chronic disease, often all three pictures at the same time. Many workers

state that relapses occur, but there are no published reports of this actually happening.

Although calves can develop the classical lung lesions and show the same signs as the adult, this is uncommon. The more typical picture is one of swollen joints caused by a fibrinous bursitis (Fig. 49.3). For some unknown reason it is more commonly the forelegs that are affected.

Post-mortem findings

In the animal that has died from acute disease, the first thing seen is the vast quantities of straw-coloured pleural fluid in the chest cavity; 10 litres or more have been reported (Fig. 49.4). The fluid may contain pieces of fibrin that have broken off from the pleural adhesions, and up to 10^9 mycoplasmas per ml. A localized or diffuse pleurisy may be present, appearing like an omelette.

Acute lesions vary in size from 1 to 2 cm in diameter to those affecting the whole of the lobe. More than one lesion may be present but they are usually restricted to

Fig. 49.3 A young calf with CBPP, showing swollen joints caused by a fibrinous bursitis.

Fig. 49.4 Carcass of an animal with acute CBPP, vast quantities of straw-coloured pleural fluid in the chest cavity; 10 litres or more have been reported. Note that one lung is diseased but the other appears normal.

Fig. 49.5 Lungs of an animal with acute CBPP. The characteristic lesion is 'marbling', identical to that seen in acute pasteurellosis.

one lung. The characteristic lesion is 'marbling', identical to that seen in acute pasteurellosis (Fig. 49.5). Interlobular oedema and fibrin deposits highlight the structure of the lung. The lung tissue itself may be dark red or changing to grey and thrombi may be seen in the vessels. These thrombi result in infarction of the portion of the lung supplied. The tissue dies, separates from the healthy surrounding tissue and becomes walled off into a sequestrum. The nineteenth century Dean of the Edinburgh School, Thomas Walley, likened the sequestrum to an 'Egyptian mummy in its case' (Fig. 49.6). Small sequestra will disappear over time, to be replaced by scar tissue, but the larger ones can remain for life. *M. mycoides* has been isolated from the tissue in a sequestrum up to 27 months after the animal was infected. It was rare for these sequestra to become secondarily infected by other bacteria, but in recent outbreaks such infection has been seen. This may be a result of antibiotic treatment.

Histological examination is not very useful in making a diagnosis as the lesions are not pathognomonic. The lesion commences with a severe hyperaemia of the affected lung and associated pleura with effusion of erythrocytes, neutrophils and macrophages. There is a massive serofibrinous effusion into the alveoli and the interlobular septa. Vasculitis and thrombosis of arteries occur in the affected parts of the lung. This results in the necrosis of that area supplied by the vessel and the onset of sequestration. This commences with a layer of inflammatory cells separating the infarcted area from the surrounding healthy tissue. Granulation and fibrosis separate the infarct from the healthy tissue.

Lesions resembling sequestra may be seen in the mediastinal and bronchial lymph nodes and they are always enlarged and oedematous. Infarcts in the kidney are common in animals with acute disease, and they are

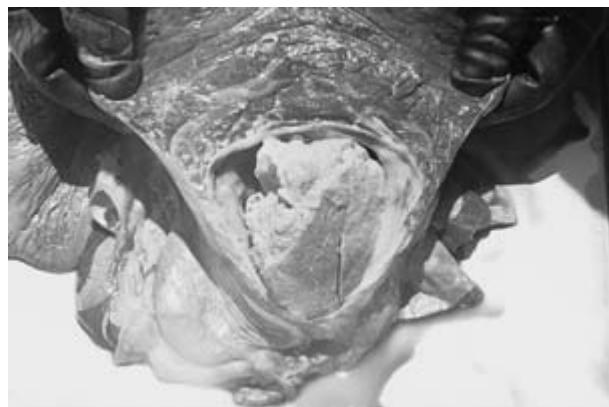

Fig. 49.6 Lung of animal 27 months after infection, showing a walled-off sequestrum. Thomas Walley, likened the sequestrum to an 'Egyptian mummy in its case'.

thought to be caused by emboli from the lung settling in the kidney. They can be of any size and number and one or both kidneys may be infected; the colour of the infarcts varies from white to red to black. Lesions affecting the joints of calves are normally bilateral, serofibrinous tendosynovitis or occasionally arthritis. Lesions are mostly seen in knees and lower joints of the forelegs. A valvular endocarditis has been reported in calves.

Diagnosis

A presumptive diagnosis should be based on the history, the clinical signs and the post-mortem findings. However, it is essential that the presence of *M. mycoides* be confirmed. The isolation and identification of the mycoplasma gives a certain diagnosis; growth inhibition or immunofluorescent antibody tests can be used to identify the organism once it has been isolated. Under African conditions this may not always be possible, particularly if the outbreak occurs at a great distance from the laboratory. In such cases samples of pleural fluid can be taken onto blotting paper and then dried. These papers can then be examined by an agar gel diffusion test (AGT) or the newer polymerase chain reaction (PCR).

In the live animal serological tests are required to confirm a diagnosis. The simplest crush-side test is the slide agglutination serum or blood test (SAST or SABT) using a stained antigen. It is cheap to produce, easy to carry out and has therefore been discarded! False positive results to this test occur, but they do to all serological tests. The complement fixation (CF) test is the test approved by the Office International des Épizooties (OIE) as the definitive test for the confirmation of CBPP. This workhorse was developed in Australia and has been used successfully throughout Africa

for the control of the disease. It does not require expensive equipment or reagents but it is a complicated test to perform, although once mastered, the technique can produce excellent results on a regular basis. The complaint is that CF antibodies do not persist in animals with sequestra. If these animals play no part in spreading the disease, then this is of no importance. The technique has been modified to be carried out in the African bush, but apart from Zambia, this field test is no longer in use in Africa. After vaccination some cattle develop CF antibodies but by 12 weeks these antibodies have gone and at present there is no satisfactory way of determining whether or not an animal has been vaccinated. The new enzyme-linked immunosorbent assay (ELISA) suffers from the same deficiencies. In the absence of post-mortem evidence, it would be a brave veterinarian who diagnosed CBPP on serological findings alone.

Differential diagnosis

Acute pasteurellosis (p. 286) is the condition with which CBPP is most likely to be confused, but the former regularly affects both lungs. A cultural examination of the lesions should identify the cause. Pneumonic lesions of east coast fever (ECF) (p. 750) could be confused with those of CBPP, although pleurisy is not normally a feature of ECF and there are concurrent lesions in the spleen and lymph nodes of animals with ECF. Examination of Giemsa-stained preparations of smears from spleen or lymph node should confirm the diagnosis of EFC.

Sequestra can be mistaken for the cysts of parasitic infestations, particularly echinococcus (p. 281), or aberrant liver flukes (p. 276).

Vaccination (see p. 1011)

There is no treatment for this disease and so vaccination is an important means of protection of the animals. At the turn of the last century, pleural fluid or diseased lung was injected under the skin of the tail to protect the animals. Rider Haggard in his novel 'King Solomon's Mines' refers to this technique for protecting cattle from the 'lung sick'. He points out that this often resulted in the animal losing its tail, which he considered preferable to losing its life. Throughout the twentieth century workers have looked for vaccines. It appears that only live vaccines produce protection. The Australian workers developed the V5 vaccine, which was acceptable in Australia, because there farmers considered that if a few animals did not die after vaccination, then the vaccine had not worked. Such a vaccine could not be used in Africa. In the Sudan the KH3J vaccine was used; although it caused no reactions it also failed to protect cattle. The T₁ vaccine was first used as an 'egg vaccine',

but caused many adverse reactions and some deaths; however, the broth vaccine gave good protection without producing too many adverse reactions. Laboratory and fieldwork showed that it produced a solid immunity for more than a year. The T₁ broth vaccine was then lyophilized, but it was too expensive to test this new vaccine and so it was assumed that since it was a T₁ vaccine it would work! By passage in the presence of streptomycin, a streptomycin-resistant variety of the T₁ strain was produced. This enabled the vaccine to be mixed with the rinderpest vaccine and so reduce the delivery costs. Again this new vaccine was not tested. Perhaps this is why the new T₁ does not work very well!

Control

CBPP is a disease of cattle movement; stop movement and the spread of disease is halted. Many countries freed themselves from infection by prohibiting movement and slaughtering infected animals or herds. When CBPP was introduced into Botswana in 1995, the disease was eradicated by preventing animals from moving and a stamping-out policy. The price of freedom from CBPP was in excess of \$200 million and there are few African countries that can afford such an expense. For Botswana this was an economically sound policy because it protected their markets in Europe.

In almost all African countries CBPP is a notifiable disease and there are official controls on the import of cattle. However, in many countries there are nomadic people who have moved from country to country before the borders existed, e.g. the Fulani in west Africa and the Maasai in east Africa. A recent outbreak of CBPP in Tanzania resulted from the theft of two animals in Kenya by Tanzanian Maasai who moved the animals across the unmarked 'border'. Lack of appropriate action by the Tanzanian authorities has resulted in the disease spreading the length and breadth of the country. Wars, famine and inadequate financing of veterinary departments have resulted in CBPP running riot in east and central Africa. Unless something is done to stop the spread it will not be long before the disease topples over into Malawi and Mozambique, two of the countries in sub Saharan Africa which have never experienced CBPP. From there the whole of southern Africa is at risk. Early warning of the arrival of the disease is imperative for adequate control. To this end, it is essential that all animals that are slaughtered, be it in an abattoir, on a slaughter slab or in the bush, and are examined by a trained member of the veterinary department to ensure that they are not carrying lesions of CBPP.

Rinderpest has almost been eradicated from Africa; it is time that the international community turned its attention to the control of CBPP on the continent. To this end research into vaccines, epidemiology and diag-

nostic methods are required. Strangely enough these were the topics of investigation for Joint Project 16 over thirty years ago.

| Atypical mycobacteriosis | 886 |
| Dermatophilosis (bovine streptothricosis) | 886 |
| Horn cancer | 887 |
| Lumpy skin disease and pseudo-lumpy skin disease | 887 |
| Lumpy skin disease | 887 |
| Pseudo-lumpy skin disease | 888 |
| Other conditions having skin signs | 888 |

The skin of the ox shows general conformity with the anatomical characteristics of the large domestic animals (Fig. 50.1). Approximately 7 mm in thickness, it consists of epidermis and dermis and their adnexa. The hair follicles are simple and carry a single hair, the colour of which, depending on body site and breed, may be black, white or a wide variety of variants of brown or grey. Single hairs leave the skin surface at an angle, each follicle having an erector pili muscle allowing the hair to be raised to a more upright position.

Hair growth and replacement is a cyclic process of active growth (anagen) when the hair follicle is producing a new hair, and a period of rest (telogen) when the mature hair, which now has a constricted bulb and is referred to as a 'club' hair, is held in the hair follicle before being shed.

Sweat and sebaceous glands are distributed over the body surface and show specialization in certain areas, e.g. the mammary gland, naso-labial glands of the muzzle. At the extremities of the limbs and on the head of horned breeds the skin is specially modified to form the hooves and horns.

Skin diseases of cattle

Primary disease of the skin of cattle is more commonly attributable to parasite infestation or fungal infection.

Bacteria and viruses play a minor role except when skin signs are associated with systemic infection by these organisms. Allergic disorders are also uncommon and genetic diseases rare.

The effect of skin disease on the livestock industry

Where animals are reared to provide food and other byproducts, skin disease, although clinically not in itself serious and rarely life-threatening, may cause significant losses to the agricultural industry through the following effects:

- The debilitating effect of pruritus on the affected animals. Heavy louse infestations or infestation by sarcoptic mites causes irritation, restlessness and weight loss.
- Damage to hides from self-trauma or the migration of parasitic larvae.
- Damage to tissue from bacterial infection or larval migration resulting in condemnation or trimming of meat at slaughter.
- Limitation of sale value or show potential of infected animals and their danger as vectors of disease to other stock.

Warble fly

The insect is also known as warbles, cattle grubs, gad fly or *Hypoderma* infestation and is due to the migrating stages of a parasitic insect (see p. 740). Two species of warble fly are recognized in many countries of the northern Hemisphere, namely *Hypoderma lineatum* and *Hypoderma bovis* and they differ little in their territorial distribution. These parasites are not found in the southern hemisphere as they have not become established, despite importation of infected cattle.

Cattle, particularly young stock at pasture, are the definitive host for the parasitic stages of the life cycle although other species are recorded as occasionally being infested, such as horses, deer, goats and even man. In species other than cattle the life cycle is rarely, if ever, completed.

Life cycle (see Figs 50.2 and 50.3)

Warble flies become active in the spring and on warm days in the summer months adult females (up to 15 mm long) home in on grazing cattle and alight on the hairs of the lower limbs, on which they lay their eggs. *Hypoderma bovis* lays its eggs singly while *H. lineatum* lays a row of six or more on a hair. The egg-laying behaviour of the flies causes irritation and restlessness to cattle and attempts are made to avoid the flies by running away. Characteristically, this is seen as initial

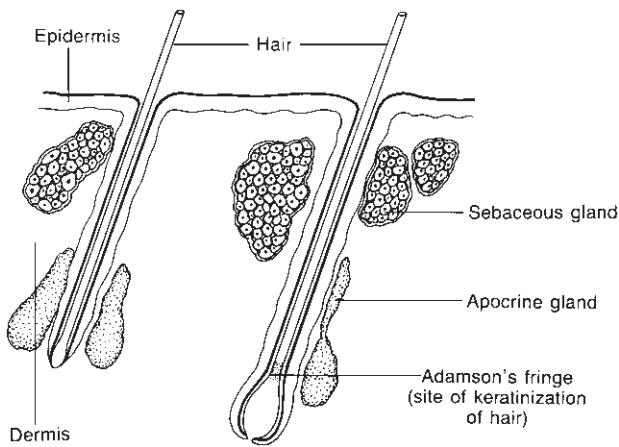

Fig. 50.1 Diagrammatic representation of bovine skin.

apprehension among a group or an individual animal, followed by suddenly taking flight at a gallop, tail in the air, suddenly turning and repeating the movement in an effort to shake off the pursuing flies. This is known as 'gadding'.

Once ova are attached to the hairs they hatch in four days and larvae crawl to the skin surface, through which they penetrate to the connective tissue and wander for four to five months. Migratory patterns within the host differ: *H. lineatum* moves to the submucosal connective tissue of the oesophageal wall while *H. bovis* goes to the region of the spinal canal and epidural fat. At these sites they remain for the autumn and winter. As second-stage larvae they migrate towards the back of the host where further maturation takes place.

Large domed nodules are formed under the skin within 30–45 cm (12–18 inches) on either side of the spine, in which the now third-stage larva produces a ventral breathing pore. Grubs within the nodules progressively increase in size to 25–28 mm in length, depending on species. In the spring the larva emerges from its cyst, falls to the ground and pupates. After a period of four to six weeks the adult fly emerges.

Effect of *Hypoderma* larvae on the host

Fly attacks: Considerable 'worry' is caused to cattle when approached by these flies; this results in restlessness that interferes with grazing and may result in poor weight gain. Milking cattle show a fall in milk yield.

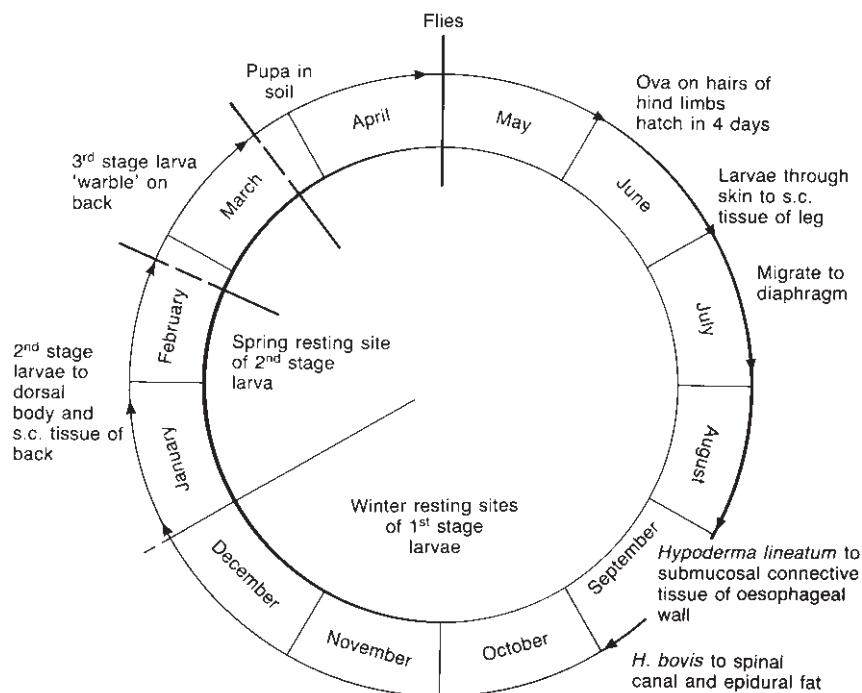

Fig. 50.2 *Hypoderma* spp. life cycle.

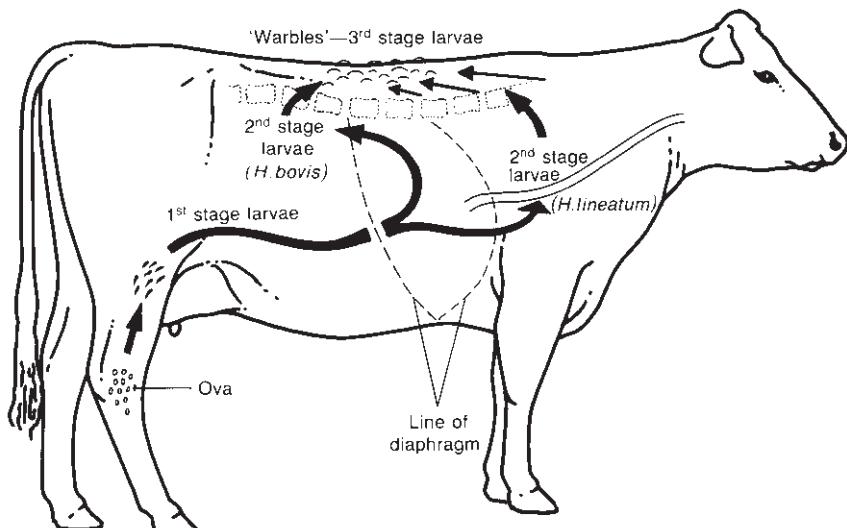

Fig. 50.3 Migration of warble fly larvae within cattle.

Damage by larvae

- Carcasses. The presence of grubs may necessitate trimming of meat at slaughter or, in some cases, condemnation. Trimming makes the carcass less aesthetically acceptable and so it can disproportionately reduce the price when meat is plentiful.
- Hides. Maturation of warble fly grubs to the stage where they make breathing pores causes serious damage to the dermis and results in downgrading of affected hides.
- Rupture of larvae. This occasionally precipitates an immunological reaction.

When migrating in the earlier stage of the life cycle, *H. lineatum* larvae may cause an oesophagitis when they reach the oesophageal wall; *H. bovis* larvae can result in posterior paralysis.

Treatment and control (see p. 1031)

Treatment of lesions associated with the maturation of the migrating larvae has now been superseded by preventive measures.

Since the range of activity of *Hypoderma* flies is limited to 5–14 km (3–9 miles), control of infestation by eradication is feasible provided neighbouring stockkeepers treat their animals.

Organophosphorus preparations. Organophosphate systemic insecticides have been found to be the most effective agents for the eradication of *Hypoderma* larvae, the aim being to destroy them early in the infestation before they reach resting sites near the neural canal or are themselves very large.

Table 50.1 Dose rate for pour-on treatment using Phosmet 13 per cent w/v.

| Weight of animal (kg) | Dose (ml) |
|-----------------------|-----------|
| Up to 130 | 20 |
| 131–200 | 30 |
| 201–260 | 40 |
| 261–330 | 50 |
| Over 330 | 60 |

Preparations used include phosmet, trichlorfon, fenchlorphos, coumaphos and fenthion. All are cholinesterase inhibitors and knowledge of their actions, in particular their toxic effects and antidotes, is essential before using them for warble treatment (see p. 940).

Organophosphorus preparations have been employed by dip, spray and wash. The most satisfactory method of application has been shown to be the 'pour-on' procedure. An example of pour-on treatment, using Phosmet 13.3 per cent w/v solution, is shown in Table 50.1.

Cattle should be treated in autumn (15 September to 30 November) or in the spring (15 March to 31 June). Best results are obtained by autumn treatment and prevent skin nodule formation by the third-stage larvae in the spring. No treatment should be given between 1 December and the following 14 March because of possible reactions at the winter resting sites due to the death of the warbles.

Animals being treated on the above regimen should not be given organophosphorus anthelmintics, levamisole or diethylcarbamazine citrate at the same time.

Special precautions regarding the use and handling of organophosphorus preparations, particularly with regard to wearing protective clothing, are applicable and reference to the manufacturer's data sheet is essential before their use.

In Great Britain warble fly infestation is a notifiable disease. The efficacy of control measures aimed at eliminating warble infestation can now be monitored serologically.

Ivermectin: The systemic parasiticides based on ivermectin are also effective in destroying warble grubs. One per cent ivermectin injection may be used according to the manufacturer's recommendations after the end of the period of fly activity and before the larvae reach their resting sites. The milk of treated cattle may not be used for human consumption, or manufacturing purposes or within 60 days prior to parturition. Meat animals must not be slaughtered within 35 days of their last treatment.

Dermatophytosis (ringworm)

The infection of hair and skin keratin with the dermatophytes *Trichophyton verrucosum*, and less commonly *T. mentagrophytes*, causes lesions commonly referred to as ringworm. This disease has a worldwide distribution, the incidence of which is considered to be high although an accurate figure for its occurrence is not known. It is particularly common in young stock between two and seven months of age and during the autumn and winter months of the year. Adult cattle are also frequently affected.

Animals kept in close contact with one another, e.g. under intensive management systems, are particularly at risk. Other species may also be infected, including horses, sheep and also man in whom it may cause serious skin lesions. Although not giving rise to serious systemic debilitating symptoms, the effect of ringworm is on the value of the animal or its hide.

Show animals with the disease may not be shown or sold, infected stock carry a depreciated market value when offered for sale and the hides of animals slaughtered show defects that render them less valuable for top-quality leather manufacture.

Epidemiology

The spores of ringworm fungi survive for many months and in some cases years in the farm environment. They may be transmitted either by fomites or by asymptomatic carrier animals to susceptible hosts.

The *incubation period* of the disease is generally considered to be approximately one week although four weeks has been suggested as the period in some outbreaks. Once in contact with the skin surface of a susceptible animal, the fungus invades the anagen hairs (telogen hairs are not affected) by enzymatic destruction of keratin. Hyphal growth extends only as far as the point at which keratinization of the hair takes place (Adamson's fringe).

The hair, so weakened, breaks off, leading to the partial alopecia seen on clinical lesions of dermatophytosis. A generally mild inflammatory reaction accompanies the infection; only occasionally is this severe in cattle, leading to excess production of skin scale, folliculitis or furunculosis.

Signs

The disease is usually non-pruritic in cattle. Lesions are characteristically greyish-white and have an ash-like surface. Their outline is circular and they are slightly raised due to the accumulation of many layers of scale and the swelling of tissues beneath due to a moderate inflammatory reaction. Some lesions may show areas of mild exudation and yellow crust formation where the skin reaction is more severe. Removal of hair tufts or some of the accumulated crust will often leave a raw bleeding surface. Broken hairs remain as hair stubble encased in scale and crust (Plate 50.1).

The size of lesions varies, 3–5 cm (1–2 inches) diameter being common; in the more severely affected animals lesions become confluent to form extensive areas of infection (Plate 50.2).

The distribution of lesions in calves commonly involves the periorbital skin, ears and back, while in adult cattle the thorax and limbs are the more favoured sites. In show cattle subjected to grooming, multiple small lesions develop over the whole of the body and limbs following the spread of infective spores by contaminated grooming brushes. Very occasionally the udder can be affected (Plate 27.29).

Duration of the disease

Ringworm infection is generally considered to be self-limiting and the course of the disease to be one to four months, although in some cases a period as long as nine months has been necessary for resolution to take place. These periods may be shortened by implementing the appropriate therapeutic measures.

Diagnosis

Diagnosis is made on the clinical signs of classic lesions of dermatophytosis confirmed by the laboratory examination of hair and crust samples.

Collection of samples

- (1) By forceps epilation of hair from areas of active infection.
- (2) Scrapings of crust, hair and scale using a scalpel blade.

Using either of these procedures the material obtained is collected in a paper envelope (ensuring that the quantity of sample is adequate for the diagnostic procedures to be carried out), sealed and labelled for transmission to the laboratory.

If culture is contemplated, swabbing the area with 70 per cent alcohol prior to collection of material may reduce contaminants in the specimen.

Laboratory diagnosis: Arthrosporic hyphae on hairs can be demonstrated using the microscope.

- (1) Wet preparation of suspect material on a microscope slide with coverglass mounted in 20 per cent potassium hydroxide solution and gently warmed.
- (2) Wet preparation in lactophenol cotton blue on a microscope slide under a coverglass.
- (3) Wet preparation on a microscope slide under a coverglass mounted in potassium hydroxide/Super Quink solution.

In all procedures using the microscope for the examination of wet preparations care is necessary in adjusting the microscope illumination in order to visualize arthrosporic hyphae. This is equally applicable to the examination of portions of cultured material.

Definitive diagnosis of the species of fungus may be obtained by culture techniques using Sabouraud's agar, mycobiotic agar, or dermatophyte test medium (DTM), and observing the characteristics of the organism, i.e. colonial morphology and that of the hyphal growth. In order to arrive at a conclusive answer culture time may need to be extended, i.e. for as long as three weeks.

Using Sabouraud's agar, rapid identification of *T. verrucosum* may be achieved by culture at 30–37°C (34°C), when the colony shows long chains of chlamydospores characteristic of the organism.

The DTM may be used to suggest a positive diagnosis of a pathogen by observation of the indicator colour change.

Definitive diagnosis is only by identification of cultural characteristics.

Treatment

Owing to the difficulty in eliminating the organism from the environment in which many cattle are kept, and the number of animals involved, the reward for treating the disease with such preparations as are suitable (these

may only succeed in moderately reducing the duration of the disease) has brought the therapy of ringworm in cattle into question. Scott (1988) refers to 'a sea of anti-fungals' for the treatment of animal ringworm, many of which are of questionable efficacy. The choice of therapy depends on the availability of appropriate antifungal agents.

Systemic treatment

- (1) *Griseofulvin*. An oral feed supplement given at a dose of 10mg/kg body weight for 7–14 days. In the USA an alternative routine of 15–35 mg per kg body weight for 18–30 days is considered more effective. Pregnant animals should not be treated with this preparation. Milk from treated animals should not be used for human consumption until 48 hours after the last treatment. Cattle should not be slaughtered for human consumption until five days after the last treatment. It is no longer available for cattle in the UK.
- (2) *Sodium iodide*. A dose of 1g/14kg body weight as a 10–20 per cent aqueous solution is given by intravenous injection, followed by a repeat injection seven days later. Pregnant cattle should not be treated with iodide therapy. Cattle so treated may show signs of iodism (pp. 261, 302, 823).

Topicals

Imidazoles: A wide range of imidazole preparations have been formulated for the treatment of fungal skin infections.

Enilconazole (Imaverol, Janssen Animal Health): Cattle may be treated by spray or wash using a 0.2 per cent w/v emulsion of enilconazole in water. It is recommended that excess scab and crust be removed by scrubbing with a stiff brush soaked in the antifungal emulsion. Subsequent treatments by spraying or wash are made on three to four occasions at three-day intervals.

Other preparations:

Natamycin (Mycophyt, Intervet UK Ltd): A dry powder for the preparation of a 0.01 per cent suspension in water is available for application to cattle by spray or wash. Special care is necessary in reconstituting the powder, for the final suspension reference should be made to the manufacturer's data sheet. Following an initial treatment a repeat application may be made four to five days later. Subsequent treatments can follow at 14 day intervals. Following treatment with natamycin suspension animals should be sheltered from direct sunlight for several hours.

Copper naphthenate (Kopertox): A topical preparation presented as an aerosol containing 2.19 per cent w/v copper naphthenate. Lesions to be treated should be thoroughly soaked with a solution. A repeat treatment may be given after an interval of 10 days if necessary. The product is now not available in some countries.

Iodine: A liquid made up of equal parts of tincture of iodine and glycerin has been used for the treatment of individual lesions of ringworm on cattle.

Note: Special precautions are necessary in the application of topical preparations. Care should be taken to avoid sensitive areas, the eyes in particular and also the transfer of topical applications to other animals in contact with those under treatment.

Prophylaxis

Griseofulvin at a dose of 7.5–60 mg/kg per day for five weeks has been suggested as a prophylactic against dermatophyte infection. Pregnant animals should not be treated. However, animals so treated will not be immune to disease and so may become infected at a later date.

Immunity

The role of immunity in the epidemiology of outbreaks of cattle ringworm remains unclear. Re-infection after natural infection appears to be uncommon.

Vaccination (see p. 1017)

The immunization of cattle against *Trichophyton verrucosum* infection has been practised in Russia and Norway and a vaccine is now available in the United Kingdom (Ringvac Bovis LTF-130, Intervet Ltd). Freeze dried material prepared from an attenuated non-pathogenic strain of *T. verrucosum* is reconstituted for the inoculation of young calves at two weeks of age. Two inoculations are recommended at an interval of 10–14 days by intramuscular injection into the neck.

Disinfection

Viable spores of ringworm fungi may remain in buildings and particularly on porous surfaces, e.g. wood, brick, for months or years, making disinfection difficult.

Cleansing with high pressure water jets, scrubbing down with hot detergent solutions or disinfectants (e.g. benzalkonium chloride) or alternatively, disinfection with 2 per cent formaldehyde solution after prior scrubbing can remove infection. When using disinfection procedures, i.e. spraying and scrubbing walls, doors, etc., special precautions should be taken to prevent contact with the preparation used, e.g. on the skin, in the eyes and by inhalation, particularly when using solutions of

formaldehyde. The wearing of appropriate protective clothing in conformation with health and safety regulations is essential.

Parasitic skin disease

Lice (*pediculosis*) (Plate 50.3)

Lice are somewhat dorso-ventrally flattened insects up to 6 mm in length that are host-specific parasites.

The distribution of lice is world-wide. The species infecting cattle are the biting louse *Bovicola (Dama-linia) bovis*, and the sucking lice *Haematopinus eurysternus*, *Linognathus vituli*, and *Solenopotes capillatus*. The biting lice feed on tissue debris while the sucking species suck blood and tissue fluid (see p. 741).

Life cycle

The entire life cycle of approximately three to six weeks' duration is spent on the host. Adult females lay their eggs and attach them singly to hairs. These appear as pearly or opalescent bodies (nits) 1–2 mm long. From the egg immature nymphs emerge, and pass through several moults before becoming adult. Survival off the host is short, usually less than one week. However, under certain conditions lice have been recorded to survive for periods up to three weeks.

On the host, populations of lice vary seasonally, being highest in colder seasons when the coat is long and transmission by contact from animal to animal readily occurs. Lower populations in the warmer seasons are due to the higher environmental temperature of the skin and coat in which lice cannot survive.

In spite of these factors, small populations may survive in protected areas, i.e. the ears, axillae, jowl, tail, ready to multiply when environmental conditions become beneficial.

Distribution of infestation on the host

Biting lice occur mainly on the neck, withers and tail head. Sucking lice are commonly found as a more generalized infestation, occurring on the head, neck, withers, down the brisket, tail, axillae and groin.

Signs

The cardinal sign is pruritus, the resulting restlessness leading to poor feeding and poor weight gain. The coat is poor in condition, often with alopecia and excoriation due to self-trauma, with loss of coat lustre and excess dandruff as well as hide damage. Animals in milk may show lowered production. Infestations with sucking lice may give rise to anaemia and consequent increased susceptibility to concurrent disease.

Diagnosis

This depends on the demonstration of lice and eggs within the coat. Because of pruritis, the only major disease to be differentiated is mange.

Treatment (see p. 1030 onwards)

Louse infestations of cattle may be controlled by the application of antiparasitic sprays, powders, washes, 'pour-ons' and certain injectable preparations. The use of these should be complemented by attention to management and husbandry aimed at eliminating reservoirs of infection and improving nutrition.

Antiparasitics for louse control, of which there are many, are based mainly on organochlorine, organophosphorus and synthetic pyrethroid active principles, e.g. Gamma BHC powder (0.625 per cent), Coumaphos powder (1 per cent), Diazinon wash (2 per cent), Phosmet 'pour-on' (13.3 per cent) and Permethrin 'pour-on' (4 per cent).

Ivermectin 200–300 µg/kg subcutaneously is effective against sucking lice but of variable efficacy against the biting species. Before use reference should be made to the manufacturer's data sheet for details of special precautions to be observed, e.g. milk withholding times of dairy cattle, permissible intervals between treatment and slaughter of meat animals.

Mite infestations: mange, scabies

Infestation of the skin of cattle with parasitic mites may be by any of four species: *Sarcoptes scabiei*, *Psoroptes communis*, *Chorioptes bovis* or *Demodex*. The incidence of disease due to these shows variation in different parts of the world in respect of the species of mite and pathogenicity (p. 742).

Sarcoptic mange, sarcoptic scabies

Sarcoptes scabiei (bovis) (Plate 50.4) has a life cycle of 10–17 days and may infest cattle of any age, breed or sex. Infection takes place by direct contact with infected cattle or with environmental fomites, although survival of the mites in the environment is limited to a few days.

Signs: *Sarcoptes scabiei* causes an intensely pruritic papular dermatitis due to the burrowing activities of the female mites within the superficial epidermis and a concurrent hypersensitivity reaction. This results in a non-follicular papular response, exudation and crusting with self-trauma in an attempt to relieve the itching. This produces excoriation, alopecia and thickening of the skin (Plate 50.5).

Lesions commonly commence about the head and spread to become generalized with gross thickening of skin folds. In some animals these lesions may be accom-

panied by secondary infection with bacteria (Plate 50.6).

The persistent intense pruritus causes debility, loss of condition, poor food conversion, hide and skin damage and in dairy cattle a reduction in milk yield. Workers in close contact with affected animals may show papular skin lesions.

Diagnosis: Physical examination, history, possible human involvement, demonstration of *S. scabiei* in skin scraping material examined microscopically all help the diagnosis. In exceptional cases skin biopsy may be helpful.

The main differential diagnosis is with psoroptic/chorioptic mange.

Treatment and control (see also p. 1030)

- (1) Organophosphorus pour-ons, dips, sprays.
- (2) Gamma BHC 7.5 per cent (not milking cows) 5–25 ml in 6 l water.
- (3) Diazinon 2 per cent wash, 28 ml in 4.5 l water.
- (4) Phosmet 20 per cent pour-on.
- (5) Permethrin 4 per cent pour on.
- (6) Ivermectin 200–300 µg/kg by subcutaneous injection.
- (7) Amitraz (Taktic, Intervet Ltd). A 0.025 per cent solution in water is applied by spray at 5 to 10 litres per animal to wet the whole body. This should be repeated after an interval of 7 to 10 days in severe cases. Further applications if necessary may be made at two to three month intervals. Special precautions apply to operatives using this preparation in respect of the wearing of protective clothing for which reference should be made to the manufacturer's data sheet. The milk withholding time for milking cattle treated with amitraz solution is 48 hours after the last treatment.
- (8) In circumstances where the above preparations are not readily available, lime/sulphur dips can be effective. The disadvantage associated with this treatment is that repeat applications at 7 to 10 day intervals may be required on as many as six occasions.
- (9) Synthetic pyrethroids.

These are examples of preparations available. Application routines may vary and response to treatment will determine how many applications may be required. Reference to the appropriate data sheet is essential for information on special precautions and withdrawal times to be observed (see for lice, above).

Psoroptic mange, psoroptic scabies

Psoroptes mites are non-burrowing and have a two-week life cycle. Survival off the host may be as long as

three weeks. Transmission of infection is by direct or indirect contact.

Signs: Infection commences over the withers and spreads to the rest of the body. Lesions are papules accompanied by severe pruritus leading to extensive serous exudation and crusting with alopecia and lichenification. Irritability and consequent debility may result in unthriftiness, poor weight gain, hide damage and reduced milk yield in lactating animals.

Diagnosis: The diagnosis is by demonstration of mites by microscopic examination of wet preparations of skin scrapings. Differential diagnosis is with sarcoptic scabies, and chorioptic scabies.

Treatment: Treatment is the same as for sarcoptic scabies, although care is needed to ensure that infection has been eradicated. Resistance to treatment has been recorded.

Chorioptic mange, chorioptic scabies

Chorioptes bovis is a superficial, non-invasive inhabitant of cattle skin. Living on epidermal debris, it has a life cycle on the host of two to three weeks. It survives only a few days off the host under natural environmental conditions although under experimental conditions it may live as long as 10 weeks.

Transmission of infestation is usually by contact. Outbreaks among housed dairy cattle are higher in the winter time when mite populations are greatest.

Signs: Non-follicular pruritic papules result in self-trauma accompanied by erythema, excoriation, exudation, alopecia and the formation of crusts. These mostly involve the limbs, particularly the hindlimbs, the udder, scrotum, perineum and tail. The neck and flanks may also be involved.

Diagnosis: Diagnosis is by the microscopical demonstration of causal mites in wet preparation of skin scrapings. The differential diagnosis is with infestations with lice (p. 880) and other parasitic mites.

Treatment: Treatment is the same as for sarcoptic scabies. Apparent spontaneous regression may occur in the summer months when infestation appears to be confined to the distal limbs.

Demodicosis

Demodectic mites are considered to be normal residents of the skin of many species of wild and domestic animals. They are apparently host specific and live mainly within the hair follicles and sebaceous glands.

Three species of *Demodex* mites have been identified in cattle, the life cycle of which, as in other hosts, is obscure. Transmission of infection occurs from dam to calf by contact during suckling. No age or sex predilection has been established, nor is it clear why an organism living as a commensal should suddenly become a pathogen by its rapid unpredicted multiplication; immunodeficiency has been suggested as one cause.

Signs (Plate 50.7): Multiple nodules, sometimes secondarily infected, result in folliculitis and furunculosis of the face, neck and shoulders, occasionally becoming generalized. The disease is usually non-pruritic but nevertheless results in severe hide damage and consequent economic loss.

Diagnosis: With skin scrapings, wet preparations of expressed nodule contents examined microscopically show caseous sebaceous masses and large numbers of mites.

Histology of skin biopsy shows distended hair follicles packed with mites. Secondarily infected lesions show folliculitis, furunculosis and dermal granuloma formation.

Differential diagnosis is with dermatophytosis (p. 878) and dermatophilosis (p. 886).

Treatment: Demodicosis is often difficult to treat and prognosis is always guarded. Organophosphorus 'pour ons' have in some cases been found to be beneficial.

Warts (viral papillomatosis)

Bovine papillomatosis is commonly thought of as an infectious disease of the skin of mainly young cattle, usually self-limiting, widely distributed about the world, posing little difficulty in diagnosis, prognosis or treatment. The causal agent of the condition is a virus.

This is not, however, the whole story of bovine infection with DNA papovaviruses of which the bovine papilloma virus has certainly five, if not more, strains. Cross-reactivity between strains does not occur.

Papilloma virus appears to be host specific and transmission of bovine warts to humans handling infected cattle and cattle products has not been proven.

Of the strains of virus isolated, it appears that each has an anatomically determined predilection site of infection.

- (1) BPV type I causes frond-like lesions on the nose, teats or penis: fibropapillomas in young cattle (Plate 27.31).
- (2) BPV type II causes papillomatosis of the skin of the face, head, neck and dewlap, eyelids and occasionally legs of young cattle.

- (3) BPV type III causes atypical warts, small smooth white sessile lesions on the udder and teats (p. 367; Plate 27.32).
- (4) BPV type IV causes alimentary tract and urinary bladder papillomas and ocular lesions possibly progressing to squamous cell carcinoma.
- (5) BPV type V causes non-regressing rice-grain warts on the teats.

Interdigital fibropapillomatosis, although wart-like in character, has no proven viral aetiology.

Epidemiology

Infection may be spread either by direct contact with infected animals or indirectly by fomites, e.g. from fences by trauma through minor abrasions or by direct or indirect effects of ectoparasitism. Following infection lesions appear after a two to six-month incubation period.

Signs

Viral papillomatosis is commonly seen in young cattle and once established lesions will resolve in a period of one to twelve months. Commencing as small, smooth, hairless, firm, button-like elevations projecting slightly above the skin surface, they may be from 1 mm to several centimetres in diameter (Plate 50.8). They may develop to become coarse and cauliflower-like (Plate 50.9), sessile or pedunculated and single or multiple in number. Lesions are commonly sited on the head, neck and brisket and extensive generalization may occur.

Diagnosis

On clinical grounds the lesions are characteristic as is their distribution pattern on the skin and also the age group affected.

Histological examination shows epithelial proliferation with or without connective tissue proliferation: BPV I and II produce epithelial and fibrous proliferation; BPV III, IV and V produce epithelial proliferation.

Prognosis

In infection with BPV I and II, spontaneous regression within one to twelve months is the rule, while in the case of BPV III, IV and V and 'interdigital papillomatosis', lesions tend to be persistent.

Treatment and control (see also p. 1030 onwards)

With uncomplicated cases little treatment is required since spontaneous regression in young animals is the

rule. Occasional cases of generalization may be encountered and are likely to be due to a failure in cell-mediated immunity.

Autogenous vaccines (p. 1014) for the treatment of bovine papillomatosis are of doubtful value. Where large, persistent growths are present, e.g. on the neck, removal by cryosurgery or cold steel surgery may be attempted.

For the prevention of infection with BPV I and II, commercial and autogenous vaccines are claimed to be effective. The use of lithium antimony thiomolate 6 per cent w/v solution by deep intramuscular injection, 15 ml on each of four to six occasions at 48-hour intervals is claimed to aid enucleation and necrosis of pedunculated warts.

Disinfection

While control of infection by disinfection is not commonly undertaken, where recurrent outbreaks of disease have occurred in housed cattle attempts at disinfection may be justified. Solutions of formaldehyde or caustic soda in appropriate dilution may be used, hosing down all treated surfaces well with water after these solutions have been allowed to act and prior to restocking.

Urticaria

The physical manifestation of urticaria in the form of oedematous skin plaques or of angioneurotic oedema may be caused by a wide variety of factors. These may be immunological, as in Coombs' type I and II reactions, or non-immunological associated with injected irritants or non-immunological histamine release.

Some non-immunologic factors that may precipitate urticarial responses or intensify an already established reaction are pressure, sunlight, heat, exercise, drugs, chemicals, even psychological stress. Certain genetic disorders have also been implicated in the aetiology of urticarial reactions.

Urticaria is usually seen as an acute onset disorder having no age, breed or sex predilection, which runs an acute or chronic course. It mostly affects a single individual or, on occasion, a small group.

Signs

In cattle, urticarial reactions are associated with insect and arthropod bites and stings, infection, the administration of antibiotics, vaccines or other biological products, some feedingstuffs as well as stinging plants.

Lesions of urticaria may vary in size, often being plaque-like wheals, localized or generalized over the

neck, body and upper limbs in particular. They are usually cold to touch and may pit on pressure. Pruritus is variable as is the tendency for serum leakage onto the skin surface or for there to be haemorrhage. Urticarial lesions commonly show a well-defined shape or pattern, e.g. being ovalar, serpiginous or arciform, or in the case of angioneurotic oedema involve certain structures with extensive oedematous swellings.

Acute onset angio-oedema has been seen in the UK on turning out housed cattle onto spring pasture, manifest as oedematous swelling of the periorbital skin, muzzle, perianal and perivulval tissue and occasionally the udder and teats. The condition is usually transient and apparently causes little distress. More severely affected animals may show evidence of respiratory distress.

In the USA a form of auto-allergic urticaria has been described in Jersey and Guernsey cattle. Affected individuals are believed to have a genetic predisposition to an allergic response when there is unusual engorgement of the udder or undue retention of milk. Clinical signs are of allergic urticarial skin rash and, in some individuals, respiratory distress.

Diagnosis

Diagnosis is mainly on history and lesions of rapid onset. Urticarial-like plaques with superficial exudation and crusting closely resemble the discrete active lesions of dermatophytosis (p. 878).

Treatment

Treatment is with subcutaneous or intramuscular injection of 3–5 ml of 1/100 adrenaline solution. Cattle with milk allergy should be milked out. In urticaria spontaneous resolution is often rapid and may have commenced or taken place by the time a visiting veterinarian arrives to attend the case.

Pruritus/pyrexia/haemorrhagic syndrome (PPH)

A disease of cattle, the pathophysiology of which is unclear, was first reported in cattle in the UK and in The Netherlands in the late 1970s. In The Netherlands the outbreaks were associated with the feeding of concentrates containing a urea compound, diureidoisobutane. In the UK this compound was not implicated and the causal factor has not been identified. Most cases were on self-fed silage, often after the introduction of a different silage additive to the farm. All cases were in cows, with a morbidity of 10.9 per cent and up to 25 per cent mortality, although almost all cases are culled due to loss of condition.

Signs

The systemic response is of a high fever (40–41°C; 104–106°F) with petechiation of the conjunctiva and visible mucous membranes, with general dullness. An extensive papular to exudative dermatitis with pruritus of variable intensity develops over the head, neck, perineum, udder, back and tail-head (Plate 50.10). These signs are accompanied by self-trauma (rubbing, kicking and licking), which leads to excoriation with bleeding and hair loss over a period of days to several weeks. Although the dermatitis may subside, the febrile response may persist for four to seven weeks.

Seriously affected animals may die, while those less so are unthrifty and ultimately have to be destroyed.

Diagnosis

The blood picture shows leucopenia followed by leucocytosis. Skin biopsy shows superficial and deep perivascular dermatitis with eosinophils and mononuclear cells predominating.

The post mortem reveals generalized petechiation particularly subserosal, with some cases showing free blood at external orifices.

The differential diagnosis is with other acutely febrile diseases of dairy cattle, such as anthrax (p. 717), and exudative dermatitis with severe pruritus of parasitic origin.

Treatment

This is non-specific and usually there is little response. A few cases have improved following prolonged use of injectable corticosteroids.

Photosensitization

Aetiology

This biophysical phenomenon occurs when skin becomes sensitized to certain wavelengths of sunlight, particularly within the ultraviolet range of the spectrum, in the presence within skin cells of specific photodynamic agents (see also pp. 370, 943).

Photodynamic agent in circulation → skin → irradiation by sunlight → cell death → necrosis → sloughing

Substances giving rise to these reactions in cattle may be porphyrins originating from defective haemoglobin metabolism, e.g. congenital porphyria, bovine protoporphyrina, or they may be substances of plant origin, e.g. hypericin, which is found in the plant St John's wort (*Hypericum perforatum*). This process of photosensi-

tivity is often referred to as *primary* or *direct* light sensitization.

Alternatively, another set of circumstances can lead to photosensitization, referred to as *secondary* or *hepatogenous* light sensitization. Although the final outcome, skin necrosis and sloughing, is the same as in the primary form, the process by which this is brought about differs.

Where liver damage (of diverse aetiology) interferes with the metabolism of the chlorophyll metabolite, phylloerythrin, this latter substance enters the circulation. As with other porphyrins, it initiates a light sensitivity response when present in the skin.

Both of these manifestations of photosensitivity are systemic in origin. A third, localized, form of skin reaction to sunlight may on rare occasions be induced by contact with the sap of certain plants containing psoralens. Localized lesions are more likely to be found on the distal limbs, muzzle or ventrum.

In order for photodynamic cell destruction to take place, the following circumstances are necessary:

- (1) The photodynamic agent must be present in the skin at the time of exposure to sunlight.
- (2) The exposed skin will be non-pigmented (the greater the density of melanin pigmentation, the greater is the protection against ultraviolet solar radiation).
- (3) The density of hair cover should be such that sunlight can penetrate to the skin surface.

Photosensitization leading to photodermatitis is essentially a physical process. The activation of porphyrins within skin cells by ultraviolet irradiation releases energy that causes cell death, the clinical signs of which are erythema, oedema and necrosis of exposed non-pigmented areas of skin. In some animals vesication is present prior to necrosis, sloughing and ulceration of affected areas. Pruritus and pain may also be shown.

Sites most likely to be involved in cattle are those most exposed to direct sunlight, e.g. the head, neck, back and lateral aspects of the body, udder and teats (more extensively when the photosensitive animal is lying down) (Plates 27.23, 50.11 and 50.12).

Diagnosis

The dramatic lesions of skin necrosis and sloughing should not present diagnostic difficulty in the established case. The presence or absence of systemic signs of illness, e.g. jaundice, positive blood screens for hepatic disease, should determine whether the condition is primary or secondary.

Very localized lesions on distal limbs, ventrum or muzzle would suggest a topical plant contact aetiology.

Lesions on the muzzle and udder may suggest a differential diagnosis of bluetongue (see p. 691).

Prognosis

In the primary form of the disease, provided the underlying cause is not genetic, then removal to housed, well-ventilated, shaded and cool conditions should be adequate to allow resolution of the lesions. Where severe liver damage is confirmed, prognosis is poor and may well be terminal.

Treatment

Cool, shaded, fly-free housing to avoid myiasis is necessary. Where necrosis and sloughing has taken place lesion hygiene is essential to prevent fly strike and the application of powder dressing to that end is beneficial. Resolution in severely affected animals is often a long process. Antibiotics to limit secondary infection may be justified, as may the short-term administration of corticosteroids in certain cases. In secondary photodermatitis, the justification of therapy will be determined by the acuteness or chronicity of the underlying disease.

Bovine farcy

A chronic nodular and ulcerative disease of the skin of cattle, the causal organisms of which may be either *Nocardia farcinica* or *Mycobacterium farcinogenes*. The disease is only found in Africa, Asia and South America.

Aetiology

Nocardia farcinica is a soil saprophyte that becomes inoculated into wounds by contamination or enters the skin by inoculation via tick vectors, which themselves carry the organism for long periods of time.

Signs

Once inoculated, slowly developing painless nodules appear more commonly over the head, neck, shoulders, limbs, perineum and groin. Infection may give rise to mastitis and whilst following the lymphatics cause cording of these vessels as well as lymphadenopathy. Ulceration of lesions occurs with the discharge of thick, grey/yellow material.

Infection may be protracted and confined to the skin but generalization, particularly to the lungs and viscera, can occur with a progressive loss of condition leading to death.

Diagnosis

Diagnosis is dependent on the clinical signs. The organism may be demonstrated in smears of exudate (acid-fast filaments, which are beaded). Culture of *Nocardia farcinica* is also possible.

Histopathology shows the presence of pyogranulomatous dermatitis.

The differential diagnosis is with so-called skin tuberculosis due to acid-fast bacilli, particularly nodules found on the lower limbs or cording of lymphatics of forelimbs (see below).

Treatment

Inorganic iodides have been used but the advice given is usually to have the affected animals destroyed.

Atypical mycobacteriosis

Skin infections with environmental mycobacteriaceae are recognized worldwide. Lesions arise from the introduction of organisms through sites of skin trauma. Infection gives rise to nodular lesions on the distal limbs, sometimes discrete, otherwise in chains following the course of the superficial lymphatics. Nodules occasionally rupture to exude creamy pus. The condition is commonly referred to as 'skin tuberculosis'.

Diagnosis is by the demonstration of acid-fast organisms in the smears of pus or by histopathology of biopsied lesions. The importance of this infection is its role in inducing a non-specific reaction to the intradermal tuberculin test (see p. 863). There is no treatment.

Dermatophilosis (bovine streptothricosis)

This is a chronic or acute exudative dermatitis that may affect many species of animals and is of world-wide distribution. It also occurs in humans.

The disease in cattle is of particular importance in Africa, where it is thought to have been known since the nineteenth century, in America, the Middle East and Mediterranean Europe.

In cattle the disease is of importance for its role in causing economic loss through down-grading of hides and skins, reduced milk yield, marked debility in severely affected animals with dehydration and death.

Aetiology

The agent responsible for infection is the actinomycete, *Dermatophilus congolensis*, a Gram-positive filamentous

bacterium. Infection with *D. congolensis* is confined to the epidermis where the motile zoospore stage of the organism, activated under suitable conditions of climate and skin damage, grows to form a filamentous mycelium within the epidermis. In dry conditions the spore stage of the bacterium may remain dormant in dry crust, scab and hyperkeratotic skin debris for many months.

A number of factors influence the incidence of the disease, of which high temperature and humidity play an important role. Similarly, breed susceptibility is of importance, indigenous cattle being more resistant to infection than imported exotic breeds.

The initiation of lesions requires skin damage, albeit superficial, by abrasion, e.g. thorn scratches, insect bites (biting flies or ticks may themselves carry the infective organism).

The incubation period may be as short as two weeks.

Signs

Bovine cutaneous streptothricosis commences as a circumscribed moist patch, often with raised or matted hairs, giving a characteristic 'paint brush' appearance. Discrete lesions occur in the initial stages which coalesce to form large areas of hyperkeratotic scab and crust (Plates 50.13 and 50.14). In severe infections as much as half the skin surface may be involved. Scab may be of variable thickness and on removal show a concave underside coated in thick, yellowish exudate, leaving a raw, bleeding epidermis.

Diagnosis

Impression smears of the exudate, fixed and stained by Gram's method or methylene blue, reveal numerous rows of cocci formed into branching filaments. Organisms may not be readily demonstrable in material taken from old lesions or those affected by secondary infection. *Dermatophilus congolensis* may be cultured on blood agar under microaerophilic conditions.

Differential diagnosis is with dermatophytosis (p. 878) and sarcoptic scabies (p. 891).

Treatment

Antibiotic therapy using penicillin and streptomycin as a single dose regimen (70 000iu penicillin and 70mg/kg body weight streptomycin intramuscularly) will prevent epidermal invasion by zoospores as well as re-infection. Alternatively, five daily doses of 5000iu penicillin and 5mg/kg body weight streptomycin may be given (Lloyd, 1981). Long-acting oxytetracycline by deep intramuscular injection at 20mg/kg body weight has also been found to be effective (Lloyd *et al.*, 1990). Topical appli-

cation of solutions of cresols and copper salts in appropriate dilution may have a preventive effect.

Prevention

Since predisposition to the disease is due to skin trauma from vegetation, ectoparasite infestation with poor husbandry resulting in malnutrition and/or the presence of concurrent disease, many of these factors are difficult to control. Efforts directed towards the establishment of herds of breeds resistant to *D. congolensis* may be of long-term benefit.

The quest for an effective vaccine continues but is still in the experimental stage of development (Lloyd, 1984). A combination of improved husbandry with vaccine therapy may eventually be the effective means of control.

Horn cancer

This disease, which results in neoplasia of the horn core, is usually an extension of squamous cell carcinoma that arises from the mucosa of the frontal sinus. Involvement of the horn core causes loosening of the horn, which drops off leaving the tumour exposed. While metastases occur in such conditions as squamous cell carcinoma of the eye, they do not occur in horn core lesions.

Diagnosis

This is by biopsy and clinical examination.

Treatment

Treatment has been found to have variable degrees of success and recurrence is common following surgery. Cryotherapy, surgical excision, radiodiathermy and immunotherapy have all been tried.

Lumpy skin disease and pseudo-lumpy skin disease

(see also p. 768)

Two forms of lumpy skin disease are recognized:

- True 'lumpy skin' disease, the causal agent of which is the Neethling pox virus, infection with which gives rise to acute or subacute disease among cattle in parts of Africa.
- Pseudo-lumpy skin disease due to infection with Allerton virus, bovine herpes virus type 2, which

has a world-wide distribution amongst all types of cattle.

Lumpy skin disease (see p. 768)

A seasonal disease that occurs particularly at times of high insect population and can affect cattle of any age, breed or type.

The mode of transmission of infection has not been fully determined although the association with periods of high insect population and proof that *Stomoxys calcitrans* can carry the virus suggests that the organism is insect-borne. The incubation period is one to four weeks.

Lumpy skin disease causes high economic loss through decreased milk production, abortion, loss of condition and hide damage.

Signs

The initial viraemia is associated with a febrile response, nasal discharge, excess salivation and possibly lameness. After a period of one week the first signs of skin lesions may be seen as papules/nodules with enlargement of the superficial lymph nodes.

Skin lesions can be localized or generalized, circumscribed firm and flattened intradermal nodules up to 5 cm in diameter. While lesions can be confined to the skin of the chest, neck, back, limbs, perineum, udder and scrotum, more severely affected animals may show involvement of the nasal and turbinate bones. Oedema of the ventral chest and abdomen, also the limbs, may occur.

Skin lesions may well ulcerate and be slow to resolve, persisting for months to years in some cases. In most instances the skin lesions necrose, passing through phases of ulceration and scarring before resolution in a period of one to three months.

Morbidity is usually around 50 per cent but may be as high as 90 per cent with mortality in the region of 10 per cent.

Prognosis

This is always guarded. Those animals that progress to respiratory tract involvement may well die.

Diagnosis

History, clinical examination, skin biopsy and virus isolation are all helpful. Apart from other histopathological changes present, eosinophilic intracytoplasmic inclusion bodies may be found in keratinocytes, and glandular and ductal epithelium of the skin glands.

Table 50.2 Other conditions referred to in the text which also show skin signs.

| | |
|-------------------------|---|
| Actinobacillosis | Chronic granulomatous lesions as an extension from infected soft tissues and lymph nodes (see p. 823) |
| Actinomycosis | Chronic granulomatous lesions eroding skin from underlying bone infections (see p. 824) |
| Alopecia | Congenital baldness. Baldy calf syndrome (see p. 181) |
| Albinism | Congenital oculocutaneous absence of pigment (see p. 182) |
| Bacterial infections | <ul style="list-style-type: none"> ● of the teat – blackspot; <i>F. necrophorum</i> (see p. 370) ● of the udder – folliculitis, impetigo, <i>Staph. aureus</i> (see p. 371) |
| Besnoitiosis | Gross thickening of skin, lichenification, hair loss (see p. 756) |
| Claw conditions | (See Chapter 31) |
| Congenital | <ul style="list-style-type: none"> Epitheliogenesis imperfecta (see p. 181) Epitheliokeratogenesis imperfecta (see p. 181) |
| Copper deficiency | Poor coat, change in black coat colour (see pp. 254, 298) |
| Ichthyosis | Digital disorders see also Claw disorders (p. 427) |
| Interdigital dermatitis | Congenital hair loss, accumulations of scaly epithelium (see p. 182) |
| Onchocerciasis | See also Claw disorders |
| Selenium poisoning | Multiple parasitic nodules within the skin (see p. 774) |
| Stephanofilariasis | Hoof cracking, rough coat, hair loss (see p. 305) |
| Viral diseases | Thickened skin, papules, crusts, ulcers possibly on the udder and teats (see p. 774) |
| Cowpox | Rare, erythema leading to pustule formation on teats (see p. 365) |
| Foot-and-mouth disease | Vesicles on teats, muzzle, in addition to coronary band and mouth (see p. 700) |
| Herpes mammillitis | Irregular vesicles on skin of udder and teats, discolouration, ulceration (see p. 363) |
| Papillomatosis | Warts on teats (see p. 365) |
| Pseudocowpox | Common, erythema, papules, vesicles and scabs on teats (see p. 364) |
| Rickettsial disease | Jewbrana disease, petechiation, bleeding through the skin (see p. 766) |

Treatment

None is effective. Antibiotics may be given to combat secondary infection. Measures to minimize the possibility of fly strike and subsequent myiasis should also be taken.

Prevention

Some protection is gained by vaccination with modified Neethling virus vaccine. Vaccination with sheep pox virus has also conferred some protection.

Pseudo-lumpy skin disease (see p. 768)

A much milder condition than 'true' Neethling virus lumpy skin disease and due to infection with bovine herpes virus type 2. The organism is also responsible for outbreaks of herpes mammillitis (p. 363).

Signs

There is absence of a systemic response or superficial lymphadenopathy with a clinical course similar to herpes mammillitis, resolution occurring in two to three weeks. In exceptional cases lesions may persist for considerably longer.

Skin lesions have a similar distribution and appearance to those of lumpy skin disease, with limbs, body,

neck, back, udder, perineum and scrotum showing superficial raised plaques having a central depression and superficial necrosis.

Diagnosis

History, physical examination, virus isolation and skin biopsy are helpful. Skin biopsy shows, among other changes, eosinophilic intranuclear inclusion bodies in keratinocytes of the stratum spinosum.

Other conditions having skin signs

See Table 50.2.

Introduction

Many of the neurological disorders of cattle such as lead poisoning, botulism, hydranencephaly caused by congenital bovine viral diarrhoea/mucosal diarrhoea (BVD/MD) or Akabane virus infections present as outbreaks. It is essential therefore that an accurate diagnosis is reached in order to expedite preventive and control measures. The investigation of possible central nervous system (CNS) involvement in a disease process necessitates a detailed assessment of the animal's history and a complete physical and neurolog-

ical examination. A methodical neurological examination allows the lesion to be localized to specific areas of the brain (Braund, 1985). The common diseases and conditions which affect those areas of the brain can then be listed and further investigated. This approach is much more preferable than the undergraduate student or practitioner attempting to memorize long lists of clinical signs for every neurological disease. A logical approach to neurological examination of cattle highlights discrepancies when new diseases arise because it does not limit the differential diagnoses to known diseases.

Such a methodical approach (Scott *et al.*, 1989a, 1995) was not adopted when a vague neurological disease, bovine spongiform encephalopathy (BSE), first appeared in United Kingdom dairy herds during the mid 1980s. The clinical findings were not consistent with any recognized bovine neurological disorder and led to spurious diagnoses such as brain tumours, chronic hypomagnesaemia, listeriosis, hepatic encephalopathy, etc. The lack of a methodical approach to suspected cases of BSE resulted in a correct clinical diagnosis in only 85 per cent of slaughtered cattle. Indeed, many of these cattle were examined twice some weeks apart, which should have excluded many acute neurological diseases. Despite over 15 years' experience of BSE, the clinical diagnosis remains only 85 per cent correct. Despite data collected from over 20000 suspected cases of BSE which were negative on histopathological examination of brain tissue, no summary of these clinical cases has appeared in the veterinary literature. This lack of data indicates the absence of a standard logical approach to neurological disease by many veterinarians. Too often the clinical signs are fitted to a limited number of known diseases and it is therefore inevitable that new diseases will not be recognized.

Cerebrospinal fluid (CSF) analysis is the most useful laboratory test in the clinical investigation of neurological diseases in cattle (Scott & Penny, 1993; Scott 1995a, 1996) but such samples are rarely undertaken in practice. However, lumbar CSF samples can be obtained from affected animals under local anaesthesia on the farm with immediate results available on visual examination, ensuring an accurate diagnosis and specific

treatment without further delay (Scott & Penny, 1993). For example, animals may present with neurological signs indicative of cerebellar dysfunction where a neutrophilic pleocytosis and increased CSF protein concentration indicate focal meningitis (Scott *et al.*, 1994a) while normal CSF parameters in another case do not indicate an infectious cause and indirectly support the diagnosis of a developmental abnormality causing dysfunction (Scott *et al.*, 1993a).

In many situations in practice the clinical examination is incomplete and fails to yield sufficient information to make a specific diagnosis. Consequently, in the field situation response to treatment has often been used as an adjunct to diagnosis (Morgan, 1992), despite numerous treatments being administered simultaneously (Power *et al.*, 1985), thereby limiting interpretation of the outcome.

There are specific changes in antibody titre, serum ion, metabolite or enzyme concentration in only a small percentage of bovine neurological diseases and a specific diagnosis is often reached only in fatal cases which are examined in detail at necropsy (Jeffrey, 1992). However, for cost reasons few cattle are subject to a detailed post-mortem examination. Histopathological examination of the CNS is expensive and multiple sections are cost-prohibitive. Accurate lesion localization by the clinician is therefore essential before euthanasia is carried out, otherwise discrete lesions may not be sectioned at necropsy and an incorrect diagnosis reached.

Development, structure and function of the nervous system

Development

Development of the nervous system of mammals takes place as a sequence of intensely active events that occur from early embryogenesis and continue in cattle into postnatal life. During these phases cells undergoing rapid division and differentiation are susceptible to a wide variety of physical, chemical and infectious agents.

The physical factors include extremes of temperature, especially maternal hyperthermia, and direct or indirect trauma. Chemical factors include organic, inorganic and plant poisons, nutritional imbalances and toxic products of microbial activity in the maternal or external environment. The direct invasion of the fetus by microorganisms presents a further hazard and inherited defects or spontaneous errors in nucleic acid templating may produce effects at all stages of development.

Structure and function

Structurally, the nervous system of higher vertebrates comprises neurones and neuroglia. The neurones form

the conducting system for neural impulses. The neuroglia are also of two types; the oligodendroglia are responsible for the formation and maintenance of the myelin sheaths of the axons and astrocytes which provide the supporting scaffold of the CNS and also contribute to the blood-brain barrier. In the peripheral nervous system the Schwann cell is the homologue of the oligodendrocyte.

The nervous system is heavily dependent upon glucose and oxygen to sustain functional activity; consequently there is a rich capillary network, especially in regions of high neuronal density. Even brief disruption of blood supply will interfere with membrane function with accumulation of toxic metabolites, such as lipid peroxides, resulting in swelling or cell death. When a nerve cell is lost it cannot be replaced and the circuit containing it is diminished. If substantial numbers of nerve cells are lost, functional deficits will result.

Infectious agents, toxic incidents and traumatic events may damage not only the neurone but also the glial components of the nervous system. Following injury astrocytes can proliferate to produce an astrogliotic scar, which itself may distort the tissue and further interfere with neural function. Oligodendroglia can also be regenerated from stem cells, but in the mature CNS the ability to replace myelin is to a large extent dependent upon the viability of the neurone.

The nature and causes of signs of neurological disorder

Endogenous biochemical causes

(see also Chapters 21, 46, 54)

This group of conditions includes those metabolic diseases that are associated with the stresses of production and systems of management and includes milk fever, hypomagnesaemic tetany and acetonæmia. These disorders produce no specific pathological changes in the CNS and the clinical condition in most instances can be readily reversed by rapid correction of the specific deficiency.

Inborn errors of metabolism are usually considered to be heritable, mainly with an autosomal recessive mode. A gene may control a specific enzyme or enzyme system and a defect therein will block the normal metabolic pathway. In some cases, however, there may be alternative pathways to modulate or minimize the consequences and these may influence the time of onset and rate of progress of clinical disease.

In inherited congenital myoclonus in the polled Hereford (Harper *et al.*, 1986), affected calves, although bright and alert, are unable to stand from birth and show stimulus-responsive myoclonic spasms. A second

genetically mediated disorder, neuraxial oedema, also occurs in Herefords and possibly other breeds. Affected calves appear normal at birth but within a day or two they become dull and recumbent with opisthotonus. The significant pathology is in the CNS and consists of vacuolation at all levels of the neuraxis.

Lysosomal storage diseases comprise an important group of genetically-mediated diseases whereby the products of faulty degradation accumulate in lysosomes and the cell bodies swell. The cells of the heterozygote contain approximately half the normal concentration of enzyme, but the animal itself appears normal, whilst the diseased animal is homozygous for the defect and the enzyme is absent. Heterozygote recognition by appropriate enzymatic assay offers a means of controlling the disease within a population. Examples of lysosomal storage diseases include lipidosis GM₁ gangliosidosis in the Friesian, glycoproteinosis mannosidosis in the Angus, Murray Grey and Galloway and ceroid lipofuscinosis, which has been described in Beefmaster cattle. The clinical signs of GM₁ gangliosidosis are reluctance to feed, dullness, progressive ataxia and ill-thrift, and appear one to three months after birth (see p. 179). Clinically, mannosidosis (pseudolipidosis) presents as wasting, altered behaviour with aggression and progressive ataxia (see p. 179).

Exogenous biochemical causes

There is a wide range of exogenous biochemical causes of neurological disorder. Some compounds, e.g. organophosphorus compounds, organochlorides and carbamates, are specific neurotoxins whose mode of action is known. However, a great many toxicants whose primary targets appear to be gut, liver or the cardiovascular system also cause neurological disturbances. In the early phases these usually take the form of excitement, muscle fasciculations, tachycardia and hyperpnoea, whilst convulsions and coma frequently characterize the terminal phases. The mechanisms of this toxic stimulation and depression of the nervous system are poorly understood (see Chapter 54).

In cattle, intoxication by chemical compounds is not uncommon for reasons that include their innate curiosity, considerable appetite and non-selective habits of grazing and licking. Lead, the organophosphorus compounds, ragwort, copper, urea and sodium chloride are known to cause neuropathological changes. Lead is by far the most important and is considered in detail later. Organophosphorus compounds used as insecticides and herbicides are variably potent inhibitors of cholinesterase (see p. 940). The clinical signs of acute intoxication, miosis, salivation, polyuria, muscle fasciculations, apprehension and ataxia are the consequences of cholinergic overstimulation, but produce no charac-

teristic neuropathology. The clinical signs of hepatic encephalopathy, e.g. ragwort poisoning, may be intermittent and slowly progressive or acutely fatal, depending upon the severity and duration of hepatic overload by nitrogenous compounds. There are behavioural changes, with compulsive walking, circling, twitching of ears and eyelids, blindness and, in severe cases, recumbency with opisthotonus (see p. 945).

Genetic causes

The plurality of genetic neurological disorders in cattle (Table 51.1) is possibly a reflection of intensive selection for particular production traits from within small populations of superior animals and is facilitated by artificial breeding techniques.

Micro-organisms

Neurological disorders in cattle can result from the activities of all types of infective agents. Some invade the nervous system, usually causing inflammation of the brain (encephalitis), spinal cord (myelitis) or the membranous coverings (meningitis). Others that may be present in the alimentary tract or external environment produce neurotoxins or antimetabolites, which cause degenerative encephalopathies and myelopathies.

Viruses

Viruses form an important group of neural pathogens. The oronasal route is the most common portal of entry, but some viruses gain access via the conjunctiva or percutaneously by the bite of an insect vector or infected animal. Initial replication at the site of infection and in local lymphoid tissues is typically followed by viraemia with fever during which the virus penetrates the blood-brain barrier and invades the neural parenchyma. Typical inflammatory responses are focal and diffuse proliferations of microglial cells and perivascular and meningeal infiltrations of lymphocytes. As the CNS is normally impermeable to circulating immunoglobulins, synthesis of antibody by B cells in the perivascular cuffs may play an important role in the recovery of the individual. Other virus infections, e.g. bovine virus diarrhoea/mucosal disease (Trautwein *et al.*, 1987) and Akabane disease (Inaba *et al.*, 1975), generally cause mild or inapparent disease in the adult, but cause severe transplacental infections of the fetus. Fetal meningoencephalitis or gross intracranial malformations from destruction of the granuloprival elements of the developing fetal brain may be the result, depending upon the stage of fetal development at infection.

Table 51.1 Inherited neurological diseases of cattle.

| Disease | Mode R/D | Breed(s) | Age at onset | Clinical features | Pathology | Reference |
|---|----------|------------------------------|-------------------|---|---|--|
| Cerebellar abiotrophy | R | Holstein | 3–8 months | Progressive spastic ataxia, dysmetria. Loss of menace response | Degeneration of cerebellar neurones sparing the vermis | White <i>et al.</i> (1975) (p. 178) |
| Hereditary congenital ataxia 'jittery' | R | Jersey | Birth to 3 months | Ataxia and intention tremor | Hypomyelination and oedema of cerebellar white matter | Saunders <i>et al.</i> (1952) |
| Cerebellar ataxia | R? | Shorthorn Hereford | 1–3 days | Rapidly progressive ataxia with recency | Spongy transformation of cerebellar white matter, shrinkage and loss of neurones | Hulland (1957) (p. 178) |
| Familial cerebellar hypoplasia and degeneration | R | Hereford | Birth | Recumbent, stuporose, intermittent rigidity | Narrow disorganized cerebellar folia. Paucity of cerebellar cortical neurones | Innes <i>et al.</i> (1940) |
| Familial convulsions and ataxia | D | Aberdeen Angus | Birth to 6 months | Recurrent seizures with gradual development of spastic ataxia and hypermetria | Swelling and vacuolation of Purkinje cells and Purkinje cell axons | Barlow (1980) (p. 178) |
| Doddler | R | Hereford | Birth | Muscular spasms and convulsions, nystagmus, respiratory difficulties | Calcification of cerebellar and medullary neurones | High <i>et al.</i> (1958) |
| GM ₁ gangliosidosis | R | Friesian | 1 month | Reluctance to feed, dullness and progressive ataxia | Cerebrospinal lipidosis with ballooning of neurones by accumulations of glycolipid | Donnelly <i>et al.</i> (1973) (p. 179) |
| Mannosidosis | R | Angus, Murray Grey, Galloway | Birth onwards | Wasting, aggression and progressive ataxia, lymphadenopathy | Vacuolation of neurones and fixed macrophages, renal epithelial cells and exocrine pancreas | Hocking <i>et al.</i> (1972) (p. 179) |
| Neuraxial oedema: maple syrup urine disease | R | Hereford and polled Hereford | 1–3 days | Dullness, recency and opisthotonus: nystagmus. Urine smells of burnt sugar | Raised urine ketones. Vacuolation throughout neuraxis especially white matter | Healy <i>et al.</i> (1986) (p. 180) |
| Inherited congenital myoclonus | R | Polled Hereford | Birth | Stimulus-responsive myoclonic spasms | Contusions of coxofemoral joint with fractures/deformity of articular cartilage | Harper <i>et al.</i> (1986) (p. 180) |

contd.

Table 51.1 *Continued*

| Disease | Mode R/D | Breed(s) | Age at onset | Clinical features | Pathology | Reference |
|--|----------|-----------------------|--------------|---|--|--------------------------------------|
| Bovine generalized glycogenosis | R | Shorthorn | 12 months | Muscular weakness, incoordination, deficiency of α -1,4-glucosidase or acid maltase | Accumulation of PAS-positive and Bests carmine plus granules in neurones of midbrain, medullary and cerebellar roof nuclei | Richards <i>et al.</i> (1977) |
| Chediak–Higashi syndrome | R | Hereford, Brown Swiss | Young adults | Partial albinism (ghost pattern colouring). Susceptibility to infection. Premature ageing | Yellow pigmented PAS, LFB and Sudan black B-positive inclusions in nerve cells of brain, cord, myenteric plexuses. Similar to lipofuscin granules | Padgett (1968) |
| 'Weaver syndrome': progressive degenerative myelencephalopathy | R | Brown Swiss | 8–12 months | Motor dysfunction with swinging gait progressing to loss of movement and inability to stand | Axonal degeneration predominantly in spinal white matter, axons in some brain stem nuclei and Purkinje cells of cerebellar cortex. Paramembranous densities and synaptic junctions | Stuart & Leipold (1985) (p. 179) |
| Neuronal lipodystrophy | R | Beefmaster | 12 months | Blindness, circling, recumbency and coma | Neuronal multilamellar and curvilinear inclusions. Similar structures may be found in fixed macrophages in spleen and lymph nodes. | Read & Bridges (1969) |
| Progressive ataxia of Charolais | R? | Charolais | 8–24 months | Progressive weakness and ataxia terminating in recumbency | Segmental demyelination of CNS with retraction of internodes, formation of eosinophilic plaques from oligodendroglial processes | Palmer <i>et al.</i> (1972) (p. 179) |
| Recumbent calf syndrome | R? | Red Danish milk breed | 6 weeks | Progressive ataxia, paresis and immobility | Degeneration of neurones in ventral horns of spinal cord | Hansen <i>et al.</i> (1988) |

R, recessive; D, dominant; PAS, periodic acid shift.

Bacteria

Bacteria, with possibly *Listeria monocytogenes* as the sole exception, do not invade the neuroparenchyma as a primary event. Infection of the neuraxis usually arises from a bacteraemia causing meningitis, which may be purulent or non-purulent depending on the organism involved. Infection of the meninges may also arise directly following local trauma. Subsequent invasion of the neuroparenchyma, however, depends upon damage to the blood-brain barrier, such as may occur following rupture of a meningeal abscess, devitalization of the tissue by toxic products or infarction due to infective emboli as in thromboembolic meningoencephalitis (Ames, 1987).

Other manifestations of bacterial involvement in neurological disease include those caused by the exotoxins of clostridial infections occurring elsewhere in the body, e.g. focal symmetrical encephalomalacia (Buxton *et al.*, 1981) and tetanus, which are discussed elsewhere. Also in this category are the thiaminolytic organisms that proliferate in rumen contents and are implicated in polioencephalomalacia.

Protozoa (see p. 284)

Protozoan infections with *Toxoplasma gondii* and *Sarcocystis* species have been implicated in neonatal necrotizing non-suppurative encephalomyelitis in calves (O'Toole & Jeffrey, 1987). Congenital sarcocystosis infestation has been recorded as a cause of recumbency in newborn calves. Severe coccidiosis in calves is uncommonly associated with neurological disorder in Britain, although more widely reported in North America. Pelvic limb paresis in yearling cattle progressing to tetraparesis over two to three days has been reported, caused by *Sarcocystis zurnii* encephalomyelitis.

Nematodes

The intermediate stage (*Coeneurus cerebralis*) of the dog tapeworm *Taenia multiceps* may occasionally occur in cattle in well-defined regions of Britain, but is much less common than the disease in sheep. The clinical signs are of a slowly progressive, space-occupying lesion in one cerebral hemisphere, circling to the affected side, proprioceptive deficits and contralateral blindness.

Neurological examination

A methodical neurological examination allows central nervous system lesions to be localized to specific area(s) of the brain (Braund, 1985). The common diseases and

conditions which affect those areas of the brain can then be listed and further investigated. The most useful and cost effective ancillary test is lumbar cerebrospinal fluid analysis (Scott, 1992, 1995a, 1996). For example, the clinical presentation in a young calf of depression, lethargy, cortical blindness and dorsomedial strabismus is consistent with diffuse cerebral dysfunction; CSF analysis reveals a markedly elevated protein concentration and neutrophilic pleocytosis. These clinical signs are consistent with a diagnosis of bacterial meningoencephalitis which is then confirmed on gross CSF inspection and laboratory findings (Scott & Penny, 1993). There is no need to consider an endless list of obscure differential diagnoses when the neurological findings and lumbar CSF tap yield pathognomonic results. The methodical clinical examination explores all aspects of the animal's presentation rather than attempting to fit the clinical signs to a recognized condition/disease. For example, the clinician may believe the calf described above is suffering from bacterial meningoencephalitis because it is four days-old, dull and depressed – this description may equally apply to enterotoxigenic *E. coli*, starvation/hypothermia, polyarthritis, etc. The diagnosis is not confirmed until a lumbar CSF tap is taken and examined, when all potential diagnoses except bacterial meningoencephalitis can be excluded.

Considerable confusion arose with the clinical recognition of bovine spongiform encephalopathy in the United Kingdom during the mid 1980s because practitioners could not assign the clinical findings to any known disease and spurious diagnoses such as tumour, hepatic encephalopathy and chronic hypomagnesaemia were commonplace. The accuracy of clinical diagnosis was approximately 85 per cent with a wide range of diseases incorrectly reported as BSE, including listeriosis. Bovine spongiform encephalopathy presents with clinical signs of cerebral and cerebellar dysfunction with no intrathecal inflammatory response (Scott *et al.*, 1989b); listeriosis shows the classical presentation of the pontomedullary syndrome with an elevated protein concentration in CSF and increased white cell concentration with predominance of large mononuclear cells (Scott, 1996). A methodical clinical examination should readily differentiate these two common neurological disorders of adult cattle in the UK.

While the brain can be conveniently divided into six areas, each with a recognized neurological 'syndrome' (Braund, 1985) only four syndromes concern the veterinary practitioner: cerebral, cerebellar, pontomedullary (brainstem) and vestibular.

Cerebral syndrome

Diffuse cerebral disease is common in ruminants, associated with metabolic disease in adults and bacterial

meningoencephalitis in neonates. The cerebrum is concerned with mental state, behaviour and, in conjunction with the eye and optic (II) nerve, vision. Clinical signs which suggest cerebral dysfunction include blindness, but with normal pupillary light reflexes (II, III), compulsive walking, circling, constant chewing movements, severe depression, dementia, yawning, head pressing, hyperaesthesia to auditory and tactile stimuli, and opisthotonus. It is important to note that the clinical signs change as the disease condition progresses; for example, calves with bacterial meningoencephalitis may present with different clinical signs depending upon the duration of CNS infection.

Ipsilateral compulsive circling, sluggish gait, postural deficits, deviation of the head (not a head tilt) and depression with contralateral blindness are variably seen in animals with unilateral cerebral lesions.

Cerebellar syndrome

The cerebellum is primarily concerned with fine coordination of voluntary movement. In cerebellar dysfunction limb movements are spastic (rigid), clumsy and jerky. Initiation of movement is delayed and may be accompanied by intention tremors. Cerebellar disease is characterized by a wide-based stance and ataxia (incoordination), particularly of the pelvic limbs but with preservation of normal muscle strength. In addition to the ataxia, dysmetria may be observed with hypermetria the more common form observed in cerebellar disease. Opisthotonus can occur in animals with severe lesions of the rostral cerebellum.

Vestibular syndrome

In growing cattle unilateral peripheral vestibular lesions are not uncommon. The major clinical signs include ipsilateral (to the same side) head tilt, leaning and drifting sideways when walking. Circling may also be observed. Positional nystagmus may be depressed or absent in animals with a vestibular lesion. There is spontaneous horizontal nystagmus with the fast phase directed away from the side of the lesion. There is frequently ipsilateral ventral strabismus (eye drop) which is exaggerated when the head is raised. Facial nerve paralysis is common in peripheral vestibular disease since both facial and sympathetic nerves fibres pass close to the middle ear. In central vestibular disease the nystagmus may be horizontal, vertical or rotary.

Pontomedullary (brainstem) syndrome

As most of the cranial nerve nuclei are present in the brainstem, dysfunction is characterized by multiple cranial nerve deficits. Depression is also a key sign of

brainstem disease which is attributed to a lesion involving the ascending reticular activating system. Circling, ipsilateral hemiparesis and proprioceptive defects are also common. Circling can be observed in diseases affecting the brainstem caused by involvement of the vestibulo-cochlear nucleus. Involvement of the facial nucleus results in ipsilateral facial nerve paralysis. Facial palsy is evident as drooped ear, drooped upper eyelid (ptosis) and flaccid lip. Involvement of trigeminal nerve or the trigeminal motor nucleus results in paralysis of the cheek muscles and decreased facial skin sensation. Listeriosis is the classical brainstem lesion.

Collection of CSF

Collection of CSF forms an integral part of the clinician's detailed neurological examination. Lumbar CSF can readily be collected under local anaesthesia from cattle of all ages (Scott & Penny, 1993; Scott *et al.*, 1995). While it may be preferable to collect cisternal CSF for a more representative sample, this technique is inherently more difficult to perform and is not without risk to the patient. Numerous studies in ruminant species (Scott, 1992, 1995a, 1996) have shown that lumbar CSF samples provide meaningful data which assist the clinician in formulating a more specific diagnosis. Lumbar CSF can be collected under local anaesthesia in the standing animal. Cisternal CSF collection requires appropriate restraint and, in many situations, either deep sedation or general anaesthesia.

Collection of lumbar CSF is greatly facilitated when the animal is positioned in sternal recumbency with the hips flexed and the pelvic limbs extended alongside the abdomen. In adult cattle that are ambulatory the lumbar CSF sample is collected from the standing animal which must be suitably restrained in cattle stocks which prevent lateral movement. The site for lumbar CSF collection is the mid point of the lumbosacral space which can be identified as the mid line depression between the last palpable lumbar dorsal spine (L6) and the first palpable sacral dorsal spine (S2). The site must be clipped, aseptically prepared and 1–2 ml of 2 per cent lignocaine solution injected subcutaneously. Sterile surgical gloves should be worn. A guide to needle length and diameter (Scott, 1996) is included in Table 51.2.

Table 51.2 Guide to needle length and gauge for lumbar CSF sampling in cattle.

| | |
|-------------------|-----------------------------------|
| Calves <80 kg | 1 inch 20 gauge |
| Calves 100–200 kg | 2 inch 19 gauge |
| Cattle >200 kg | 4 inch 18 gauge + internal stylet |

When the lumbosacral site has been surgically prepared the needle is slowly advanced at a right angle to the plane of the vertebral column or with the hub directed 5–10° caudally. It is essential to appreciate the change in tissue resistance as the needle point passes sequentially through the skin, subcutaneous tissue, interarcuate ligament then the sudden ‘pop’ due to the loss of resistance as the needle point penetrates through the ligamentum flavum into the epidural space. Once the needle point has penetrated the dorsal subarachnoid space, CSF wells up in the needle hub within 2–3 seconds. There is no justification whatsoever in collecting CSF from the ventral subarachnoid space. Between 2–3 ml of CSF is sufficient for analysis and can be collected by free flow from the needle hub or by gentle syringe aspiration. Care must be taken not to dislodge the needle point from the dorsal subarachnoid space when the syringe, with the seal already broken, is attached to the needle hub. Sedation of the animal is not usually necessary but intravenous xylazine (0.05–0.1 mg/kg bodyweight) or diazepam (0.04 mg/kg bodyweight) can facilitate positioning of the pelvic limbs in recumbent animals. It is not necessary to compress the jugular veins to facilitate CSF collection.

Samples of CSF are collected into EDTA containers. The specific gravity value is determined using a hygrometer. Many cerebrospinal fluid samples have first to be concentrated before CSF protein concentration can be determined using the pyrogallol method. White cell concentration in CSF is determined using a haemocytometer. Cytological examination of CSF is facilitated when the sample is first concentrated by cytocentrifugation. The sample is then air-dried and stained with Leishman stain and the differential white cell count based on a minimum of 20 cells. Further laboratory testing, such as protein electrophoresis (Scott, 1993b), adds little additional information and is rarely undertaken for cost reasons.

An assessment of CSF pressure can be made by determining the rate of CSF flow from the needle hub once the needle point has penetrated the dorsal sub-

arachnoid space. The normal flow rate is one drop of CSF every 2 to 3 seconds. A steady flow of CSF is obtained immediately following puncture of the arachnoid mater in calves with meningoencephalitis, indicating increased CSF pressure. The use of a manometer has no practical application in farm animal practice.

The analysis of lumbar CSF from a range of neurological disorders, and other conditions which present with abnormal mental state, is presented in Table 51.3.

General principles of treatment for CNS infections

The important factors to consider in the treatment of central nervous system infections include:

- Bacterial pathogen;
- Duration and extent of the disease process;
- Ability of the selected antibiotic to penetrate the blood-brain barrier and achieve concentrations 10 to 30 times the minimum bactericidal concentration in order to sterilize the CSF (Prescott & Baggot, 1988; see also Chapter 61).

Supportive treatments include corticosteroids, diuretics, dimethyl sulphoxide and non-steroidal anti-inflammatory drugs (NSAIDs) e.g. flunixin meglumine, carprofen, meloxicam and ketoprofen. In addition, certain situations necessitate appropriate intravenous and oral fluid replacement therapy to correct secondary acid-base and fluid disturbances.

For an antibiotic to be effective in bacterial meningitis, it must penetrate into the CSF in sufficient concentration to be bactericidal to the invading organism (Lambert & Wall, 1991) and achieve CSF concentrations 10 to 30 times the minimum bactericidal concentration to sterilize the CSF (Sande, 1981; Prescott & Baggot, 1988). Even with successful CSF antibiotic penetration, the intrathecal defence mechanisms are inadequate to control bacterial infection and treat-

Table 51.3 Lumbar CSF results (median, range) for some common bovine CNS diseases.

| Disease | Number | Specific gravity | Protein (g/l) | White cells ($\times 10^9/l$) |
|------------------------|--------|---------------------|------------------|---------------------------------|
| Control | 31 | 1.007 (1.006–1.011) | 0.28 (0.06–0.73) | 0.0125 (0.012–0.25) |
| Meningitis | 17 | 1.010 (1.007–1.017) | 2.5 (0.5–7.1) | 2.0 (0.012–12.6) |
| Listeriosis | 12 | 1.009 (1.008–1.017) | 1.69 (0.39–10.4) | 0.3 (0.012–1.7) |
| Bovine viral diarrhoea | 5 | 1.007 (1.006–1.010) | 0.22 (0.09–0.24) | 0.0125 (0.012–0.1) |
| Septicaemia | 11 | 1.009 (1.007–1.011) | 0.77 (0.19–2.04) | 0.05 (0.01–0.2) |
| Acidosis | 5 | 1.009 (1.007–1.011) | 0.35 (0.2–1.3) | 0.012 (0.012) |

ment necessitates the use of bactericidal antibiotics (Landesman *et al.*, 1981; Del Rio *et al.*, 1983).

The blood–brain barrier can be divided into the blood–brain and blood–CSF barriers, although some researchers consider them functionally synonymous because extracellular fluid of the brain is in equilibrium with CSF. Morphologically, the blood–brain barrier comprises the continuous tight junctions (*zonulae occludens*) of the endothelial cells which form the brain capillaries. The permeability of the blood–brain barrier is dramatically increased by the inflammatory process, whatever the cause (Oldendorf, 1975). The increased permeability of the blood–brain barrier in experimental meningitis models was in part caused by the separation of intercellular tight junctions of the cerebral microvascular endothelium which was augmented by the presence of CSF leucocytes (Quagliarello *et al.*, 1986).

Few broad-spectrum bactericidal antibiotics are capable of penetrating the intact blood–brain barrier, but it has generally been assumed that the disruption of the blood–brain barrier, which occurs in bacterial CNS diseases, increases the degree of antibiotic penetration (Barlow, 1991). Such increased permeability may be sufficient to allow passage of antibiotics which achieve minimum inhibitory concentrations within the CSF (Rings, 1987), but few studies have been undertaken in animals with naturally-occurring CNS infections to support such assumptions.

Antibiotic penetration of the blood–CSF barrier depends upon lipid solubility; the greater the degree of ionization of an antibiotic in plasma, hence reduced lipid solubility, the lower the penetration through the blood–CSF barrier. Antibiotic penetration also depends upon the degree of protein binding. Large molecular weight antibiotics, such as aminoglycosides, achieve very poor CSF concentrations even in the presence of meningeal inflammation (Stone & Wise, 1991).

As well as the selection of antimicrobial agent, there is considerable disagreement regarding the duration of treatment for CNS infections. Prescott and Baggot (1988) quote the experimental findings of Tauber *et al.* (1987), that the single most important factor in achieving a favourable outcome for streptococcal meningitis is the peak concentration of antibiotic in the CSF. Conversely, Rebhun and deLahunta (1982) recommended a six week course of antibiotic treatment for bovine listeriosis. In farm animal practice the cost of antibiotic treatment is an important limiting factor in the animal's treatment and high dose/short duration therapy is perhaps the best compromise in many situations.

Penicillins

In man, penicillin and ampicillin are usually considered the antibiotics of choice for meningitis caused by *L.*

monocytogenes (Tuazon *et al.*, 1982). It is strongly recommended that the first penicillin treatment is administered intravenously. The minimum inhibitory concentration (MIC⁹⁰) of penicillin G for *L. monocytogenes* has been quoted as 0.02 µg/ml (Prescott & Baggot, 1988). While lumbosacral CSF penicillin G concentrations between 0.09 and 1.02 µg/ml were achieved in three cases of bacterial meningitis 48 hours after the commencement of treatment of 44 000iu/kg procaine penicillin b.i.d. (Scott & Sutton, 1992), the median CSF protein concentration in those animals was higher than values encountered in listeriosis cases (2.5 g/l compared to 1.7 g/l), suggesting greater disruption of the blood–brain barrier. However, it is possible that the CSF penicillin G concentrations achieved in brain tissue were considerably higher than those achieved within CSF. High dose penicillin G or oxytetracycline treatments have been reported to give a good prognosis for listeriosis cases provided the cattle are still ambulatory when treatment commences (Rebhun & deLahunta, 1982). High dose penicillin treatment (44 000iu/kg procaine penicillin b.i.d.) of cases of ovine listeriosis, where the clinical diagnosis was supported by characteristic lumbar CSF analyses, gave a 24 per cent success rate (Scott, 1993a). It is possible that the optimum daily dose rate of penicillin G to treat acute CNS infections could be as high as 300 000iu/kg; approximately 15 times the normal dose rate. This dose rate is prohibitively expensive in most cattle except for the first day of treatment. The high cost of appropriate antibiotic therapy for infectious diseases of the CNS further emphasizes the necessity of an accurate diagnosis before commencing therapy. The use of conventional dose antibiotic therapy is unlikely to prove effective in the treatment of bovine listeriosis. Reports of successful treatment of listeriosis with certain antibiotics administered at conventional dose rates raise doubts over the clinical diagnosis and whether the cattle were indeed suffering from a vestibular lesion, which would have responded well to such therapy.

Active removal of penicillins from the CSF can be inhibited by probenecid. In horses the elimination half-life of ampicillin was increased, and total body clearance reduced, following treatment with probenecid (Sarasola & McKellar, 1992). The extent to which probenecid affects the clearance of penicillin from bovine CSF is not known and requires further study before its use can be recommended as an adjunct to penicillin therapy.

Aminoglycosides

Gentamicin is rapidly bactericidal against many potential Gram-negative organisms causing neonatal meningitis but, as a polar antibiotic, is unable to cross the

blood-brain barrier, even during meningitis. This lack of penetration into the CSF led to intrathecal and intraventricular administration of aminoglycoside antibiotics for the treatment of meningitis in infants and children, but this technique was associated with an increased mortality rate. Intrathecal injections of gentamicin in the lumbosacral region failed to result in significant concentrations in ventricular CSF (Moellering & Fisher, 1972) and, as a consequence, this technique has not been practised for the treatment of bacterial meningoencephalitis in cattle.

Chloramphenicol

Until withdrawal from the veterinary market in many countries, chloramphenicol was stated to be the antibiotic of choice for the treatment of bacterial meningoencephalitis (Rings, 1987) as it is capable of crossing the intact blood-brain barrier. In field studies 30 per cent of calves responded to chloramphenicol and showed a marked improvement within 24 hours and no relapses occurred after five consecutive days' treatment (Scott & Penny, 1993). There are no published studies of the usefulness of florfenicol, a closely-related molecule, in the treatment of bacterial meningoencephalitis.

Metronidazole

Metronidazole is highly lipid-soluble and capable of penetrating the blood-brain barrier and into brain abscesses. Unfortunately, this antibiotic is not licensed for use in veterinary medicine in Britain and there are no data regarding its use in cattle with CNS infections. In medicine, brain abscesses are frequently mixed aerobic and anaerobic infections and in such situations metronidazole is administered in conjunction with either penicillin or chloramphenicol.

Ceftiofur

Third generation cephalosporins are widely used for the treatment of bacterial meningoencephalitis in medicine but there are no data relating to the field use of ceftiofur in cattle. As chloramphenicol is no longer available to many veterinary practitioners, ceftiofur would present a logical choice for bacterial meningoencephalitis.

Trimethoprim-sulphonamide

Trimethoprim-sulphonamide has been recommended for the treatment of bacterial meningoencephalitis and listeriosis in cattle but there are no published field studies.

Anti-inflammatory agents

In certain neurological diseases, particularly polioencephalomalacia and bacterial meningoencephalitis, the control of cerebral oedema is an important factor affecting prognosis (McGuirk, 1987). The increased intracranial pressure in bacterial meningoencephalitis results from cerebral oedema, which may be a factor contributing to death, brain infarction and alterations in CSF hydrodynamics. The development of potentially-serious increased intracranial pressure is indicated by coma, seizures, abducens nerve palsy, persistent bradycardia and respiratory depression. The recommended treatment for the control of cerebral oedema is either 1–2 mg/kg dexamethasone given intravenously, 1–2 g/kg of dimethyl sulphoxide as a 10 per cent solution given intravenously or frusemide 1–2 mg/kg given intravenously (McGuirk, 1987).

There are no comparative field investigations of corticosteroid treatments in bovine CNS disease. While the potential benefits of the concurrent use of dexamethasone with cephalosporin antibiotics have been demonstrated for the treatment of bacterial meningitis in children, it is reported that there may be a number of potential deleterious effects including a reduction in cellular immune function and reduced penetration of antibiotics into CSF (Scheld & Brodeur, 1983).

Non-steroidal anti-inflammatory drugs (NSAIDs)

The potential application of NSAIDs such as flunixin or ketoprofen in the treatment of LPS-induced intrathecal reaction in bovine meningoencephalitis has not been reported. Bacterial meningoencephalitis is commonly associated with septicaemia where intravenous NSAID administration would be of benefit in the treatment of septic shock. The analgesic properties of NSAIDs may also prove of benefit in the treatment of bacterial infections of the CNS. Therefore, there are a number of indications for NSAID administration in calves with bacterial meningoencephalitis, although this statement is not supported by field results. The potential benefits of NSAID therapy in more chronic CNS infections have not been investigated.

Dimethyl sulphoxide (DMSO)

There is no licensed DMSO product for veterinary use in Britain, but analytical quality DMSO has been used in the treatment of cattle with CNS dysfunction. DMSO has many properties, including reduction of cerebral oedema and free radical scavenging (Brayton, 1986), but special handling precautions preclude its use in most situations encountered in general practice. In veterinary practice, DMSO administration would most

likely be restricted to the very valuable calf suffering from bacterial meningoencephalitis.

Intravenous/oral fluids

Severe dehydration can be corrected by the intravenous infusion of isotonic saline. Metabolic acidosis, which is commonly encountered in listeriosis cases caused by saliva loss, can be corrected by regular administration of sodium bicarbonate by oro-gastric tube.

Summary

Successful treatment of bovine CNS infections necessitates a rapid and accurate diagnosis. Cerebrospinal fluid collection is a simple procedure and visual inspection can reveal much useful information, particularly in neonatal calves with bacterial meningoencephalitis, permitting a rapid diagnosis and prompt treatment. Encephalitis lesions, such as those caused by listeriosis, result in minor changes in the CSF and laboratory examination is necessary. Ceftiofur, a third generation cephalosporin antibiotic, and trimethoprim-sulphonamide are indicated for the treatment of bacterial meningoencephalitis but field data are limited. The usefulness of florfenicol in the treatment of bacterial meningoencephalitis has not been reported but this molecule is sufficiently similar to chloramphenicol to justify its use and clinical evaluation in the treatment of bacterial meningoencephalitis in calves. Penicillin G (>44 000iu/kg b.i.d.) is the treatment of choice for listeriosis and peripheral vestibular lesions, with the first treatment administered intravenously. Insufficient data are available to comment upon the efficacy of either corticosteroids or NSAIDs for the treatment of central nervous system bacterial infections.

Specific diseases

Cerebellar hypoplasia/hydranencephaly

The cerebellum is the most common CNS site for *in-utero* insult. The cerebellum is primarily concerned with fine coordination of voluntary movement. In cerebellar dysfunction, limb movements are spastic (rigid), clumsy and jerky. Initiation of movement is delayed and may be accompanied by intention tremors.

Aetiology

Cerebellar hypoplasia/hydranencephaly can be the result of an autosomal recessive condition or caused by *in-utero* infection with bovine virus diarrhoea/mucosal disease (BVD/MD; see p. 855) or Akabane virus.

Pathology

In-utero BVD/MD virus infection around 90 to 130 days' gestation causes cerebellar hypoplasia and, less commonly, hydranencephaly. The BVD/MD virus invades the fetus and infects the developing germinal cells of the cerebellum and destroys the Purkinje cells in the granular layer. Microphthalmia is uncommon.

Signs and diagnosis

Cerebellar disease is characterized by a wide-based stance and ataxia (incoordination), particularly of the pelvic limbs, but with preservation of normal muscle strength. In addition to the ataxia, dysmetria may be observed with hypermetria more commonly observed in cerebellar disease. Coarse intention head tremors are frequently observed, particularly during periods of excitement such as feeding times. Opisthotonus can occur in calves with severe lesions of the rostral cerebellum. Such calves present in lateral recumbency with rigid extension of the neck and thoracic limbs and flexion of the pelvic limbs with clinical signs noted soon after birth.

In addition to the cerebellar signs, calves with hydranencephaly exhibit blindness and depression/somnolence (dummies). In extensively-managed beef herds, calves with hydranencephaly may not be detected until the calf is several months old. Often the demeanour of such calves is attributed to another cause and such calves are not presented for veterinary examination. Cerebellar dysfunction in young calves may be the first manifestation of active BVD/MD infection in the herd and it is important that these clinical signs are identified so that control measures can be introduced to prevent further losses.

Treatment and prevention

There is no treatment for cerebellar hypoplasia and affected calves should be culled because they pose a risk to seronegative/unvaccinated breeding cattle in the herd. Biosecurity is an important aspect of herd health which is frequently overlooked on British farms and worldwide. Increasingly, more British dairy and beef herds will become self-contained with high health status, but in the meantime introduction of disease by carrier animals is a major concern. Depending upon the health status of the herd, purchased cattle should either be screened for BVD/MD antibody and antigen status upon arrival or vaccinated during the quarantine period. Establishment of a BVD/MD-free herd is presently included in numerous health schemes packages in Britain but is not without risk from introduction of infection with carrier-status

cattle and from adjacent herds via direct contact, water courses, carrion, etc (Chapter 57).

Bacterial meningoencephalitis (see p. 251)

Bacterial meningoencephalitis most commonly affects calves 3 to 8 days old and is associated with poor immunoglobulin status and high bacterial challenge in the environment (Rings, 1987). The early clinical signs of lethargy, depression and failure to suck rapidly progress to hyperaesthesia, opisthotonus and death (Scott & Penny, 1993). Compulsive wandering and head pressing have also been reported (Jamison & Prescott, 1987) but are less common. The prognosis is poor despite intensive antibiotic treatment and supportive care.

Aetiology

Bacteraemia, with subsequent localization within the meninges, results from failure of passive antibody transfer (Jamison & Prescott, 1987) and high levels of bacterial challenge in the calf's environment. The disease is more common in those calves born indoors in unhygienic calving boxes than in those born of cows at pasture. Failure of the calf to ingest colostrum equivalent to 7 per cent of its bodyweight within the first six hours of life may be caused by calf and/or dam factors. Dystokia, weakness, nerve damage, overcrowded calving accommodation, udder shape, dirty teats and an overly-anxious dam may all contribute to poor/delayed sucking behaviour by the calf. Dystokia, nerve damage, hypocalcaemia and weakness may result in prolonged recumbency of the dam. Poor nutrition, short dry period and mastitis cause reduced colostrum accumulation in the udder. Heifers' colostrum contains 25 per cent less colostrum than cows' colostrum. Bacteraemia may result via the oropharyngeal route, respiratory tract, gastrointestinal tract or umbilicus. *Escherichia coli* and *Streptococcus* spp. were the more common isolates from lumbar CSF of calves with meningoencephalitis (Scott & Penny, 1993).

Pathology

Septic foci are prone to localize within meningeal vessels and are either rapidly walled off or may lead to diffuse suppurative meningitis. A combination of synovial, meningeal and intraocular localizations is almost invariably of streptococcal origin; coliform infections rarely cause endophthalmitis (Jubb & Huxtable, 1993). Once bacteria gain access to the leptomeninges there is little resistance to spread and the inflammatory process becomes diffuse.

In the first day or so the meninges are opaque and hyperaemic with pus accumulating in the basal cisterns

within two days or so, although this may be difficult to visualize against the surface of the brain. Over the cerebral hemispheres the exudate is largely confined to the fissures. The brain is swollen in the acute stages of disease and may be so severe to cause displacement of the cerebellum into the foramen magnum and coning.

Signs and diagnosis

The early clinical signs include lack of suck reflex, depression, failure to follow the dam (beef calves) and weakness (Green & Smith, 1992; Scott & Penny, 1993). Fever is not a consistent feature. Affected calves stand with the neck extended and the head held lowered. Flexion of the neck is painful and may result in vocalization. In the absence of appropriate treatment the calf becomes increasingly weak over the next 6 to 12 hours with an altered gait, and may be unable to stand. Diligent stockmanship is important when checking young beef calves because the early clinical signs of lethargy and weakness can easily be overlooked, especially when the calves are lying together in a group during adverse weather conditions. Depression and poor appetite are more readily detected in individually-penned dairy calves. As the disease progresses there is lack of menace response and dorsomedial strabismus. Episcleral injection is often present at this stage. Depression progresses to stupor, but the calf is hyperaesthetic to auditory and tactile stimuli which may precipitate seizure activity during handling for intravenous antibiotic injection. Opisthotonus is observed during the agonal stages of disease approximately 24 to 36 hours after clinical signs are first noted. There may be evidence of infection involving other organ systems such as hypopyon, polyarthritis, diarrhoea and omphalophlebitis. Infarcts in the liver and kidney are frequently observed at necropsy. In a study of ten calves with meningoencephalitis, three calves had polyarthritis, three calves showed hypopyon and two calves had omphalophlebitis, but none exhibited diarrhoea (Scott & Penny, 1993).

The important differential diagnosis for bacterial meningoencephalitis is metabolic acidosis resulting from diarrhoea of 2 to 3 days' duration. Septicaemia presents with similar clinical findings to meningoencephalitis as the meninges are a common site for bacterial colonization in neonatal calves.

Lumbar CSF is readily collected under local anaesthesia from depressed or stuporous calves. Calves with bacterial meningoencephalitis frequently have a CSF protein concentration above 1.0 g/l (deLahunta, 1983) and greater than 2.0 g/l (Green & Smith, 1992; Scott & Penny, 1993). The normal CSF protein concentration is <0.3 g/l with a white cell concentration less than $0.012 \times 10^9/l$. There is also a marked increase in CSF total white

cell count in the order of 100-fold and a change in the predominant white cell type from lymphocyte to neutrophil (neutrophilic pleocytosis). These CSF changes cause increased turbidity of the sample which is visible upon gross CSF inspection and affords the veterinary surgeon an immediate diagnosis. One to two days' delay in detailed laboratory examination of the CSF would undoubtedly result in death of the calf if left untreated. However, routine antibiotic therapy of all diarrhoeic calves is not recommended because many antibiotics slow the mitotic rate of enterocytes, which is an important factor in recovery from viral causes of diarrhoea. Bacteriological culture of lumbar CSF is often unrewarding and is unnecessary because of the sporadic nature of the disease and its causation by opportunist organisms.

Treatment and prevention

A successful outcome necessitates early detection of abnormal calf behaviour by the client and prompt clinical diagnosis by the veterinary practitioner supported by visual inspection of lumbar CSF. Any delay in veterinary diagnosis and implementation of treatment has a hopeless prognosis, but prompt treatment with chloramphenicol achieved a 30 per cent recovery rate (Scott & Penny, 1993). Few broad-spectrum bacteriocidal antibiotics are capable of penetrating the intact blood–brain barrier, although it is commonly assumed that the disruption of the blood–brain barrier, which occurs in bacterial CNS diseases, increases the degree of antibiotic penetration. This increased membrane permeability may allow sufficient passage of antibiotics to achieve minimum bactericidal concentrations (MBC) within the CSF. A peak CSF antibiotic concentration 10 to 30 times the effective MBC may be more important than the maintenance of CSF antibiotic MBC (Prescott & Baggot, 1988) and emphasizes that high dose antibiotic therapy is indicated as soon as possible after the onset of clinical signs of bacterial CNS infection.

It is reported that the best treatment for Gram-negative bacillary meningitis in man is the third generation cephalosporins, in particular cefotaxime (Cherubin & Eng, 1986; Feldstein *et al.*, 1987) but no data could be found in the veterinary literature relating to the use of ceftiofur in the treatment of infectious bovine neurological diseases under field conditions.

Chloramphenicol is no longer permitted in food-producing animals in many countries; there are no field studies which report the clinical efficacy of its closely-related successor florfenicol. Other antibiotics which could be administered for bacterial meningoencephalitis include trimethoprim–sulphonamide combination or ceftiofur.

Septicaemia

Calves with septicaemia frequently present with clinical signs similar to bacterial meningoencephalitis because the meninges are simply one site for localization of blood-borne pathogens. The clinical course of septicaemia is generally peracute and affected calves may be found either dead or *in extremis* within 12 hours. Other sites of infection such as eyes (hypopyon), gut (diarrhoea), joints (polyarthritis) and umbilicus (omphalophlebitis) may be identified. Foci in the lung, kidney, liver and spleen are only detected following necropsy.

Enteric infections causing metabolic disturbances

Sequestration of water and electrolytes in the gut lumen, often without overt signs of diarrhoea, caused by the heat stable enterotoxin produced by K99 strains of *E. coli*, can result in recumbency in one to four day-old calves which often rapidly progresses to coma and death. Older calves with severe metabolic acidosis secondary to enteric viral infection, typically 6 to 14 days old, are weak, unable to stand and depressed with deterioration of mental state to stupor. It can prove difficult to undertake a thorough neurological examination, e.g. menace response and spinal reflexes, in such depressed or stuporous calves to differentiate such calves from early cases of bacterial meningoencephalitis. Collection of lumbar CSF on the farm reveals a normal clear sample which allows immediate differentiation from bacterial meningoencephalitis (Scott & Penny, 1993).

Treatment of acidotic calves with intravenous isotonic saline solution, spiked with 400–600mEq of bicarbonate, is successful with a rapid improvement in demeanour and ability of the calf to stand within 6 to 12 hours.

Brain abscess

Neurological signs of a brain abscess typically appear in 4 to 12 week-old calves following localization of neonatal bacteraemia. Extension of infection through the calvarium following infection of the frontal sinus as a consequence of dehorning, while reported in the literature, is uncommon in Britain.

Aetiology

Arcanobacterium pyogenes is the most common isolate from brain abscesses.

Pathology and pathogenesis

Brain abscesses are usually of haematogenous origin. Most cerebral abscesses are small and track

inward to the white matter rather than out to the meninges.

Signs and diagnosis

Affected calves are usually dull and depressed with a sluggish gait. These calves have a poor appetite and as a consequence appear ill thriven. Approximately 90 per cent of efferent nerve fibres cross at the optic chiasma; therefore animals with a left-sided cerebral abscess are blind in the right eye but the pupillary light reflex is normal. As the abscess continues to grow the animal becomes increasingly depressed, sometimes over many months. Ipsilateral compulsive circling may lead to the calf becoming stuck with its head in the corner of the pen or fence. Once in this position, the calf may stand motionless for long periods of time, sometimes hours. The gait is often sluggish and ataxic. There is ipsilateral deviation of the head towards the flank, but this altered head carriage must not be confused with a head tilt. The calf may display ipsilateral postural deficits such as knuckling of the fetlock joints. In most cattle there are no cranial nerve deficits. There is frequently an increased protein concentration and elevated white cell concentration in lumbar CSF, which reflect any accompanying suppurative meningitis.

Treatment and prevention

Treatment with high dose penicillin (minimum 44000 iu/kg b.i.d.) for 10 days may halt progression of the abscess but the long term prognosis is very poor. Prevention of bacteraemia in neonatal calves necessitates ensuring adequate passive antibody transfer and reducing environmental bacterial challenge by maintaining good hygiene standards in the calving accommodation.

Cerebellar abiotrophy (postnatal degeneration)

Cerebellar abiotrophy is an inherited condition which has been reported in Holstein calves in the UK. The cerebellar abiotrophies are considered to be familial and degenerative but not congenital. Similar clinical signs have been reported in a six month-old Limousin cross heifer caused by selected cerebellar degeneration (Woodman *et al.*, 1993; see also pp. 178, 893).

Signs and diagnosis

Clinical signs of pelvic limb ataxia, especially when turning quickly, wide-base stance and hypermetria appear from around six weeks of age and are slowly progressive over many months, leading eventually to recumbency by one year of age. The preservation of strength and chronicity of the condition differentiates

this condition from cervical spinal lesions which often appear at around 6 to 12 weeks old.

Unilateral middle ear infections/vestibular syndrome (see also p. 252)

The vestibular system helps to orientate the animal in its environment with respect to gravity, and maintains position of the eyes, trunk and limbs during movement. Unilateral middle ear infections (otitis media) are not uncommon in growing calves and yearlings and usually arise from ascending infection of the eustachian tube, often following respiratory disease.

Signs and diagnosis

The major clinical sign in unilateral peripheral vestibular disease is an ipsilateral head tilt of 5° to 10° down to the affected side. There may be loss of balance, leaning and movement/circling toward the affected side. When walking, cattle tend to drift toward the affected side. During the early stages of unilateral peripheral vestibular lesions there is spontaneous horizontal nystagmus with the fast phase away from the side of the lesion. There is often ipsilateral ventral deviation of the eye (eye drop), which is exaggerated when the head is raised. The facial nerve travels close to the middle ear and facial palsy is often seen in conjunction with otitis media.

In central vestibular disease the nystagmus may be horizontal, vertical or rotary, and there may be ipsilateral limb weakness. Depression indicates involvement of the reticular formation.

It is important to differentiate vestibular lesions from listeriosis because of the different treatment regimens and control measures.

Treatment and prevention

The bacterial infection responds well to five to seven consecutive days' treatment with 44000iu/kg procaine penicillin s.i.d. The condition occurs sporadically and there are no specific control measures.

Polioencephalomalacia (cerebrocortical necrosis, CCN) (see also p. 261)

This is a sporadic condition that affects young growing cattle. It is characterized clinically by dullness, bilateral lack of menace response, dorsomedial strabismus and hyperesthesia to auditory and tactile stimuli, progressing over days to lateral recumbency and opisthotonus.

Aetiology

Healthy ruminants obtain their requirements from thiamine synthesized by the rumen flora. Free thiamine is readily absorbed and is actively phosphorylated to thiamine pyrophosphate (TPP). The brain is critically dependent on carbohydrate for energy and TPP has a coenzyme role in decarboxylation of α -ketoacids for entry into the tricarboxylic acid cycle. Thiamine pyrophosphate is also a coenzyme in the transketolase reaction of the hexose monophosphate shunt and the alternative, glycolytic, pentose phosphate pathway. Outbreaks of PEM have been described in cattle, and sheep (Low *et al.*, 1996), when fed diets high in sulphur.

Pathology

The brain usually appears pale and swollen with flattened gyri, which in the frontal, dorso-medial and parietal regions often show a patchy, bilaterally symmetrical, yellow discolouration. There is swelling of the cingulate and parahippocampal gyri, which may herniate beneath the tentorium cerebelli. The posterior vermis may have herniated through the foramen magnum and appear necrotic. The cut surface of the cerebrum reveals that the necrotic cortical tissues have a laminar configuration and may have separated from the underlying white matter. When viewed in ultraviolet light (wavelength 365 nm) affected regions of cortex have a bright white autofluorescence, which has been attributed to ceroid lipofuscin (Little, 1978).

Histologically, there is increased prominence of capillary endothelium (neovascularization) and dilatation of perivascular spaces with occasional small perivascular haemorrhages. Astrocytes and neurones show hydropic changes and nuclear pyknosis, which proceeds in time to a laminar necrosis. In well established cases there is a massive influx of macrophages into the necrotic areas and adjacent leptomeninges.

Signs and diagnosis

PEM occurs sporadically, affecting weaned calves and young feedlot cattle. It is associated with diets low in fibre, although cases have occurred in animals grazing lush aftermath. Under these circumstances, changes occur in the rumen flora that permit multiplication of micro-organisms such as *Bacillus thiaminolyticus* and *Clostridium sporogenes*, both of which synthesize thiaminase type 1, thereby inducing thiamine deficiency.

During the early stages of PEM there is frequently a brief period of diarrhoea before nervous signs appear. Affected animals are dull and may isolate themselves from others in the group. There is high head carriage and affected cattle may stagger. There is bilateral loss

of menace response and dorsomedial strabismus. Affected animals are hyperaesthetic to tactile and auditory stimuli. As the disease progresses animals often head press into corners and there is frequent bruxism (teeth grinding). Twitching, muscular tremors and intermittent opisthotonus are evident, followed by recumbency and clonic convulsions with intermittent periods of spasticity and terminal flaccidity. Untreated cattle die within three to five days.

Diagnosis of PEM is based primarily on the history, clinical signs and response to intravenous thiamine administration. Laboratory tests are of equivocal value and response to treatment of early cases is commonly employed as a diagnostic indicator by practitioners.

Changes in lumbar CSF include a slightly increased protein concentration, but this result is of little diagnostic value.

Treatment and prevention

The response to large doses (10–15 mg/kg) of thiamine hydrochloride given intravenously early in the disease is usually evident within 24 hours. The thiamine should be repeated within 4 to 6 hours, then twice daily for three consecutive days. Full clinical recovery may take one week. Intravenous administration of dexamethasone (1.0 mg/kg) at first presentation may aid recovery.

Prevention of PEM involves the maintenance of normal rumen fermentation with adequate dietary fibre ensuring production of volatile fatty acids which curtail the growth of thiaminase-producing organisms. The efficacy of metaphylactic thiamine injections during an outbreak of dietary sulphur-induced PEM in cattle remains equivocal, although this did appear to halt appearance of new clinical cases in housed lambs (Low *et al.*, 1996).

Listerial encephalitis (see also p. 156)

Listerial encephalitis is the result of infection of the brain substance with *Listeria monocytogenes*.

Aetiology

Listeria monocytogenes is a microaerophilic Gram-positive, flagellated coccobacillus which is present in a wide range of moist environments and may cause disease in man and a variety of domestic species. Listeriosis occurs sporadically in cattle, where most cases are associated with feeding poorly fermented silage during the winter months. Cattle show a similar age incidence to sheep with the majority of cases affecting two to three year-olds, although cattle appear much less susceptible to listeriosis than sheep. Rarely are outbreaks of listeriosis encountered in cattle.

Pathology

The pathogenesis of listerial encephalitis involves centripetal passage of the organism along branches of the trigeminal nerve from minor breaches in the buccal mucosa. Intracranial pathology initially consists of a small focus of necrosis in the lateral part of the pons, which is associated with activation of microglial cells and astrocytes followed by an influx of monocytes and a few neutrophils. The initial focus may be unilateral but thereafter (intraneuronal) spread results in micro-abscesses forming bilaterally in the mid brain and lower medulla.

Signs and diagnosis

The rectal temperature of affected cattle is within the range 38.5 to 39.2°C. There is reduced appetite with a gaunt appearance, marked fall in milk production in lactating cattle and weight loss. Loss of saliva leads to rumen impaction, causing abdominal pain manifest as an arched-back stance and frequent bruxism.

As most of the cranial nerve nuclei are present within the brainstem, ascending infection of the trigeminal nerve by *L. monocytogenes* is characterized by multiple unilateral cranial nerve deficits, depression and, in some cases, circling to the affected side. Ipsilateral hemiparesis may also be present and should be differentiated from ataxia observed in cattle with BSE.

Involvement of the trigeminal nucleus results in paralysis of the cheek muscles and decreased facial skin sensation. Facial palsy is evident as drooped ear, drooped upper eyelid (ptosis) and flaccid lip. Occasionally, there may be paralysis and protrusion of the tongue. Exposure keratitis may result from paralysis of the *orbicularis oculi* muscle. Loss of cheek and lip muscle tone result in drooling of saliva from the affected side of the mouth. Depression is attributed to a lesion in the ascending reticular activating system. A head tilt toward the affected side is an inconsistent finding. Circling can be observed with involvement of the vestibulocochlear nucleus. Cattle frequently display a 'propulsive tendency' and may be found with the head forced through a gate, under a feed trough or wedged across the front of a cubicle. Indeed, dairy cows have barged through the milking parlour under the cows ahead of them causing chaos and often falling into the milking area; such behaviour in previously quiet cattle led to misdiagnosis of BSE. Caution must be exercised when cattle are found with the head trapped under a feed barrier, etc., because casual examination may attribute the facial palsy to trauma but this would not explain the unilateral loss of jaw tone and facial skin sensation.

Loss of cranial nerves IX, X and XII function results in stertorous breathing and dysphagia, but this presen-

tation is uncommon in cattle with listeriosis. Hypoglossal nerve dysfunction leading to tongue paralysis and protrusion is more commonly observed in ovine listeriosis.

The course in untreated cattle lasts 10–14 days, progressing to coma.

A moderate increase in CSF protein concentration in the range 0.8 to 2.0 g/l is observed in meningoencephalitis caused by *L. monocytogenes* (Rebhun & deLahunta, 1982).

Listeriosis is frequently associated with the feeding of silage and may be suspected on the basis of the clinical signs and supported by findings of an elevated CSF protein concentration and monocytic pleocytosis. Vestibular lesions (p. 896), lead poisoning (p. 944), brain abscess, BSE (p. 909) and nervous acetonaemia (p. 795) should be considered amongst the differential diagnosis.

Isolation of the causal organism from the brain may require extended periods of 'cold enrichment', but the neurohistopathology is usually sufficiently characteristic to permit firm diagnosis.

Treatment and prevention

Penicillin or trimethoprim-sulpha remain the antibiotics of choice for listeriosis. Oxytetracycline is not considered an appropriate antibiotic for listeriosis because of its large molecular size, although good results have been claimed. A minimum dose rate of 44000 iu/kg procaine penicillin injected intramuscularly b.i.d. must be considered for at least 10 days in addition to 44000 iu/kg penicillin G injected intravenously b.i.d. on the first day. Penicillin dose rates as high as 300000 iu/kg have been recommended for the first day of antibiotic therapy because it is essential to exceed MICs by 10 to 30 times to achieve a successful outcome.

Loss of saliva may lead to dehydration and metabolic acidosis. Care must be taken when replacing fluids by orogastric tube because contraction of the rumen caused by anorexia of some days' duration may result in passive regurgitation of these fluids around the orogastric tube. The amount of fluids administered in this way should be restricted to 15 to 25 litres four to six times daily. Transfaunation with rumen liquor from a healthy cow may promote rumen function and aid recovery.

There are no published studies which have reported the efficacy of prophylactic antibiotic administration in the face of an outbreak of listeriosis, but such epidemiology is unusual in cattle.

Listeriosis occurs sporadically in cattle and is prevented by management practices which ensure the making and storage of high quality silage. Soil contamination is limited by rolling grass fields at the beginning

of the growing season. Good fermentation is guaranteed by cutting grass at an early growth stage (digestibility value >72) when it contains a high fermentable sugar content, and the use of various silage additives, whether sugars, organic acids or bacterial cultures. Compaction of the silage clamp is important to expel all air followed by air-tight sealing to prevent aerobic bacterial multiplication. Poor quality or spoiled silage should be discarded. Prevention of listerial encephalitis by vaccination is not an established procedure in ruminant species.

Lead poisoning (see also p. 944)

Cattle, through their innate curiosity, indiscriminate feeding habits and relative susceptibility to lead, are the species most commonly poisoned by lead compounds. Lead poisoning in cattle is characterized by an acute encephalopathy.

Aetiology

The common sources of lead include discarded storage batteries, flaking old lead-based paint, putty, asphalt roofing materials and used motor engine oil. Intoxication may result from a single large dose of lead or from ingestion of smaller amounts over a long period of time. In both forms the neurological signs are acute in onset and similar in type.

Pathology

The severity of neuropathological change in lead poisoning correlates more closely with survival time than with the concentration of lead in the tissues, being most severe in cases that survive longest.

Grossly, the brain appears pale and slightly swollen with flattened gyri, but without herniation of the hippocampal gyrus beneath the tentorium or cerebellar coning (cf. PEM). Some gyri, most commonly those in the occipital region, show a yellow discolouration. The cut surface may show separation of these yellow zones of cortical tissue from the underlying white matter at the tips of the gyri with actual cavitation in the deeper cortical laminae. In cases of longer survival these changes may extend to the tips of almost all gyri and extend down the sides of the convolutions (Christian & Tryphonas, 1971).

Histologically, the earliest changes in affected gyri comprise swelling and prominence of capillary endothelial cells, which is sometimes referred to as neovascularization. Swelling of astrocytes, and fine microvacuolation of the neuropil, also occur at an early stage, advancing to spongy transformation with necrosis of neurones, malacia and infiltration by

macrophages. In cattle with long survival periods these cortical lesions may be extensive, and similar lesions may be present also in the thalamus and hypothalamus, medulla and spinal cord.

Signs and diagnosis

Irrespective of the rate of uptake of lead, the clinical signs of intoxication are sudden in onset and characterized by behavioural changes. During the early stages of lead poisoning affected cattle become isolated and depressed. These animals are hyperaesthetic to tactile and auditory stimuli and may show muscle twitching, especially of the palpebral muscles. Affected cattle are blind and may head press forcibly into corners and against walls. The disease progresses and cattle become frenzied, bellow, stagger and crash into obstacles. There may be signs of abdominal pain including kicking at the abdomen and frequent bruxism (teeth grinding). Bloat is often seen and attempts to alleviate this problem often precipitate frenzy. Death may occur suddenly or within days.

The diagnosis of lead poisoning is suspected on the basis of clinical signs and the presence of a source of lead. Confirmation depends upon the histopathological findings and the chemical determination of the concentration of lead in tissues. In kidney and liver concentrations >4 ppm wet weight and blood values in excess of 0.3 ppm are considered diagnostic.

Treatment and prevention

Cattle with severe neurological signs of some days' duration probably have extensive neuropathological changes and are unlikely to respond to treatment. However, if a source can be identified, in-contact animals at risk from a single large dose may be drenched orally with magnesium sulphate (500–1000 g) to precipitate and remove lead from the alimentary tract and injected with calcium disodium edetate at 110 mg/kg by slow intravenous infusion on alternate days for three treatments. The similarity of the pathological changes to those of PEM has encouraged the use of thiamine (10–15 mg/kg intravenously) along with EDTA therapy and is reportedly beneficial. Control of convulsions proves very difficult because drugs such as diazepam have such a short half-life in cattle. Chloral hydrate sedation may be attempted but this drug is not licensed for use in cattle in Britain. Pentobarbitone is frequently used to control seizure activity in cattle with acute hypomagnesaemia and could be used in emergency situations for lead poisoning to control convulsive episodes.

Prevention is a matter of good management, not allowing access by cattle to sources of lead.

Thromboembolic meningoencephalitis (TEME) (see also p. 240)

Under conditions of stress or intercurrent disease a fulminating *Haemophilus somnus* bacteraemia may occur with disseminated intravascular coagulation. Thromboemboli may lodge in meninges, brain, muscles and joints causing depression, blindness and recumbency with muscular weakness. Retinal haemorrhages may be found.

Aetiology

Thromboembolic meningoencephalitis (TEME) is a fulminating *Haemophilus somnus* bacteraemia. TEME is a significant problem in feedlot cattle in North America associated with stresses of weaning, long journeys (often thousands of miles), co-mingling in auction markets and the feedlot, changes in diet, husbandry, altitude and nutrition, and processing on admission to the feedlot. Processing is a collective term used to describe a range of procedures undertaken on admission to the feedlot and may include castration, dehorning, anthelmintic treatment, ectoparasite treatment, vaccination against a wide range of viral and bacterial pathogens including parainfluenza 3 virus, bovine respiratory syncytial virus, infectious bovine rhinotracheitis, *Mannheimia haemolytica* and *Pasteurella multocida*, implantation with hormonal growth promoters and ear tagging. These procedures and stresses render the weaned beef calf susceptible to a wide range of respiratory tract and other infections. Infection with *H. somnus* probably occurs through the respiratory tract from asymptomatic carriers to non-infected cattle. Bacteraemia results in thrombosis in the brain-stem, spinal cord, synovial membranes, pleurae and lungs. Outbreaks of TEME are often preceded by respiratory disease, which is all too common in large feedlots where morbidity rates may exceed 40 per cent despite prophylactic antibiotic administration during processing.

Signs and diagnosis

The neurological signs of TEME are sudden in onset and death may occur within 36 hours of onset. Affected cattle are pyrexic (40 to 42°C), anorexic and depressed. The depression may extend to somnolence and has led to the term 'sleeper calves'. Proprioceptive deficits are commonly observed and affected cattle appear ataxic. Cattle may be found recumbent in the pen with the head averted against the chest and are unable to raise themselves. Blindness, nystagmus and strabismus are variably present. Terminally, there is opisthotonus and coma. Lesions are also present in the lungs and auscul-

tation reveals widespread wheezes. Pleural friction rubs are described in some reports but significant pleurisy severely restricts movement of the underlying visceral pleura such that no sounds are generated by this localized pathology. Localization of bacteria within joints causes joint effusion and swelling with associated severe lameness which may result in recumbency. Retinal haemorrhages, hyphaema and hypopyon have also been described in some cattle following localization of the bacteraemia.

Treatment and prevention

Prompt detection of early neurological signs is important to ensure early antibiotic therapy; therefore cattle should be regularly inspected by trained stockmen during the high risk period following introduction of groups of cattle to the feedlot. *H. somnus* is susceptible to a wide range of antibiotics *in vitro* including oxytetracycline, penicillin and ampicillin; however, oxytetracycline does penetrate the blood-brain barrier well. Penicillin offers the most cost effective treatment at dose rates greater than 44 000iu/kg b.i.d., which should be administered for at least five consecutive days.

Vaccination is not undertaken in Britain due to the sporadic nature of *H. somnus* infections where respiratory disease is the more common clinical presentation. Prophylactic injection with long-acting oxytetracycline and in-feed medication have been described in North American feedlot situations, but these are of doubtful use. Greater attention must be paid to the sourcing of feedlot cattle. Preconditioning including weaning, dehorning, castration, vaccination and introduction of concentrate feedstuffs must be undertaken at least three weeks before sale and transportation. Cattle sourced directly from ranches have a much lower incidence of respiratory disease than those from auction markets or sale barns. Unfortunately, such sensible husbandry practices will not be undertaken until a significant premium is paid for such calves. The use of prophylactic antibiotic administration on admission to feedlots in North America requires urgent review.

Aujeszky's disease

Aujeszky's disease is a herpes virus infection principally of pigs, which can be transmitted to most other mammalian species including cattle.

Aetiology

Infections in cattle are generally sporadic and result from contact with infected pigs, foodstuffs or other materials contaminated with virus. The disease in cattle

is extremely severe with self-mutilation necessitating immediate slaughter for welfare reasons.

Pathogenesis and pathology

Infection in cattle is generally by the oronasal route. Centripetal intra-axonal transport of virus causes first a severe ganglioneuritis followed by meningoencephalitis or myelitis. Lesions are most severe in the olfactory lobe, hippocampus and cerebellum, whereas infection of a spinal peripheral nerve results initially in a segmental myelitis. Grey matter is principally affected with degenerative changes in nerve cells and astrocytes in which multiple, small, granular, eosinophilic, intranuclear inclusion bodies may be found. The inflammatory response is essentially non-suppurative and is characterized by lymphocytic perivascular cuffing and focal microgliosis.

Signs and diagnosis

The clinical course is short, rarely extending beyond 48 hours in adult cattle, whilst calves may die without obvious prior signs of illness. Usually, however, there is a brief period of excitement with high fever, bellowing, and aggressive behaviour accompanied by trembling, hyperpnoea, salivation and compulsive licking of the nostrils. Intense pruritus of the neck, trunk or hind legs is accompanied by frantic efforts to relieve the itch to the point of self-mutilation. Affected animals may become bloated and there is incoordination and, terminally, recumbency, convulsions and coma.

Except in calves, the clinical signs are usually distinctive enough for a provisional diagnosis of Aujeszky's disease to be reached. Confirmation is dependent upon demonstration of the characteristic neuropathology or virus isolation from nervous tissue.

Treatment and prevention

There is no effective treatment and affected cattle are killed immediately for welfare reasons. Prevention is dependent upon control of disease in the pig population. Attenuated and inactivated vaccines are available and are effective in preventing disease in pigs. However, they will not protect pigs from infection with field virus, which will replicate and be shed for some time after infection. Thus control in pigs must be through the establishment and maintenance of clean closed herds by serological testing and slaughter. This has been undertaken as a successful national campaign in Britain. The disease in cattle and sheep is notifiable in Britain and in some other countries.

Rabies (see Chapter 70)

Rabies is a neurotropic viral disease that can affect all warm-blooded animals. The virus is excreted in saliva

and transmitted by the bite of an infected animal. It is manifested by irritability, mania, hydrophobia and paralysis. It is usually fatal, although recoveries have been documented.

Aetiology

The causal agent is a delicate rhabdovirus readily destroyed by disinfectants and desiccation. It causes pathological changes only in nervous tissue. Rabies occurs worldwide except in certain island territories (Australia and New Zealand) and a few countries from which it has been eradicated, such as the British Isles and Scandinavia. In the western hemisphere the infection is endemic in dogs, foxes, wolves, skunks, raccoons and bats of several species. Infection is transmitted with the bite of a rabid animal.

Pathology and pathogenesis

Cattle are very susceptible to rabies and become infected, usually on the hindquarters or limbs, from the bite of a rabid fox, dog or bat. Following local replication, virus travels centripetally in the axoplasm of a peripheral nerve to reach the spinal cord and thence to the brain. *En route* it replicates in neurones. From the brain, in the later stages of the incubation period, the virus passes centrifugally along nerves to the salivary and lacrimal glands and is present in their secretions. Rabies virus is highly neurotropic and viraemia is minimal or absent.

Signs and diagnosis

The incubation period of rabies in cattle varies from about two to three weeks to several months. Clinical signs classically occur in two distinct forms, the mild paralytic or dumb form and the furious form, depending upon the pathogenicity of the strain of virus. In paralytic rabies there may be partial loss of sensation in the hind legs, knuckling of the fetlocks, locomotor weakness and paralysis of the tail. Flaccid dilatation of the anus may be accompanied by straining and passage of air in and out of the rectum. Drooling of saliva and yawning are common features. The entire clinical course lasts about one week and is terminated by recumbency, generalized paralysis with death probably due to respiratory failure. In the furious form the animal is hyperaesthetic and sexually excited. It bellows hoarsely and becomes violently aggressive towards people, other animals and inanimate objects. Purposeful attacks, however, are frustrated by rapidly progressive incoordination and ataxia. Death occurs quickly following recumbency and paralysis.

Cattle are normally 'end hosts' with respect to rabies, although human infection may follow manual examination of the oral cavity in which virus in saliva is inoculated into scratches caused by teeth.

Clinical diagnosis of rabies is difficult, especially in those countries in which it rarely occurs. The possibility of rabies should be borne in mind in the differential diagnosis of bloat, nervous acetonaemia (p. 795), listerian encephalitis (p. 904) and bovine spongiform encephalopathy (see below). Rabid cattle invariably die and fluorescent antibody staining of impression smears from appropriate parts of the CNS will establish the diagnosis rapidly.

Treatment and prevention

No treatment of clinical cases should be attempted, nor should they be euthanased prematurely as this may prejudice the post-mortem diagnosis. Post-exposure vaccination is a routine procedure in man, but in cattle clinical disease and death would probably occur before an effective immunity had time to develop.

Bovine spongiform encephalopathy (BSE)

Bovine spongiform encephalopathy (BSE) was first reported in the United Kingdom in 1987 as a previously unrecognized spongiform encephalopathy affecting dairy cows (Wells *et al.*, 1987). While the first documented BSE cases were reported in 1987, retrospective case record studies suggest BSE occurred as early as 1985. Some cattle practitioners suggest that clinical cases occurred sporadically over the previous 25 years, but there is no supporting evidence in limited studies of archived pathology material.

Bovine spongiform encephalopathy is a new member of a group of subacute transmissible spongiform encephalopathies characterized by certain physical properties, including long incubation period but relatively short clinical course which is invariably fatal, progressive neurological signs with rapid deterioration terminally, spongiform change visible under light microscopy and presence of scrapie associated fibrils on electron microscopy. All members are transmissible to laboratory animals and many other species by intracerebral injection and other routes. This group includes scrapie of sheep and goats, chronic wasting disease of mule deer, transmissible mink encephalopathy of ranched mink, Kuru and Creutzfeldt–Jakob disease(CJD) of man and new variant Creutzfeldt–Jakob disease (v-CJD) of man.

The postulate that BSE resulted from the ingestion of meat and bone meal contaminated with a scrapie-like agent (Morgan, 1988) has been supported only indirectly by epidemiological data (Wilesmith *et al.*, 1988).

Some change in exposure of cattle to infection in 1981–82 resulted in BSE appearing in the cattle population in 1985–86. A change in rendering practices with an end to hydrocarbon fat extraction of rendered material (NB the scrapie agent is lipotrophic) has been suggested as an important factor in BSE epidemiology. Subsequent studies have demonstrated that operating procedures in many rendering plants during the early 1980s would have been incapable of destroying the BSE agent. To date there are no experimental data which demonstrate that scrapie can be transmitted to cattle by the oral route.

BSE was made a notifiable disease in the United Kingdom on 21 June 1988. Compulsory slaughter with destruction of carcass (incineration since 1991) with compensation was introduced on 8 August 1988. On 18 July 1988 the 'ruminant feed ban' was introduced which prohibited the feeding of ruminant-derived protein to ruminants. Brain, spinal cord, tonsil, thymus, spleen and intestine (specified bovine offals) of cattle over six months old were no longer permitted to be sold for human consumption. In September 1990, specified bovine offals were banned from all other animal feeds.

The introduction of a ban on the inclusion of ruminant-derived protein in cattle rations in July 1988 has resulted in a reduction in the incidence of BSE in younger cattle since 1991 (Wilesmith & Ryan, 1993) which continued throughout the 1990s and into the 2000s.

Aetiology

All the epidemiological evidence presently available strongly suggests that the geographically widespread incidents of BSE are not the result of cow-to-cow transmission but conform to the concept of a single source epidemic, with concentrate feedstuffs containing animal protein as the probable source. Many farms have experienced only one BSE case although many cattle were exposed to the same feed source. In some herds outbreaks have involved the majority of animals in a particular cohort (Winter *et al.*, 1989). It is possible that the transmissible agent was very unevenly distributed in the feed because, unlike sheep, host genotype appears to have little effect upon either susceptibility or the length of the incubation period.

An alternative postulate to the feeding of scrapie-contaminated diets as the origin of BSE is that of spontaneous prion mutation giving rise to histopathological changes and clinical disease of a spongiform encephalopathy of cattle (Scott *et al.*, 1995). The origin of the BSE epidemic could, therefore, have been the inclusion of infected material from 'spontaneous cases' of BSE subsequent to changes in the rendering process, and not contamination of cattle rations with the scrapie agent. The simultaneous widespread appearance of

BSE in the UK could be explained, in part, by the sale and movement of meat and bone meal concentrate derived from cattle. In this respect it is interesting to note that the origins of chronic wasting disease of mule deer and elk have not been determined. It is possible that a scrapie-like disease did occur in cattle from another species (not sheep) and until transmission studies demonstrate classical BSE in cattle after feeding scrapie-contaminated feedstuffs this lack of conclusive evidence remains a serious concern.

Reports of transmissible mink encephalopathy (TME) in ranched mink in Wisconsin, fed from 95 per cent downer or dead dairy cattle and a few horses (Marsh & Hartsough, 1985), raise the question whether an unrecognized spongiform encephalopathy also occurs sporadically in cattle in the USA. However, experimental exposure of mink to BSE produced an encephalopathy with minimal resemblance to TME (Robinson *et al.*, 1994). BSE has recently (2003) been confirmed in Canada. The worldwide sporadic occurrence of CJD, with no obvious reservoir of infection or mode of transmission except for iatrogenic cases, may support the postulate that spontaneous changes of the prion, eventually resulting in clinical disease, do occur. The existence of scrapie in many countries of the world with large sheep populations means that sporadic cases resulting from spontaneous changes in the prion would not be differentiated from those scrapie cases originating from horizontal or vertical transmission of the scrapie agent. In countries that are scrapie-free, such as New Zealand and Australia, 'spontaneous cases' of scrapie, occurring at approximately 0.1 per 100 000, could easily be overlooked due to the extensive system of agriculture and unwillingness of sheep producers to employ veterinary services for single sheep. In this respect it is widely regarded that the majority of BSE cases have been overlooked in France and Germany for political as well as animal health reasons.

Experimental transmission of spongiform encephalopathy after intracerebral injection or oral dosing with brain homogenate derived from cattle with BSE has been confirmed in sheep and goats (Foster *et al.*, 1993) and by a combination of intravenous and intracerebral injection to cattle (Dawson *et al.*, 1990). Intracerebral injection of calves with strains of scrapie agent from five flocks in four states in the USA produced neurological signs, brain lesions and distribution of prion protein distinct from BSE (Cutlip *et al.*, 1994), but these differences could be explained, in part, by strain variation in scrapie and route of infection.

Pathology and pathogenesis

The pathological changes consist of bilaterally symmetrical degenerative changes affecting the neuropil and

neurones of certain brain stem nuclei (Wells *et al.*, 1987). There is fine vacuolation of the ground substance whilst neurones and neurites develop one or more well-defined intracytoplasmic vacuoles, which may distend the cell body and processes. The nuclei principally involved are the dorsal nucleus of the vagus, the nucleus of the solitary tract, the reticular formation, the vestibular and spinal trigeminal nuclei and in the mid brain the red and oculomotor nuclei.

An additional pathological characteristic of the transmissible spongiform encephalopathies is the presence in extracts of brain prepared for electron microscopy of fibrils 100–500 nm in length that are known as scrapie associated fibrils (SAF).

Signs and diagnosis

Bovine spongiform encephalopathy affects cattle 2 to 13 years of age, with peak prevalence in the four to five year age group. Early epidemiological investigations (Winter *et al.*, 1989) revealed that affected cattle could have had access to feedstuffs containing ruminant-derived protein only during the first four months of life. The disease is less common in beef suckler herds because most replacement heifers are reared naturally with their dam and receive no concentrate feeding. Disease has been commonly reported in beef herds where replacement heifers were sourced from dairy herds, these cattle having received supplementary concentrates containing ruminant-derived protein during calfhood. In dairy cattle the incidence within breeds appears to be a reflection of population size, the majority of cases occurring in Friesian/Holstein cattle.

Early signs include chronic weight loss and decreased milk yield over four to six weeks (Aldridge *et al.*, 1988; Scott *et al.*, 1988a, 1989a). Affected cattle are often isolated from other cattle in the field. Cows stand with an arched (roached) back and a wide-based stance. There is frequent independent ear movement with the ears often directed backwards towards the poll. The abdomen appears drawn up with sunken sublumbar fossae consistent with reduced appetite. During the latter stages, affected cattle spend very little time ruminating. There is a profound change in attitude; affected cattle become anxious, apprehensive and hyperaesthetic to tactile, auditory and visual stimuli. When trotting there is marked pelvic limb hypermetria and ataxia, but normal muscle strength. When in a group, BSE cattle frequently push other cows along with vigorous head butting. Cows have considerable difficulty when encountering obstacles such as steps, ramps and narrow gateways and will frequently attempt to jump over low objects such as slurry scrapers and run through gateways, etc. As the condition progresses cattle frequently slip, especially when turning on wet concrete, have great

difficulty raising themselves and excoriation of the carpi results (Scott *et al.*, 1995). When confined for veterinary examination, stimulation often provokes violent kicking (ballism) with the pelvic limbs and bellowing. Repetitive contractions of individual muscle groups (myoclonus) are frequently observed in the shoulder region, ventral neck and proximal regions of the pelvic limbs. There is rapid progression of clinical signs and cattle may become weak and recumbent within two to ten weeks of clinical signs first being detected.

Differential diagnoses include listeriosis, hypomagnesaemia, space occupying lesions, lead poisoning, organophosphorous poisoning, hepatoencephalopathy and rabies. In common with the other transmissible spongiform encephalopathies, there is no immune system response to infection; therefore routine biochemical investigations serve only to exclude other diseases from the differential diagnosis list. There is no intrathecal inflammatory response (Scott *et al.*, 1989b), which assists the clinician to exclude conventional infectious agents from the differential diagnoses (e.g. listeriosis). Confirmation of diagnosis depends upon a neuropathological examination.

Treatment and prevention

There is no effective treatment for BSE. Notification and elimination of affected animals have been in operation in the UK since 1988. The occurrence of approximately 1700 BSE cases per annum 12 years after the implementation of the ban on inclusion of ruminant-derived protein in ruminant rations suggests that vertical/maternal transmission of BSE does occur. A maternal effect resulting in an increased number of BSE cases in the progeny of affected cattle compared to controls was demonstrated (Wilesmith *et al.*, 1997), but the study design was flawed because the progeny were probably exposed to dietary BSE. While the control measures adopted for BSE control, and human safety, were closely modelled on data from scrapie research, regulatory authorities failed to take account of the possibility of vertical/maternal transmission and cull all progeny of confirmed cases. Such short-term monetary expediency has proved extremely costly. Offspring of affected cattle are now culled in the UK.

Idiopathic brainstem neuronal chromatolysis of cattle

Idiopathic brainstem neuronal chromatolysis of cattle has numerous clinical features similar to BSE (Jeffrey & Wilesmith, 1992) and 8 to 27 cattle with this condition have been mistakenly slaughtered annually (Jeffrey & Wilesmith, 1996). The consistent clinical signs include tremor, weight loss and ataxia, but the

clinical presentation is claimed to be not dissimilar to BSE (Jeffrey & Wilesmith, 1996). The incidence of disease appears to be more common in beef suckler cows with a mean age of eight years old compared to four to five years old in BSE. The disease is more commonly reported in Scotland than England, despite approximately similar numbers of beef herds.

Brainstem chromatolysis and degeneration of brainstem neurons are found in all cases and are generally associated with a florid and severe lesion (Jeffrey & Wilesmith, 1996). Scrapie-associated fibrils have not been found in the brains of cattle with idiopathic brainstem neuronal chromatolysis nor is there evidence of disease specific PrP (prion protein).

The cause of this disease remains unknown but a toxic or metabolic insult has been suggested (Jeffrey & Wilesmith, 1996).

Sporadic bovine encephalomyelitis (SBE, Buss disease)

Sporadic bovine encephalomyelitis is a generalized inflammatory disorder of serous membranes, synoviae and vascular endothelium. It has no specific neurotropism, the neurological signs being a consequence of inflammation of the mesodermal elements in the CNS.

Aetiology

Sporadic bovine encephalomyelitis is a specific disease of cattle and buffalo caused by a strain of *Chlamydia psittaci*. The disease has been observed in the USA, Eastern Europe, the Middle East, Japan, Australia and South Africa.

Pathology and pathogenesis

The disease is usually fatal within four to five days. The gross post-mortem findings include a serofibrinous peritonitis, pleurisy and pericarditis. A serofibrinous exudate is also found over the surface of the brain, especially the cerebellum and medulla. Histological examination of the brain reveals a predominantly histiocytic and plasma cell infiltration of the meninges.

Signs and diagnosis

Calves less than six months old develop a staggering, stiff gait with circling and stumbling. Affected calves are dull and depressed and may exhibit muscle tremors. About 70 per cent of infected animals recover slowly. Clinical diagnosis of SBE may be confirmed by rising titres of group-specific chlamydial antibody in complement fixation or enzyme-linked immunosorbent assay (ELISA) tests in the live animal or by isolation of the organism from brain and lymph nodes.

Treatment and prevention

Successful therapy depends upon treatment early in the course of the disease using high dosages of tetracycline (50mg/kg s.i.d.) for five to seven days.

Spinal cord lesions

Spinal cord lesions, whether focal or diffuse, are less common in cattle than sheep but present the veterinarian with a diagnostic challenge as they may result from a wide range of aetiologies including vertebral body abscess, extradural abscess, trauma, protozoan (encephalo-) myelitis and, in those countries where enzootic bovine leucosis virus is prevalent, neoplasia. Bacteraemia occurring during the neonatal period occasionally results in vertebral body abscess and extradural abscess formation causing clinical signs in two to four month-old calves. The neurological signs are frequently sudden in onset despite the chronic nature of the compressive spinal cord lesion.

Accurate localization of a focal spinal cord lesion is important to enable further investigation such as radiography; surgery is rarely, if ever, undertaken in ruminant species. Localization of the lesion(s) relies upon the assessment of simple spinal reflex arcs which indicate the presence of either upper or lower motor neuron signs in the affected limbs.

The simple spinal reflex arc comprises three neurons:

- The sensory neuron (stretch receptor in tendon)
- The internuncial neuron
- The lower motor neuron (contraction of limb muscle)

While the reflex motor response to sensory stimuli can occur without the input of higher centres, the higher motor centres exert control of voluntary movement via the upper motor neurons which synapse on the lower motor neuron. Flexor (withdrawal) reflexes can be determined by pinching the interdigital skin or applying pressure across the coronary band with resultant unconscious flexion and withdrawal of the stimulated limb. Recognition of pain indicates integrity of the spinal cord above the reflex arc. To determine tendon 'jerk' reflexes for the thoracic limb, the triceps tendon is tapped 2–5cm proximal to its attachment onto the olecranon process. The normal response is extension of the elbow joint. The pelvic limb is gently supported in the mid femoral region and the middle patellar ligament lightly tapped. The normal reflex is extension of the stifle joint.

Lesions affecting the upper motor neurons result in conscious proprioceptive deficits evident as changes in flight of the foot and abnormal placement of the foot on the ground, resulting in stumbling and knuckling of

the lower limb joints. Stimulation of the skin over the thoracic wall and flank with a blunt object produces a normal local response of muscle contraction (panniculosus reflex). In the case of a spinal lesion the skin caudal to the affected area of the cord has a reduced (hypalgesic) response, with a possible increased (hyperaesthetic) response cranial to the spinal lesion.

The presence of a spinal lesion at the level of the reflex arc results in a lack of muscle contraction in response to stimulation. Denervation of the effector muscle results in flaccid paralysis with atony (lower motor neuron disease). A spinal lesion cranial to the reflex arc removes the normal controlling inputs from higher centres via the upper motor neurons and results in exaggerated responses and spastic paralysis (upper motor neuron disease).

Cervical spinal cord C₁–C₆

The pelvic limbs are more severely affected than the thoracic limbs. There is a range of muscle weakness progressing to complete paralysis. It is important to differentiate weakness from ataxia, which can be achieved by pulling sideways on the tail as the animal is walking. Weak animals can easily be pulled to the side, may stumble and fall over. Spinal reflexes are increased (upper motor neuron signs to all four limbs) but this aspect of the neurological examination may prove difficult in adult cattle which are not recumbent. Cervical pain may be evident as rigidity of the neck with resentment to forced movement of the head. Typically, the neck is extended and the head held lowered. With severe lesions the animal may be unable to maintain sternal recumbency but will make frequent attempts to raise itself from lateral recumbency.

Cervico-thoracic spinal cord C₆–T₂

Spinal cord lesions involving the brachial intumescence may result in equally severe deficits in both the thoracic and pelvic limbs. There is ataxia and weakness of all four limbs. Thoracic limb reflexes are reduced (lower motor neuron signs) with increased pelvic limb reflexes (upper motor neuron signs).

Thoraco-lumbar spinal cord T₂–L₃

Animals with a spinal cord lesion caudal to T₂, but cranial to L₃, have normal thoracic limb function but upper motor neuron signs affecting the pelvic limbs. Affected cattle frequently adopt a dog-sitting posture with normal thoracic limb function (Holmes *et al.*, 1989) but with the pelvic limbs extended alongside the abdomen. The dog-sitting position should immediately alert the clinician because ruminants raise themselves

using their pelvic limbs before the thoracic limbs. The withdrawal and patellar reflexes are increased and there are conscious proprioceptive deficits and paresis of the pelvic limbs. The panniculus reflex may be useful when attempting to localize a thoracolumbar spinal lesion.

Lumbo-sacral spinal cord L₄-S₂

A lesion involving the sacral outflow results in lower motor neuron signs of the pelvic limbs with superficial sensation loss, paresis and reduced or absent reflexes.

Sacrococcygeal spinal cord: cauda equina syndrome

The cauda equina syndrome results from lesions involving the sacrococcygeal spinal cord and results in hypotonia, hypalgesia and reduced reflexes of the tail, anus and perineal region, bladder atony and dilation of the rectum.

Once a lesion has been localized to a specific section of the spinal cord a number of ancillary tests can be performed, including radiography and myelography, to define the lesion precisely. Before such examinations are undertaken, which are expensive and may require general anaesthesia to perform, considerable useful information can be obtained relatively easily and inexpensively following the collection and analysis of lumbar CSF.

Lumbar CSF collection and interpretation

A focal inflammatory lesion within the vertebral column involving the leptomeninges results in leakage of protein and some inflammatory cells into the CSF. If the lesion also causes spinal cord compression this will arrest the craniad flow of CSF and prevent equilibration of CSF protein concentration within the lateral ventricles. Such compression results in accumulation of protein within the CSF caudal to the lesion (Scott *et al.*, 1991). In practical terms, where there is a compressive spinal lesion cranial to L₅, collection of lumbar CSF will yield a sample with a marked increase in protein concentration relative to the cisternal sample which is usually normal (Scott & Will, 1991; Scott, 1992).

Typical aetiologies include extradural and vertebral body abscess formation in young calves from which *Salmonella dublin* and *Salmonella typhimurium* are frequently isolated, indicating previous bacteraemia. The isolation of *Arcanobacterium pyogenes* and *Staphylococcus* spp. from ovine vertebral body abscesses (Finley, 1975) has led to the treatment of such lesions with high doses rates of penicillin, but with no success (Scott *et al.*, 1991).

Treatment and prevention

Traumatic lesions in calves following dystokia, indicated by xanthochromic CSF collection, may improve within two weeks with good management and dedicated care with frequent turning of the calf. Treatment of extradural and vertebral body abscesses is hopeless (Scott *et al.*, 1991) and affected calves should be euthanased for welfare reasons.

Prevention of bacteraemia in neonatal calves dictates high hygiene standards in the calving accommodation and ensuring timely ingestion of adequate levels of good quality colostrum by the calf within the first six hours of life. Repeated dipping of the umbilical remnant in strong veterinary iodine BP during the first 12 hours will prevent omphalophlebitis. Control of salmonellosis in calves from endemically-infected herds can be attempted by prior vaccination of the dam and feeding stored colostrum during the first two weeks of life.

Introduction

Ophthalmic disorders in cattle are more common than is generally believed, but it is only those that are of considerable economic importance that generally receive much attention. Infectious bovine keratoconjunctivitis (IBKC), variously known throughout the world as New Forest disease, pinkeye, contagious ophthalmia and blight, is undoubtedly the commonest and most important ocular disease that occurs in this species. In the USA alone it is estimated that IBKC is responsible for an annual loss in excess of £25 million (Punch & Slatter, 1984). Approximately three times as many calves are

affected as adults and failure to produce effective vaccines means that this disease will continue to inflict severe economic loss for as long as young cattle are managed intensively. Disease of epidemic proportions occurs all the year round and, while the aetiological controversy may continue, the term IBKC generally embraces all keratoconjunctivitis of infectious nature in this species. Similarly, ocular squamous cell carcinoma of probable heritable nature in breeds with reduced palpebral pigmentation continues to account for a high carcase condemnation rate and runs second only to lymphosarcoma in terms of condemnation for neoplastic reasons. At the other end of the scale there are many congenital, inherited and acquired defects that tend to escape diagnosis on the basis of there being no untoward effect on function, no associated discomfort or pain and no necessity to treat. Were cattle subjected to the same degree of scrutiny as the dog, then it is likely that the literature would indicate a similar incidence of disease. In one study of 500 cattle of all ages, almost 20 per cent overall demonstrated ocular anomalies of one sort or another, the incidence ranging from 3 per cent in young cattle to in excess of 70 per cent in the older individuals (Amman, 1968). Examples of this kind of survey work in cattle are few and far between, but general interest in ophthalmology as a refined discipline in today's veterinary scenario will probably stimulate further ophthalmic studies in animals that are primarily produced for food purposes in our society.

Anomalies of the orbit and globe

Congenital and acquired defects of these structures both occur, some congenital anomalies being inherited while others are probably environmental in origin (see also p. 180). The acquired defects are due to trauma, infection and neoplasia.

Anophthalmia

Absence of the optic vesicle means that an eye cannot develop. Histologically, primordial ectodermal and mesodermal tissues cannot be identified. The condition

is rare and is often confused with the type of microphthalmia in which there has been some early differentiation of the optic vesicle but no subsequent maturation.

Microphtalmia

Variable degrees of development can be seen, ranging from minimal differentiation of ocular tissue to the development of a small but otherwise normal eye. Other ocular anomalies may also be present, however, and persistent pupillary membrane (PPM), aniridia, cataract and neuroretinal fold and rosette formation may be seen in association with microphthalmos. Like anophthalmia, the condition is rare in cattle, but inheritance has been postulated (Gilmore, 1957) and it has been described in calves with vertebral column deformation (Leipold & Huston, 1968).

Multiocular defects

Bilateral congenital blindness due to multiocular defects not involving microphthalmos has been recorded in Jersey calves (Saunders & Fincher, 1951). The defects are mainly related to the lens, with microphalmia, ectopia lentis and cataract being seen in association with iridaemia. A recessive mode of inheritance has been suggested, but subsequent literature contains no further references to this condition in this breed.

Cyclopia

The development of one eye in calves is extremely rare (Plate 52.1), but the condition has been induced teratogenically in sheep.

***Strabismus* (see p. 181)**

Bilateral convergent squint (esotropia) has been described as a recessively inherited defect in Jersey cattle, and it is probably inherited in Shorthorn and Friesian cattle too (Willoughby, 1968; Bedford, pers. obs.). A degree of exophthalmos may or may not be additionally present. The condition is usually noticed at four to eight weeks of age (Plate 52.2a) and the degree of convergence increases until the sixth or seventh month when only sclera presents within the palpebral fissure (Plate 52.2b). Impaired vision gives way to total blindness, and attempts at corrective surgery may be ill perceived in the presence of possible optic nerve, central visual pathway and visual cortex anomalies.

Nystagmus

Nystagmoid movement of the globe is most commonly associated with congenital or paranatal blindness. It is

also seen in adult cattle, with various causes including brain tumour and abscess formation. It has been noted as an occasional feature early in the course of BSE.

Orbital neoplasia

Retrobulbar and periorbital lymphosarcoma can result in exophthalmos and possible squint. The lesions may be seen unilaterally or bilaterally. Squamous cell carcinoma of the membrana nictitans may invade the orbital tissues to produce a similar clinical picture.

Anomalies of the eyelids

Congenital/paranatal defects

Unlike other species, inherited and non-inherited congenital palpebral defects are few and far between in cattle. Eyelid colobomata and agenesis are of rare incidence. Although primary conditions in sheep, both entropion and ectropion occur most commonly as secondary defects in cattle and are associated with microphthalmia, blepharitis, keratoconjunctivitis and trauma. Correction of the cause alleviates the lid distortion except where there is palpebral or orbicularis oculi damage and where cicatrization has occurred.

Congenital supernumerary openings of the proximal part of the nasolacrimal duct and the canaliculi at the medial canthus have been described in calves, hereditary predisposition or intra-uterine dacryocystitis being the suggested possible aetiology.

Trauma

Laceration of the eyelid occurs infrequently, but when the palpebral fissure is involved repair is essential. Such wounds left to granulate or inadequately sutured may result in distortion of the margo-intermarginalis, and secondary entropion, secondary ectropion and an incomplete blink can result in conjunctival or corneal disease. Delayed closure is complicated by the problem of wound contraction. Repair is easily effected using manual restraint and the same seventh nerve block as that used in disbudding and dehorning can be employed should blepharospasm be a problem. Such wounds may require debridement, but the removal of tissue should be avoided whenever possible. The sutures are placed at two levels (Fig. 52.1). Tarsal plate and subconjunctival tissue are first repaired without penetrating the palpebral conjunctiva, and the knots are buried in the substance of the eyelid such that no suture material can cause corneal irritation. The margo-intermarginalis must be accurately reformed, the first suture ensuring precise apposition at this level. The second row of

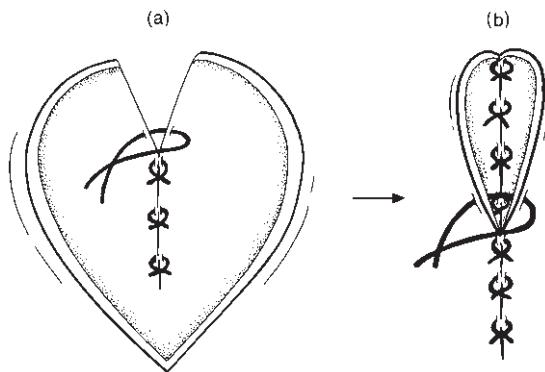

Fig. 52.1 Repair of an eyelid wound by two-layer closure. (a) Tarsal plate and subconjunctival tissue apposed; (b) subcutis and skin apposed.

sutures involves the subcutis and skin, and single interrupted sutures are used to ensure accurate repair and reduce the chance of wound breakdown. Absorbable material is used for the buried sutures and nylon is preferable for the cutaneous repair.

Congenital porphyria

Congenital porphyria is a rare, recessively inherited defect of haemoglobin metabolism which results in the production of abnormal porphyrins. Clinical signs associated with photosensitization are seen in light-skinned cattle upon exposure to sunlight. Adenexal inflammation is characterized by oedema, photophobia, blepharospasm and excessive lacrimation.

Diseases of the conjunctiva and cornea

The occurrence of IBKC and squamous cell carcinoma renders this part of the eye important in economic terms, and as the two disease conditions commonly involve both structures it is convenient to discuss them both under the same section.

Epibulbar dermoid

Dermoid formation (choriostoma) is due to the poor differentiation of the palpebral tissue with the result that plaques of hair-bearing skin and subcutis may be found involving the lateral aspect of the globe (Plate 52.3). Both the cornea and episcleral tissues can be affected, the dermoid replacing the corneal epithelium and bulbar conjunctiva, respectively. Bilateral involvement is unusual, and dermoids are only of clinical significance if they impair sight, cause trigeminal irritation

and conjunctival inflammation or they physically interfere with effective blinking and lid closure. Removal is then advocated, and topical and regional anaesthesia can be complemented by using the auriculopalpebral nerve block. The lesion must be removed in entirety to prevent recurrence. While a suprascleral lesion is easily excised, care is required with the superficial keratectomy needed to remove the corneal dermoid.

Infectious bovine keratoconjunctivitis (IBKC, New Forest eye, pinkeye)

Aetiology

This disease has been recognized for at least 100 years (Billings, 1889) since when it has demonstrated both common incidence and worldwide distribution. It is highly contagious, and outbreaks of epidemic proportions can affect grazing herds during the summer and autumn months, and housed cattle the whole year round. Young animals are more severely affected, dictating the development of possible local immunity to the disease in those previously exposed. Over the years IBKC has been attributed to several organisms (Bedford, 1976), but currently *Moraxella bovis* is still regarded by most authorities to be the cause. The root of the controversy lies in the fact that *Moraxella bovis* can be found in the normal conjunctival sac, and attempts to produce the disease using pure cultures of this bacterium have not always been successful. In addition, infectious bovine rhinotracheitis (IBR) virus, known to cause conjunctivitis in addition to rhinitis, and *Mycoplasma bovirhinitis* and *M. laidlawii* have been isolated with *Moraxella bovis* from IBKC patients. Rather than representing cause, however, these organisms may act synergistically as enhancing factors. Undoubtedly, other enhancing factors can be at work, and the increased incidence of IBKC during the warmer months has indicated that ultraviolet light, flies and dust play potentially important roles in the overall picture. Certainly flies of the *Musca* and *Stomoxys* species have been incriminated as mechanical vectors, but the occurrence of epidemic disease among winter-housed cattle suggest that flies and the other environmental factors are not essential.

Epidemiology

Variation within the clinical picture of the disease may be related to the input of the several possible enhancing factors, but may also be due to the susceptibility of the animal to infection and the type of *Moraxella bovis* present in its conjunctival sac. Older cattle are more resistant to infection, it being calves and cattle of less than two years of age that demonstrate the highest

morbidity and the most severe disease. Such resistance may be the result of previous exposure, but local factors as well as antibody formation may be involved (Pugh, 1969). It has been demonstrated that two forms of the bacterium exist: a smooth non-haemolytic form that is avirulent and can usually be isolated from recovering and clinically normal carrier animals, and a rough haemolytic virulent form that causes the acute disease (Pedersen, 1973). The rough form is fimbriated for adherence (Sandhu *et al.*, 1974), and repeated passage has demonstrated its conversion into the smooth form. The presence of fimbriae would appear to be necessary for disease to occur and for immunity to develop. The difficulties experienced in the production of an effective vaccine against *Moraxella bovis* may be overcome as the result of further structural studies to determine the possible immunogenic status of the fimbriae. In the past, alteration of the surface components of bacterial cells in the preparation of vaccines may have been wholly responsible for the ineffectiveness of such vaccines. The economic importance of IBKC demands that an effective vaccine be developed, but it could be many years before the solution is finally produced.

Signs

Epidemics occur as the result of the introduction of incubating, chronically affected or carrier animals into the herd. The presenting clinical features may vary considerably depending on the immunity of the exposed individual and the level of enhancing factors present. This variation is not only seen on a herd-to-herd basis, but between individual animals within the same herd. Both unilateral and bilateral cases will be seen; in the latter a variation in the degree of severity may be noted between the two eyes. Usually, inflammation of the bulbar and possibly the palpebral conjunctivae precedes the keratitis, but occasionally the conjunctival involvement is not seen until after corneal inflammation has made its appearance. Blepharospasm, photophobia and copious ocular discharge herald anterior segment pain, the discharge, primarily clear and thin, becoming purulent quite rapidly to mat the lashes and circumorbital hair. The conjunctiva is chemotic and swelling of the eyelids may occur. Corneal changes usually develop within 48 hours, a 3-mm wide, slightly raised area of cloudiness normally making its appearance centrally. Epithelial loss can be demonstrated using fluorescein stain, and the lesion itself may take on the yellowish blue of pyogenic necrosis. The surrounding cornea becomes oedematous and hazy, and a low-grade anterior uveitis with aqueous flare may be noticeable in some animals. Corneal vascularization from the limbal blood vessels is well established by the sixth day, the new vessels rapidly progressing towards the central lesion in the anterior

stroma (Plate 52.4a). Throughout this stage of the disease the eye is extremely painful, and a bilateral involvement means that the patient is either blind or experiencing impaired vision. Inappetance, suppressed weight gain and reduced milk production are related to the severity of involvement. At this stage, and particularly in young animals, loss of epithelium and anterior stroma in the central lesion may occur, and this ulcer may rapidly enlarge to involve deeper stromal tissue. Less severe forms of the disease resolve within two or three weeks, the cornea gradually clearing from its periphery towards the centre as the vessels cease to transmit blood to the healing ulcer site. Recovery takes longer when extensive ulceration has occurred and deep stromal scarring and keratoconus may result. In some patients descemetocoele formation may complicate deep ulcers and actual rupture may lead to panophthalmitis (Plate 52.4b). Blindness may result, and the eye may become glaucomatous but will eventually shrink (phthisis bulbi). The occasional death has been attributed to meningitis following presumed ascending infection of the optic nerve.

Treatment

Moraxella bovis is susceptible to most antimicrobial agents including many antiseptics, and this, combined with uncertainties concerning the aetiology of the condition and a tendency for spontaneous resolution in some patients, renders the accurate assessment of any treatment difficult. It is generally agreed, however, that the earlier the treatment the less severe the disease and the greater the chance of controlling the outbreak. In the absence of isolation facilities, it is suggested that treatment of the entire herd will protect the unaffected cattle. Consideration of potential carrier status dictates the use of antibiotics in newly acquired stock before they are introduced into the herd.

Antimicrobial drugs may be administered topically, by subconjunctival injection and parenterally. The ideal therapy for a herd problem demands effective one-time dosage and, as such, topically applied preparations, which require frequent administration to maintain therapeutically effective levels in the precorneal tear film (PCTF), cannot be very effective. Their short contact time is reduced further by the presence of ocular discharge and lacrimation, and blepharospasm renders their application difficult. Currently, increased contact time as the result of specific formulation is claimed for several antibiotic preparations including cloxacillin, cephalonium and a penicillin and streptomycin combination. The subconjunctival injection of antibiotics can be used as an alternative to the topical route, but the antibiotic must be placed beneath the dorsal bulbar conjunctiva. This is difficult to do for the unpractised

hand and a topical analgesic agent (proxymetacaine hydrochloride) must be used. From this site the antibiotic leaks into the PCTF and thus has an effect. Intra-palpebral injections of various antibiotics are used commonly, but there is evidence to demonstrate that a drug deposited in palpebral muscle gets into the lacrimal gland or the PCTF. Long-acting ampicillin, oxytetracycline and penicillin may be used parenterally for repeated good effect. *Moraxella bovis* is usually resistant to lincomycin, tylosin and erythromycin but has variable susceptibility to cloxacillin (George, 1990). In an original study, Pedersen (1973) claimed that intravenous sulphadimidine was the treatment of choice for IBKC. He showed that although *Moraxella bovis* is present on the corneal and conjunctival surfaces, it colonizes the lacrimal and tarsal glands, and that any treatment must effectively penetrate these tissues. A single injection of sulphadimidine at dose rate of 100 mg/kg bodyweight will do this, and the drug will remain in the RCTF at a therapeutically active concentration for 24 hours. It is still surprising that this method of treatment is not utilized to any great extent for it seems to answer both theoretical and practical aspects of therapy. However, some strains of *Moraxella bovis* have proved resistant to sulpha drugs (Pugh & McDonald, 1977). In the future other delivery systems may be evaluated and ocular inserts that allow prolonged drug release would appear to be of potential value in this respect.

Surgery can have a part to play in the treatment of IBKC. The membrana nictitans can be used to support the severely ulcerated cornea or protect a ruptured anterior chamber, and this technique is preferred to a temporary tarsorrhaphy in which the eyelids are sutured together. Using local anaesthesia together with an auriculopalpebral nerve block to overcome any blepharospasm, the membrana nictitans and the loose bulbar conjunctiva can be apposed to cover the cornea (Fig. 52.2). Mattress sutures of non-absorbable material are used, and the cornea is left covered for two to three weeks. The sutures should not penetrate the membrana's full thickness, otherwise corneal erosion will occur. Should a more resilient method of repair be required then under a general anaesthetic a pedicle of bulbar conjunctiva can be sutured directly into the corneal defect (Fig. 52.3). The pedicle is separated from its bulbar conjunctival attachment several weeks later and the residual conjunctival tissue is usually involved in the scar. This technique offers the advantages of directly strengthening the cornea and introducing a blood supply to the ulcer site.

Vaccination (see p. 1018)

There have been considerable difficulties experienced by those attempting to produce an effective vaccine

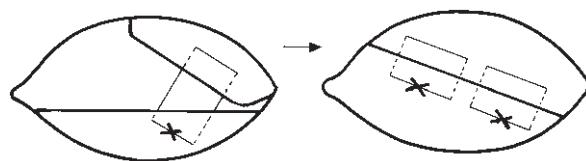

Fig. 52.2 The membrana flap. The membrana is sutured into the loose dorsal bulbar conjunctiva using two or three mattress sutures.

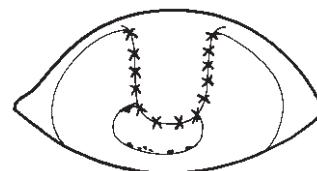

Fig. 52.3 The bulbar conjunctival pedicle flap used in the repair of deep corneal ulceration.

against *Moraxella bovis*, but some recent results are quite optimistic (Lepper, 1993). The research has concentrated on the fimbriae or pili found in the rough form of the organism and recombinant DNA technology has been involved. Certainly pilus-antigen vaccines have demonstrated acceptable levels of protection in several studies (Lepper, 1988; Moore & Rutter, 1989) and workable protocols are now possible. Calves are vaccinated at approximately one month of age, with a second vaccination three weeks later. There is no evidence that colostrum derived antibodies will negate this procedure. Adult cattle should have yearly boosters.

Infectious bovine rhinotracheitis

(see also p. 286)

The role of infectious bovine rhinotracheitis virus in anterior segment disease is not fully understood. The virus is thought to enhance the effects of *Moraxella bovis* in some patients with IBKC, but it is also known to cause conjunctivitis in its own right. Respiratory disease may or may not be present, and abortion rates may be high in IBR-affected herds.

The ocular involvement may be unilateral or bilateral. Varying degrees of chemosis may be present, and a number of white plaques may be found in both the bulbar and palpebral conjunctivae. The discharge may vary from serous in early disease to a mucopurulent type later. Anterior uveitis and corneal opacity are occasional findings, and this latter should not be confused with the corneal abscess or ulcer that routinely occurs in IBKC. Confirmation of diagnosis is not always

easy, for it requires virus isolation from swabs taken only in the early part of the disease. Seroconversion from negative to positive or a rising titre for IBR antibody will provide the final proof. There is no specific treatment for the condition, but antibiotics will help control any bacterial secondary infection. Normally, the disease takes three to four weeks to complete its course.

Endothelial dystrophy

Bilateral neonatal corneal oedema has been reported in several breeds including the Friesian (Deas, 1959). The oedema is uniformly present throughout the whole stroma, and its persistent nature ensures permanent impairment of sight. Treatment is not possible, but short-term clearing of the cornea can be obtained using topically applied glycerol or hypertonic saline. Signs of possible precursor or accompanying anterior uveitis and other ocular abnormalities are not present, and defective endothelial function alone is the indicated cause. The defect is considered to be inherited as a recessive trait, and affected animals and their carrier parents should be avoided in any breeding programme.

Neoplasia (see p. 1126)

Ocular squamous cell carcinoma (SCC) or 'cancer eye' is the commonest bovine neoplasm, and its economic importance has already been stressed. Although SCC has worldwide distribution, its incidence increases in countries where cattle experience long-term exposure to intensive sunlight. The Hereford would appear the most commonly affected breed, and tumour formation is rarely seen before five years of age. A presumed inherited predisposition is postulated, and genetic analysis has suggested that it is a recessive trait (Anderson & Chambers, 1957; Vogt & Anderson, 1964). However, several contributory facts seem to be involved, perhaps one of the most important being the role of melanin in palpebral, conjunctival and scleral tissues. Pigmentation is determined genetically, and undoubtedly the presence of melanin protects tissue from SCC development. As such ultraviolet light is considered to be a significant contributory factor in the development of SCC, its absorption by melanin being the significant protective factor. Much SCC finds origin in the bulbar conjunctiva at the lateral and medial limbi, but other areas where pigmentation may be reduced (the palpebral conjunctiva, the membrana nictitans and eyelid skin) can also be affected. Other possible contributory factors are IBR virus, dust, flies and high levels of nutrition.

The indications that ultraviolet light may be an important aetiological factor are the actual tumour sites

and the marked geographic variation in incidence. Squamous cell carcinoma occurs in ocular tissue where there is little or no pigment, and the bulbar conjunctiva at the lateral and medial limbi is more exposed than conjunctiva elsewhere on the globe or lining the eyelids. The incidence of ocular SCC is greater in those parts of the world with high levels of ultraviolet light, and at high altitude. The IBR virus and its inclusion bodies may be found in the neoplastic tissue (Taylor & Hanks, 1969) and it has been postulated that the virus may play a part in initiating tumour growth or be involved in the transformation of precursor lesions into carcinoma. Surprisingly, perhaps, the incidence of SCC is greater in cattle on higher levels of nutrition, but this may be associated with enhanced age changes induced by such diets (Anderson, 1970).

Several stages of development are described in SCC formation. Conjunctival plaques of hyperplastic epithelium (Plate 52.5a) or hyperkeratosis of palpebral skin represent the initial lesion. Regression may occur, but the plaques are generally replaced by papilloma formation, and this in turn is replaced by non-invasive carcinoma. Eventually, most of these carcinomas become invasive, and the whole globe can be involved (Plate 52.5b). Invasion of orbital bone can occur, and with long-standing SCC, metastasis via the lymphatics to involve the lungs, heart, liver and kidney is possible (Cordy, 1978).

Treatment is related to the extent of tumour involvement, and the possibility of metastasis may dictate a policy of early slaughter. Excision of the neoplasm, removal of the membrana nictitans, enucleation or exenteration of the orbit represent possible early treatment. Alternative techniques of cryosurgery, hyperthermia, radiation therapy and immunotherapy have all been tried with some success, again early in the course of tumour development. Small neoplasms can be excised irrespective of site, but recurrence and subsequent extension should be expected. Large lesions of the membrana nictitans may already have invaded the orbit. Premalignant lesions and small carcinomas can be destroyed using liquid nitrogen sprays, but adequate freezing demands the use of thermocouple assessment. Limbal-based lesions can be difficult to treat effectively. Again neoplastic cells can be selectively destroyed by heating tissue to 45°C, and early SCC will respond to hyperthermic therapy. Various forms of ionizing radiation therapy have been used successfully. Beta-irradiation will destroy small lesions, and radioactive caesium, cobalt or gold implants can be similarly effective if the dose rates can be adequately calculated. Immunotherapy offers potentially effective treatment, with the parenteral use of modified or whole-cell tumour cell suspensions having demonstrated considerable promise (van Kampen *et al.*, 1973).

Diseases of the uveal tract

(see also p. 180 onwards)

Both congenital and acquired disease of the uveal tract occur in cattle, with uveitis presenting the clinician with as much difficulty in treatment as it does in the other domestic species.

Congenital anomalies

Several congenital anomalies occur in cattle, including aniridia, colobomata, polycoria, persistence of the pupillary membrane and anterior uveal cyst formation. Aniridia is seen as part of a multiocular defect in Jersey calves, in which bilateral partial absence of the iris is accompanied by microphakia or lens luxation (Saunders & Fincher, 1951). Vision can be affected to the point of blindness, and the defect is inherited as a simple recessive trait. Iris colobomata, polycoria and uveal cysts are of no clinical significance, but persistence of the pupillary membrane may be associated with lens and corneal opacities. The vascular mesoderm in which the pupil develops should be resorbed by the time of parturition, but strands of this tissue may persist to span the pupil or become adherent to the anterior lens capsule or the corneal endothelium. Cataract or corneal endothelial and deep stromal opacities mark the areas of adherence, the size of these opacities varying with the amount of the attaching remnant tissue. Heterochromia iridis, due to a reduction or absence of melanin, is seen in the colour dilute breeds, and it may occasionally be accompanied by photophobia, nystagmus and typical papillary coloboma formation.

Uveitis

Inflammation within the uveal tract occurs in association with systemic disease, corneal ulceration, keratitis, trauma and intraocular neoplasia. Anterior uveitis can accompany IBR infection, toxoplasmosis, tuberculosis and neonatal coliform septicaemia; panophthalmitis in which the whole uveal tract is involved may be seen in malignant catarrhal fever. Infectious bovine rhinotracheitis virus may be involved in IBKC and will cause conjunctivitis; occasionally there is an associated uveitis. In calves with coliform septicaemia, acute anterior uveitis characterized by episcleral congestion, miosis and hypopyon formation may be seen in association with septic meningitis in which paresis, ataxia and convulsions are the obvious clinical features. Occasionally, the choroid is involved, and haemorrhage and exudate will be seen in the vitreous. In peracute malignant catarrhal fever severe photophobia, marked palpebral and corneal oedema, mucopurulent discharge and

panuveitis may all be seen. Anterior uveitis, choroiditis and retinitis may all be present as a result of vascular necrosis and vasculitis (Plowright, 1968). A recurrent uveitis, referred to as specific ophthalmia (Marolt *et al.*, 1963) has been described for cattle. It is similar clinically to equine recurrent uveitis (periodic ophthalmia) with corneal oedema, anterior chamber and intravitreal exudates, and retinal haemorrhage being seen in the acute stage. A viral aetiology is suggested, with IBR and other respiratory viruses isolated from affected animals.

Listeria monocytogenes has been previously associated with outbreaks of keratoconjunctivitis and uveitis in housed cattle in the UK (Morgan, 1977), but more recently this organism has been isolated from housed cattle fed on silage, presenting with anterior uveitis as the only clinical feature (Watson, 1989). It has been considered that the organism in the silage gains entry to the eye either directly from conjunctival sac contamination or from the gingival margins by trigeminal migration. The uveitis presents clinically in the same way as any other anterior segment inflammation; it is usually unilateral with marked miosis, thickening and folding of the iris, keratic precipitate (KP) and hypopyon formation and vascularization of the limbal cornea being the presenting signs (Plate 52.6). Treatment includes the use of systemic antibiotics, but subconjunctival corticosteroids and topical atropine are essential for effective resolution.

Neoplasia

Primary uveal tract tumours in cattle are rare, but secondary involvement with squamous cell carcinoma occurs not infrequently.

Disease of the lens

Ectopia lentis (lens luxation) occurs as part of a congenital multi-ocular defect syndrome in Jersey and Friesian cattle, and cataract probably enjoys higher incidence than the literature dictates. Intraocular examinations are not commonly practised in cattle, and cataract is only diagnosed if it is large enough to be noticed initially with the naked eye, has an effect on sight or is present with other noticeable ocular anomalies.

Congenital cataract has been recorded in several breeds (Odorfer, 1995) and in Jersey and Friesian cattle its inheritance is as a simple recessive trait (p. 181). There would appear to be a particularly significant incidence of this lesion in the Friesian and Friesian crosses in the UK, demonstrating marked regional variation. In congenital cataract the nuclear part of the lens is always involved, but cortical extension may severely affect vision (Plate 52.7). There may also be a posterior polar cortical opacity with posterior lenticonus and possible

hyaloid attachment. Nystagmoid movements of the globe may accompany the larger opacities. In both these breeds and in the Shorthorn other ocular anomalies including buphthalmia, microphakia, lens luxation and retinal detachment may accompany cataract.

Cataract may be secondary to uveitis, but the aetiology of other capsular and cortical lens opacity remains obscure (Gelatt, 1971).

The treatment of cataract is by surgery, and two techniques are possible. In young calves of several weeks of age lens dissection can be successful if the attendant uveitis is minimal (P.G.C. Bedford, pers. obs.). The technique is a simple one in which the anterior capsule of the lens is disrupted using a Bowman's needle inserted into the anterior chamber at the dorsal limbus (Plate 52.8). Normal and cataractous lens material is released into the anterior chamber and is usually almost completely resorbed, leaving the posterior capsule *in situ* to retain the vitreous behind the pupil. Corticosteroids are used to suppress the possible phacoanaphylactic inflammatory reaction, but in young calves this is minimal. After the operation cataract reformation is unusual, despite the retained presence of the anterior capsule and the lens epithelium. In older animals the attendant uveitis renders this technique unacceptable, and extracapsular lens extraction or phacoemulsification offers the best chance of success. In the former the anterior chamber is opened either through a corneal or limbal section, the anterior capsule removed and the cataractous material dislocated from the posterior capsule out through the section. The postoperative therapy must include corticosteroids and, just as in other species, loss of pupil as the result of iris spasm and posterior synechiae formation is the common complication that may render the eye blind. However, the uveitis is usually controllable, and the overall prognosis for sight is good. In phacoemulsification the cataract is removed from within the confines of its capsular bag and then the anterior capsule is removed. This kind of surgery is less intrusive and the degree of associated uveitis is usually minimal.

Diseases of the retina and optic nerve

Both congenital anomaly and acquired disease can involve the bovine fundus but, as with cataract diagnosis, such lesions are not normally detected unless there is an associated effect on sight or other more noticeable ocular defects are present.

Congenital defects

Papillary and peripapillary choroidal colobomata, persistence of the hyaloid artery, retinal dysplasia and

maternal hypovitaminosis A induced papilloedema and optic nerve atrophy are seen in the neonate. Choroidal colobomata are reported to be commonplace but may be of no clinical significance. Typical papillary colobomata in Hereford cattle with incomplete albinism are seen bilaterally but have no reported noticeable effect on vision. However, the same bilateral defect in Charolais may blind the affected animal (Plate 52.9). In both breeds the lesion is considered to be inherited, and genetic studies in the Charolais have indicated that it is a polygenic trait (Barnett & Ogden, 1972) (p. 181).

The hyaloid artery is part of the primary vitreous, but with the development of the ciliary vasculature it regresses and becomes non-functional. Large remnants of this vessel can be seen commonly in cattle (Plate 52.10), but they are of no clinical importance. The vessel overlies the optic disc and extends forward from this structure into the posterior vitreous. Blood is often seen within its lumen in young calves up to eight weeks of age, and remnants of the avascular vessel will persist throughout the animal's life.

Retinal dysplasia, in which there is typical rosette formation and usually non-attachment of the neuroretina, is seen in Shorthorn cattle with hydrocephalus and multiple ocular defects, and in Herefords with microphthalmia, cerebellar hypoplasia and hydrocephalus (Blackwell *et al.*, 1959; Green & Leipold, 1974). Congenital retinal degeneration and optic nerve atrophy have been seen in association with microphthalmia, cataract and cerebellar hypoplasia in calves born of dams infected with bovine viral diarrhoea/mucosal disease. Congenital optic nerve degeneration and papilloedema can be produced by maternal hypovitaminosis A.

Inflammation

Retinal and optic nerve lesions will accompany several systemic infections including the neonatal pyo-septicaemias, bovine viral diarrhoea/mucosal disease, thromboembolic meningoencephalitis, toxoplasmosis, tuberculosis and rabies.

Septic chorioretinitis characterized by haemorrhages, exudate and bullous retinal detachment can accompany septicaemia in young calves caused by *Escherichia coli*, streptococci, *Mannheimia* spp. and *Arcanobacterium pyogenes* infections. Maternal infection with bovine viral diarrhoea/mucosal disease can cause congenital optic neuritis among other ocular anomalies, and in thromboembolic meningoencephalitis caused by *Haemophilus somnus* conjunctivitis and corneal oedema may be accompanied by retinal vasculitis and detachment. Blindness is usually due to septic thrombosis of the visual cortex. Both anterior and posterior uveitis with possible retinal detachment can accompany

tuberculosis (p. 862). Focal retinitis has been reported in bovine rabies (p. 1164).

Hypovitaminosis A (see also p. 256)

Hypovitaminosis A has been described in three situations with variability of the presenting clinical features. It occurs congenitally, and here either papilloedema or optic nerve atrophy is present. In the growing calf there is obvious papilloedema in which the disc becomes very swollen, and the resultant papillary vascular congestion may cause focal superficial haemorrhage (Plate 52.11). Optic nerve atrophy will occur if the deficiency is maintained. The papilloedema is due to compression of the optic nerve by bony overgrowth within the optic canal, and the accompanying vascular occlusion results in ischaemic necrosis of the nerve (Hayes *et al.*, 1968). Early papilloedema is reversible and optic nerve atrophy preventable if the diet is suitably adjusted. Nyctalopia due to rod degeneration also occurs. Vitamin A is essential in the formation of the visual pigment rhodopsin, and without rhodopsin the photoreceptors degenerate. This process is also reversible should vitamin A be supplemented soon enough. It is likely that the sight problems experienced by the calf are more likely to be caused by the optic nerve lesions rather than the retinal degeneration. In the adult deficient in vitamin A papilloedema is much less noticeable and optic nerve atrophy does not occur. Here the outer segment degeneration is probably more significant in terms of the effect on sight.

Male fern optic neuropathy

Permanent or transient blindness will accompany weakness, malaise and constipation in the early stages of male fern (*Dryopteris filix mas*) poisoning. The toxic effect is on the optic nerve, and varying degrees of papilloedema and associated haemorrhage are seen ophthalmoscopically. In severe cases optic nerve atrophy follows the papilloedema.

Arthrogryposis (see p. 177)

The aetiology of arthrogryposis is open to speculation, and inheritance, fetal lupin toxicosis, manganese deficiency and maternal viral infection have all been considered to be involved. Joint deformities, syringomyelia and cleft palate may be seen, and blindness is due to abnormal photoreceptor development.

Progressive retinal degeneration

A form of retinal degeneration characterized by nyctalopia, progressive pigmentation within the tapetal

fundus and attenuation of the superficial retinal vasculature has been described in cattle, and compared with canine progressive retinal atrophy (PRA). It would appear to be a rare condition, and the comparison with PRA may have been somewhat premature.

Glaucoma

Glaucoma is the process of ocular degeneration caused by an elevation of the intraocular fluid pressure (IOP) beyond its physiological upper limit. The incidence is less than 1 per cent in cattle. All bovine glaucomas are due to the impairment of aqueous drainage through a defective or diseased iridocorneal angle, and in the majority of cases the glaucoma is secondary to inflammation or neoplasia. Uveitis may result in pupillary block due to extensive posterior synechiae formation. This results in the forward displacement of the peripheral iris, the so-called pathological iris bombé, and closure of the ciliary cleft. The presence of exudation speeds the transformation of the trabecular meshwork into an impervious physical barrier to aqueous outflow. Alternatively, these peripheral anterior synechiae and ciliary synechiae may form directly to deny bulk aqueous drainage. Tumour cells and the products of any associated inflammation will block the iridocorneal angle to produce secondary glaucoma.

A primary glaucoma has been recorded in the Friesian (Carter, 1960); the condition is inherited as a dominant trait and is seen in association with cataract formation and lens luxation.

Treatment of glaucoma in cattle is determined on the basis of whether the enlarged blind eye is of nuisance value, and enucleation may be necessary in the presence of associated corneal damage or degeneration.

| Malignant catarrhal fever | 935 |

Anaphylaxis

Aetiology

Anaphylaxis is the result of antigen–antibody reaction and when severe it can cause anaphylactic shock.

Epidemiology

The condition is usually very uncommon. Most cases follow the parenteral injection of drugs or biological products such as blood. Occasionally, the problem can arise through exposure via the alimentary tract or lungs. Signs may be seen in the system exposed, or they may be generalized. Most cases follow the introduction to the blood of an antigen to which the animal has already been sensitized, but reactions can occur where the animal is not known to have been exposed previously. More anaphylactic reactions occur in some herds and families of cattle than others. Reactions are most prevalent in Channel Island breeds. Initial signs tend to be largely of a respiratory nature, but other areas affected can be the alimentary tract and skin.

Signs

Reaction can occur about 20 minutes after the introduction of the antigen. The animal exhibits pronounced dyspnoea with, on auscultation, bubbling and emphysematous sounds. Muscle tremors can occur, which cause pyrexia to 40°C (104°F). Other reactions include bloat, diarrhoea, increased salivation, urticaria and rhinitis. Occasionally laminitis occurs. Death is due to anoxia. Following i.v. blood transfusion, there are usually hiccoughs and then dyspnoea, muscle tremors, salivation, coughing, lacrimation and fever.

Necropsy

At necropsy usually only the lungs are involved in acute cases, with marked pulmonary oedema and vascular engorgement; some animals develop emphysema. Longer-standing cases show hyperaemia and oedema of the abomasum and small intestines.

Diagnosis

Diagnosis depends on the history of recent introduction of an antigen to which the animal may previously have been exposed. The signs are helpful, being sudden with severe dyspnoea, urticaria, etc. Haematological examination shows increased packed cell volume, leucopenia and thrombocytopenia. Biochemical changes include a hyperkalaemia and blood histamine levels are raised in some cases. Finally, there is a response to therapy.

Differential diagnoses are few because of the rapid onset but acute pneumonia could be confused, although usually there is toxæmia and lesions are more pronounced in the arterio-ventral parts of the lungs.

Treatment and control

The most effective method of treatment is an intramuscular injection of adrenaline (4–5ml of 1 in 1000 solution) and if necessary a fifth of the dose (0.5–1.0ml) can be given intravenously, diluted to about a 2 per cent solution. Otherwise, corticosteroids can be administered or they may be given immediately following

adrenaline as they potentiate the latter's activity. Antihistamines give variable results, partly because most histamine is released early in the reaction and also there are other mediators of the anaphylactic reactions. Various other compounds have been shown to alter the reaction of mediators and these include sodium meclofenamate, acetylsalicylic acid and diethylcarbamazine.

Once a reaction has occurred in an animal, the antigen causing the problem should not be reintroduced. If a blood transfusion is given, introduce up to 200 ml in a 450 kg (990 lb) animal and wait for about 10 minutes before injecting the remainder.

Amyloidosis

Aetiology

The aetiology of amyloidosis is uncertain but it is the result of a hyperglobulinaemia, probably causing an abnormal antigen–antibody response.

Epidemiology

Is a rare condition that is not fully understood. A few cases occur as the result of repeated antigen usage in the production of hyperimmune sera. However, most animals are affected sporadically and spontaneously following prolonged suppurative infections. The origin of amyloid, which is a glycoprotein, is not certain, but is thought to be due to an abnormality of the antigen–antibody reaction. Renal amyloidosis is the most commonly recognized condition, but amyloid can also be deposited in the liver and spleen. When the main organ affected is the liver, there tends to be proteinuria. This leads to hypoproteinaemia and then oedema of the organ, resulting in marked anasarca. The diarrhoea produced is partly due to amyloid deposition and oedema of the intestinal wall. Many of the animals affected are still growing. Foci of inflammation found can include traumatic reticulo-peritonitis, traumatic pericarditis, salpingitis, mastitis, metritis (Johnson & Jamison, 1984) and nephritis. Cases have occurred following repeated hormonal injections in donor cows which are superovulated several times.

Signs

Usually, the affected animal is thin and emaciated. In most cases there is marked anasarca with an enlarged liver palpated in the right sublumbar fossa and an enlarged kidney with loss of its lobular structure when palpated via the rectum. There is usually polydipsia and a profuse watery diarrhoea. The animals later become

uraemic, recumbent and comatosed. Death occurs two to five weeks after the onset of signs. Almost all cases will eventually die unless slaughtered.

Necropsy

At necropsy there are usually one or more chronic suppurative processes present in the organs. The carcass is emaciated, usually with marked oedema. The affected organs are enlarged and pale in colour. The kidney and liver have diffuse amyloid infiltration, while in the spleen it is more localized. The amyloid can be shown by aqueous iodine staining.

Diagnosis

Diagnosis depends on signs, including an enlarged kidney, diarrhoea and oedema. There is hypoproteinaemia, proteinuria and hyperfibrinogenaemia. Blood biochemical examination shows hypomagnesaemia and a serum calcium level at the lower end of the normal range. There are also a high serum urea nitrogen and high serum creatinine. The specific gravity of the urine is low and there is a prolonged bromsulphthalein (BSP) clearance test.

Differential diagnoses are few but include pyelonephritis where there is pus and haematuria, and congestive heart failure in which there is an increased heart rate, respiratory embarrassment and dyspnoea.

Treatment

No successful therapy: cattle should be slaughtered.

Congestive heart failure

Aetiology

The condition can follow diseases of the pericardium, myocardium or endocardium.

Epidemiology

It is relatively uncommon and mainly affects older cattle. Pericarditis or hydropericardium can interfere with the normal filling of the heart during diastole. Pulmonary hyperaemia, which may occur in diffuse fibrosing alveolitis, can result in right-sided congestive heart failure. In cattle, the main cause of myocardial disease is foot-and-mouth disease. Endocardial diseases are the most common and are usually due to infection or inflammation.

When extra demand is placed on the heart, or the myocardial activity is reduced, then compensation can

occur by an increased heart rate, increased filling of the ventricles and improved cardiac performance. There are also dilatation and hypertrophy. Venous return increases in speed and blood distribution changes so that there is an increase in blood volume, a decrease in renal blood flow and sodium retention. Cardiac response is reduced and the animal is less able to cope with unusual exercise or other emergencies (Blood *et al.*, 1983). There is a decrease in exercise tolerance and once the compensating mechanisms have been overcome then the heart cannot cope and congestive heart failure develops. Many of the signs of cardiac insufficiency are the result of increased venous pressure. They result in congestion of organs or oedema and the decreased output produces tissue hypoxia.

Failure of the right-sided ventricle causes congestion of the major circulation with reduced blood flow through the kidney, resulting in anoxic damage to the glomeruli and venous congestion of the portal system of the liver, and eventually there is transudation into the intestinal lumen giving rise to diarrhoea. Left-sided ventricular failure results in engorgement and oedema of the lungs. Both left and right-sided failure can occur together.

Signs

Early signs are of reduced exercise tolerance with increased respiratory effort and tachypnoea following light exercise. Pulse and respiratory rates take a long time to return to normal. On percussion the heart area may be enlarged.

In left-sided failure: lungs are mainly affected so that there is a cough, tachypnoea and hyperpnoea. The heart rate is increased and a murmur may be present in the region of the aorta or left atrioventricular valve. On auscultation there are moist noises at the ventral edges of the pulmonary field and on percussion increased dullness on the lower borders of the lung. Later on there is cyanosis and dyspnoea.

In right-sided failure or cor pulmonale: appetite is poor and the animal is dull with a rapid loss of condition. There are marked areas of oedema often affecting the skin of the lower part of the body, the neck and the submandibular space. There is ascites, hydropericardium and hydrothorax. The liver may be enlarged enough to be palpated in the right sublumbar fossa. The heart rate tends to be increased and there is hyperpnoea and often slight tachypnoea. There is a marked jugular pulse. Prognosis usually poor in all cases.

Necropsy

At post-mortem examination there are abnormalities of the pericardium, myocardium or endocardium. Usually,

there is pulmonary congestion and oedema. In left-sided failure there is subcutaneous oedema, hydrothorax, ascites and hydropericardium.

Diagnosis

Diagnosis is by the signs, particularly those of oedema. The heart rate is elevated and there is an increased area of cardiac dullness; abnormal heart sounds may be present, depending on the cause. Insertion of a needle into a vein shows a markedly increased venous pressure. Aspiration of fluid from oedematous areas shows it to be a transudate containing large amounts of protein. There is also a proteinuria.

Differential diagnosis

Differential diagnosis includes amyloidosis but diarrhoea tends to be marked and the kidneys are enlarged without heart abnormality. In chronic peritonitis there is often some pain and the aspirated abdominal fluid contains many leucocytes. In bladder rupture there is a normal heart and urine is present in the abdomen. In liver fibrosis the heart is normal and there is usually jaundice or photosensitization. Parasitic gastroenteritis occurs in a younger animal and there is oedema, mainly of the submandibular area, with a high faecal egg count. Fascioliosis could confuse, but again there is usually only submandibular oedema and a faecal egg count. Fog fever (p. 866) could cause problems in diagnosis but usually several animals are affected quite suddenly in the autumn. Anaphylaxis is also a sudden problem with no cardiac signs.

Treatment

The primary cause should be treated as effectively as possible, but with most cases the prognosis is poor. Where oedema is present it is partly due to sodium retention and so the salt intake should be kept as low as possible. Diuretics such as frusemide or hydrochlorothiazide are useful and they can be given by injection or orally. The heart can be treated to improve contractility by use of etamiphylline camsylate, theophylline or digitalis derivatives. The use of digitalis by mouth is probably of limited value because of breakdown in the rumen. Parenteral administration of digitalis extracts is little used for several reasons: intravenous use could result in toxicity whereas intramuscular administration gives variable results. There are no licensed preparations. Little can be done to control the congestive heart failure except to treat all infections quickly and adequately.

Diabetes mellitus

This is a very unusual condition in cattle compared with its relatively frequent occurrence in dogs and cats. However, lesions can occur in the pancreas resulting in this condition. It is usually seen in old cattle and often animals will have had other problems such as fatty liver. The signs are loss of condition with polydipsia and polyuria. There is no rise in temperature and the urine contains both ketones and glucose. Biochemical examination of the blood shows hyperglycaemia. Usually treatment is not contemplated.

Hypothermia

Aetiology

This is also called cold stress and is mainly seen in young calves in severe climatic conditions, particularly where there is wind chilling as well as a cold ambient temperature. The problem is not encountered anything like as commonly as in lambs.

Epidemiology

Exposure to cold conditions mainly occurs in calves of cows calving outside in the winter months with no shelter. It is particularly prevalent in suckler calves and occurs more frequently in countries such as Canada and Australia than say Britain. Mortality is usually higher in calves born in winter and early spring. There is a delay in the onset and rate of immunoglobulin absorption from colostrum in cold-stressed calves. Primary hypothermia with no associated disease can be seen in young calves, and secondary hypothermia with no other disease has been recorded in older calves.

Signs

The rectal temperature may be low and can be defined as a temperature less than 37°C (98.5°F) and there is shivering. Shivering appears to be more intense during the initial period following exposure to cold. Most calves have no problems in the cold but some are depressed and stand or walk about stiffly. A few animals may remain in sternal recumbency. The heart rate tends to be raised but respiratory rate is low.

Necropsy

At post mortem the most common lesions involve the limbs and include subcutaneous oedema and haemorrhage. Experimentally, more haemorrhages occur in the hindlimbs. Some animals show oedema of the ventral sternum. The joints may show mild to severe haemor-

rhage and acute synovitis. Some cases show haemorrhages of the adrenal glands and oedema of the iliac and jejunal lymph nodes.

Diagnosis

Diagnosis depends on the history and signs. Increased serum glucose and phosphorus levels occur with cooling but fall during recovery.

Treatment

Treatment is by immersion in warm water, which results in quicker rewarming than use of a heat pad or heat lamp. A hot air environment could be constructed with a straw bale shelter and a hot air heater. Control is by ensuring that adequate shelter is provided or by housing cattle during the bad weather.

Lightning strike/electrocution

Aetiology

This is exposure to high voltage electric currents, either natural or generated by man.

Epidemiology

The condition is uncommon but it is often of interest as it is one of the few problems that farmers have usually insured against. Problems arise from lightning, exposure of electrical wires or faulty wiring or earthing in farm buildings. Cases may be single or a group. In many instances, damp ground or floors help to conduct the electricity. Low voltages of 110–220V are sufficient to kill cattle. Outside, trees such as oak, poplar, elm and conifers are all prone to lightning strike.

Signs

The signs in the severe form are such that animals die without a struggle. Burns or singeing may be seen because of the severity and often they involve the muzzle and feet. Death is usually due to paralysis of the medullary centre, accompanied in some cases by ventricular fibrillation. In the less severe form the animal becomes unconscious for a varying time and there is usually some sign of a struggle. After regaining consciousness there may be dullness, blindness, paralysis of one or more legs, and surface hyperesthesia. The signs may persist or slowly disappear over a period of up to two weeks. If burns are present, sloughing of the skin in the area is seen. Minor problems may occur such as the animal may jump, be restless, show periodic convulsions or be knocked down.

In lightning strike the animal is usually close to a fence, barn, trees or a pond. Often there are signs of burning affecting these objects. The animal itself may show singeing of the hair or burn marks on the muzzle and feet. Half-chewed food may be present in the mouth. The animal quickly becomes distended with gas and decomposes rapidly. Blood often exudes from the nostrils, rectum and vulva. The pupils are dilated and the anus relaxed. There tend to be petechial haemorrhages throughout the body and the viscera are congested. The superficial lymph nodes are often haemorrhagic.

Diagnosis

Diagnosis depends on the history of a storm, position of the animal near trees, etc. and sudden death of a group of animals. The signs may also be helpful such as singeing of the hair, burns on the muzzle and feet and evidence of sudden death.

Differential diagnosis

Differential diagnosis includes anaphylaxis but there is marked pulmonary involvement. Acute heart failure can cause problems but there is engorgement of visceral veins and macroscopic or microscopic myocardial lesions. Brain trauma can occur but usually there is a haemorrhagic lesion of the brain. Nitrate/nitrite poisoning results in sudden death but methaemoglobin is present. Anthrax can be confused, but stained blood smears assist in determination. Bloat is a possibility but on necropsy the front part of the animal is congested, there is a distended rumen and sometimes froth present. Blackleg results in swelling of the part affected with the causal organism present.

Treatment

No treatment is usually given as often the cattle are either better or dead before any therapy can be administered. Central nervous system stimulants can be given. Artificial respiration may be helpful. Although nothing can be done about lightning strike, all electrical installations should be properly fitted and earthed.

Stray voltage

While not a very common problem, the signs are often difficult to determine and also the origin is hard to find. These stray electrical currents result in mild electric shocks to the animals and cause discomfort, often resulting in apparent behavioural problems.

Occurrence

There are a large number of different origins for this problem. Stray voltage is an electrical current passing between two points. Should an animal come into contact with these points the current will pass through the animal. Cattle are more sensitive to electrical voltages than human beings, who often do not feel any shock due to wearing clothes and boots which can insulate them from the problem. While there is individual variation in the susceptibility to electricity, most cases will only be detected when several animals show similar signs. The most common place for this to occur is in the milking parlour, although feed and water troughs as well as other farm building equipment can be involved. The history may contain the fact that there has been some alteration or modification of the electrical supply or there has been some building. Otherwise most problems result from old and exposed wiring, often with damage to the insulation covering or vermin damage.

Signs

These will vary and are related to the area of the stray voltage. If the source is in the parlour, the cattle are often reluctant to enter, are fidgety during milking and will rush out of the parlour after milking. If the source is a water trough it may be avoided by the cows or they may lap rather than drink normally. Other signs include restlessness, muscular twitching, etc. Milk production may suffer and feed intake as well if the feed area is affected.

Diagnosis

This is often difficult; any behavioural change will usually only be seen in the area of the stray current. If several animals are showing similar discomfort or behavioural changes then diagnosis is made more easy. Confirmation will depend on a qualified electrician and will require a sensitive voltmeter. It may also be necessary to set up the conditions that cause the shock, i.e. have the milking equipment working.

Differential diagnosis

Behavioural changes will usually only affect a single animal and will be less likely to be related to a particular area of the farm. BSE can result in signs such as reluctance to enter the parlour and difficulty in milking, but would always involve the same animal. Other signs would also occur.

Control

Ensure all electrical installations and equipment are properly earthed and maintained. Have wiring checked periodically.

Meloidosis

Aetiology

The cause is *Pseudomonas (Malleomyces) pseudomallei*. It can survive for long periods in the soil and water.

Epidemiology

The condition is primarily a disease of rodents but occasionally it spreads to man and farm animals such as sheep, goats, horses and pigs. It is very rare in cattle. The disease was first recognized in South East Asia but it is now seen in Australia, Malaysia, Papua New Guinea and Nigeria. Infection is passed in the faeces of rodents and is spread by ingestion of contaminated feed or water, by insect bites, wounds and possibly inhalation. Mortality is high and disease lasts about two to eight weeks.

Signs

The main signs are a marked pyrexia with anorexia and a thick yellow exudate from the eyes and nose. Nervous signs may be exhibited. Some cattle have infection without signs.

Pathology

There are multiple abscesses in many areas of the body as well as in the subcutaneous tissues and associated lymph nodes. The size of the abscesses is variable from a few millimetres to over 2.5cm in diameter.

Diagnosis

This depends on demonstrating the causal organism by culture from pus, nasal discharges or blood.

Treatment

There is little information available on satisfactory treatment of meloidosis. Chloramphenicol is used in man and *in vitro* tests suggest oxytetracycline may be of use in animals, and perhaps novobiocin, chloramphenicol and sulphadiazine. Treatment is to be discouraged because of the possibility of spread to humans.

Control

Infected animals: slaughtered, disposed of by burning. In-contact animals: slaughtered, the premises disinfected.

Mycotic diseases

Mucormycosis

Aetiology

There are various fungi of the family Mucoraceae that can cause infection, including the genera *Absidia*, *Entomophthora*, *Mortierella*, *Mucor*, *Rhizopus*.

Epidemiology

The fungi occur usually in soil and water and are often plant pathogens and food decomposers. They are opportunistic.

Signs

Infection can cause a necrotic placentitis in cattle resulting in abortion at three to seven months' gestation. There is necrosis of maternal cotyledons and yellow, raised, leathery lesions on the intercotyledony areas. Granulomatous lesions of the mesenteric and mediastinal lymph nodes can occur. Calves can develop alimentary tract lesions after prolonged antibiotic therapy. Following acidosis the ruminal wall can be invaded with *Rhizopus* spp.

Diagnosis

Hyphae are present on smears of cotyledons, fetal stomach and skin. The lymph nodes need to be examined. There may be a history of antibiotic usage and on post mortem there may be abomasal ulceration. The animal will become black tinted.

Prevention and control

As the fungi are ubiquitous it is impossible to control properly. There are no satisfactory antibiotics.

Cryptococcosis

Aetiology

The cause is *Cryptococcus (Saccharomyces) neoformans* (synonyms *C. hominis*, *Torula histolytica*).

Epidemiology

The incidence is worldwide and is high in areas of warmth and moisture.

Signs

Latent: There is a mastitis in many cases with no visible signs in the udder or milk.

Severe: The quarter(s) swells slowly and becomes firm and swollen. The subcutaneous tissue also develops oedema, which persists for several weeks. There is often some discomfort with the legs held apart. Pyrexia occurs up to 40°C (104°F) with anaemia. The supra-mammary lymph nodes are enlarged. Milk production is reduced but the milk itself shows few changes except a few flakes. Later, in persistent cases, there is a watery secretion.

Mild: A swelling of the quarter(s) is seen with little effect on the milk. Occasionally a granulomatous meningoencephalitis may develop or the nasal mucosa may show nodular lesions.

Pathology

Infection is mainly confined to the udder, although there may also be reddening and thickening of the brain tissue and oedema, and naso- or oropharyngeal nodules.

Diagnosis

Diagnosis is by direct examination of the fluids.

Prevention and control

Ensure proper disinfection.

Rhinosporidiosis

Aetiology

The causative organism is *Rhinosporidium seeberi*.

Epidemiology

The disease is distributed worldwide.

Signs

There is the formation of large polyps in the posterior nares and this interferes with respiration. The lesions are small, about 0.5–3 cm in diameter. They are soft, friable and bleed. The surface of the polyp shows many small white specks. The nasal discharge results in dyspnoea with mucopurulent and bloody discharge.

Pathology

There is a polyp of papillomatous epithelium, which is hyperplastic and contains numerous sporangia.

Diagnosis

Isolation of the organism provides the diagnosis.

Treatment

Polyps are best removed surgically.

Candidiasis (moniliasis)

Aetiology

The main causal agent is *Candida albicans* but *C. tropicalis*, *C. krusei*, *C. parapsilosis* and *C. guillermondii* can also initiate disease.

Epidemiology

The organisms are worldwide and found in animal faeces.

Signs

A chronic pneumonia can occur with dyspnoea plus only a moderate fever. There is a profuse stringy salivation and brown-streaked nasal discharge. Abortion can occur and there can also be mastitis with mild transient signs that are self-terminating. Where there is severe mastitis it may follow the use of intramammary tubes. The udder is swollen and spongy and the animal's temperature is 40–41.5°C (104–107°F).

Diagnosis

Isolation of the organism provides the diagnosis.

Treatment and control

There is a limit to what can be done but amphotericin B can be successful. An iodine in liquid paraffin intramammary infusion can be left in the udder for 10–15 minutes, and then stripped out. This is repeated in seven days, and oral iodides may be given if necessary.

Aspergillosis

Aetiology

There are many *Aspergillus* spp. including *Aspergillus fumigatus*, *A. flavus*, *A. niger* and *A. terreus*.

Epidemiology

The organisms are widespread. Placental infection of cattle is thought to be via abomasal ulcers or from the respiratory tract. It also occurs following inhalation of spores from mouldy straw, hay and sugar beet pulp. Outbreaks of abortions can occur following the feeding of mouldy silage.

Signs

Aspergillosis is a quite common cause of abortion with a placentalitis. Abortion is in the sixth to eighth month of pregnancy. Another form is a fatal gastroenteritis with ulceration of forestomachs and oesophagus. Pulmonary aspergillosis also occurs in animals subjected to diarrhoea and poor ventilation. There is fever and dyspnoea.

Diagnosis

Examine placental direct smears for fungi. Culture stomach contents or cotyledon.

Treatment and control

Nystatin can be used in the treatment of diarrhoea. There is no effective preventive but avoid feeding mouldy silage to cows in mid to late pregnancy. Definitely mouldy straw or hay should not be used in enclosed buildings, and preferably not at all.

Histoplasmosis

Aetiology

There are two species causing infection, *Histoplasma capsulatum* and *H. duboisii*.

Epidemiology

Whereas *H. capsulatum* is found worldwide, *H. duboisii* is only found in Africa. It is a rare condition but can occur in man and other species. *Histoplasma capsulatum* is found in the soil. Infection follows inhalation of contaminated dust and entry to the lung.

Signs

Affected cattle may show chronic emaciation, dyspnoea, diarrhoea, swelling of the brisket and grinding of the teeth. At post-mortem examination there is an enlarged liver, ascites, oedematous thickening of the large intestine and interstitial emphysema. Histologically, eosinophilic round bodies can be found in endothelial cells.

Diagnosis

Diagnosis is from the signs, and samples should be taken for culture and histology.

Treatment and control

Amphotericin B given intravenously at 1 mg/kg body weight daily has been effective but a prolonged course

may lead to side-effects. The imidazoles may be satisfactory.

Teat burns

Epidemiology

In parts of the world where forest and grass fires are common, burns can result in damage necessitating the slaughter of cattle. However, in other cases the animals will survive but there may be injury to the teats or udder. In such cases it is necessary to provide an accurate prognosis. Often several teats are affected.

Signs

The lesions can be assessed according to the severity of the burn (Morton *et al.*, 1987).

Mild burns: These are reddened with a loss of the outer, white, paper-thin tissue, which sloughs. A teat may have normal tissue interspersed with multiple small black areas over the teat surface or a uniform relatively thick black or red-brown surface layer. There may be areas of sloughing or crusts that develop in the tissue and milk is apparently normal. In all cases the teats are pliable on palpation.

Severe burns: The teats tend to be dull brown or black, dry and often are corrugated. If sloughing has occurred then a thick layer (over 1 mm thick) of tissue is sloughed. Underneath there is red haemorrhagic tissue. On palpation the teat is leather-like and lacks pliability. In some cases the teats tend to be distorted, especially in heifers.

Prognosis

With mild lesions prognosis is good. In severe lesions prognosis is variable but tends to be better in cows than heifers. Some cows only show partial return to function with reduced milk flow.

Treatment

Treatment can increase recovery. Application of 0.5 per cent cetrimide in lanolin daily is helpful. However, healing is slow, taking about 14 weeks. When the surface skin starts to peel antibiotic ointment is helpful. Teat orifice restrictions often respond to surgery.

Water availability

Water debility need not necessarily damage cattle in the dry season in semi-arid regions. Some breeds are obvi-

ously less susceptible. They are less affected when they are on pastures containing a very low crude protein level. If fed a high plane of nutrition without water, problems could arise, but in practice this is unlikely to occur. The amount of water required varies but is obviously higher in a dairy cow than a beef animal. Animals are capable of being watered only once every three days if necessary but they should not have to walk more than about 2.5km to it. If water deprivation occurs there is a reduction in milk or meat deposition. If dehydration persists there is circulatory collapse when the level of sodium reaches 170mEq/l.

Heat stress (see Chapter 8)

Acute heat stress

If the heat produced by the animal and the heat absorbed from the atmosphere are higher than the heat lost then the animal's temperature will rise. It thus develops hyperthermia and if the rise is great and sudden the animals will pant, salivate excessively, become restless and then prostrate. Problems often occur if cattle are made to walk long distances. Heat stroke can occur at a normal outside temperature if animals are packed tightly in poorly ventilated vehicles travelling during the hottest parts of the day.

If action is not quick death occurs. Affected animals should be sprayed with cold water. They should be kept in the shade and attempts made to increase the air flow. Clipping the hair, particularly along the mane, withers and backbone, will assist but such animals are then susceptible to direct sunlight and so they should be kept in the shade.

Chronic heat stress (see Chapter 8)

The chronic or subacute form occurs more frequently than acute heat stress. When exposed to high temperatures cattle compensate by increasing their loss of heat by panting and sweating. They can also reduce heat production by reducing food intake, drinking more and reducing activity. Cattle are able to accept high midday temperatures if the evenings and nights are cool.

In chronic heat stress there is decreased milk production, reduction in weight gain and sexual maturity. There is also some loss in fertility, particularly involving spermatogenesis in the bull. When animals are affected they should be provided with shelter or otherwise given access to well-ventilated shady areas. Oestrus suppression may also occur. When cattle are grazed in very hot conditions grazing should be restricted to the evenings, nights and mornings. If necessary zero-grazing may need to be adopted. In such circumstances, where the

air is hot and humid, then every attempt must be made to ensure good air flow by louvred windows, fans, etc. The cattle should receive an adequate amount of water. Feeding at night will also ensure maximum heat production is during the cool period.

Malignant catarrhal fever

Aetiology

Also known as bovine malignant catarrh and malignant head catarrh. Caused by two different agents but clinically identical. In many countries only one of the agents is present. The African strain, (alcelaphine herpes virus 1 and 2 or bovid herpes virus 3) is wildebeest-associated. The European, North American and Asian strain has not been characterized but is sheep-associated.

Epidemiology
