List of Colour Plates

All colour plates appear between 468 and 469.

- 16.1 Hair loss over legs and perineum associated with steatorrhoea and diarrhoea.
16.2 Alopecia due to poorly dispersed fats from milk substitute.
16.3 Rumen bloat and chronic scour.
16.4 Calf *in extremis*.
16.5 Abomasum at necropsy.
16.6 Chronic peri-weaning calf diarrhoea.
23.1 Lumen and keratinized lining in teat duct.
23.2 Signs of clinical mastitis.
27.1 Early stages of bovine herpes mammillitis.
27.2 Bovine herpes mammillitis (two days).
27.3 Bovine herpes mammillitis (four days).
27.4 Bovine herpes mammillitis and scab formation.
27.5 Bovine herpes mammillitis (about seven days).
27.6 Bovine herpes mammillitis (about two weeks).
27.7 Bovine herpes mammillitis (two to three weeks).
27.8 Bovine herpes mammillitis – teat after shedding necrotic tissue.
27.9 Pseudocowpox.
27.10 Pseudocowpox lesion (seven days).
27.11 Pseudocowpox (10–12 days).
27.12 Pseudocowpox scab.
27.13–16 Atypical Pseudocowpox lesions.
27.17 Cowpox showing vesicle development.
27.18 Cowpox following vesicle rupture.
27.19 Cowpox with scab formation.
27.20 Severe cowpox.
27.21 *Staphylococcus aureus* infection of teat.
27.22 Teat chaps.
27.23 Photosensitization of the teat.
27.24 Foot-and-mouth disease – vesiculation of the teat.
27.25 Pseudocowpox infection with cowpox infection.
27.26 Pseudocowpox infection with bovine herpes mammillitis.
27.27 Blackspot of a teat orifice.
27.28 Mud abrasion of the teat.
27.29 Ringworm lesions.
27.30 Thelitis and serous exudate in peractute mastitis.
27.31 Filamentous papillomatosis of the teat.
27.32 Nodular papillomatosis of the teat.
31.1 Hoof with corium removed.
31.2 Cross-section of white line.
31.3 Gross claw overgrowth.
31.4 Overgrowth from the sole.
31.5 White line across a square-ended toe.
31.6 Haemorrhage at the sole ulcer site and in white line.
31.7 Typical sole ulcer.
31.8 Heel ulcer and early sole ulcer haemorrhage.
31.9 Typical white line separation with impacted stone.
31.10 Rings on a cow's horns demonstrate disruption of horn formation in the periparturient animal.
31.11 Cows prefer to walk on the soft surface of a rubber mat.
31.12 Cows walking along the grass verge to avoid the stony track.
31.13 Digital dermatitis and slurry heel.
31.14 A vertical fissure.
31.15 Axial wall fissure.
31.16 Interdigital necrobacillosis.
31.17 The chronic 'hairy wart' form of digital dermatitis.
31.18–19 Necrosis of the apex of the pedal bone.
31.20 Insertion of a tube to flush and drain deep pedal infections.
40.1 Classification and grading of embryos.
44.1 *Anthrax bacillus*.
44.2 Blackleg due to *Clostridium chauvoei*.
44.3 Endocarditis.
50.1 Generalized *Trichophyton verrucosum* infection.
50.2 *Trichophyton verrucosum* infection on calf's head.
50.3 *Linognathus vituli* lice and ova on calf.
50.4 *Sarcoptes scabiei* infection.
50.5–6 Generalized sarcoptic scabies.
50.7 Nodular lesions of demodicosis.
50.8–9 Viral papillomatosis.
50.10 Pruritis/pyrexia/haemorrhagic syndrome.
50.11–12 Severe photodermatitis.
50.13–14 Dermatophilosis.
52.1 Cyclopia.
52.2 Esotropia: (a) early; (b) marked.
52.3 Epibulbar dermoid.
52.4 Infectious bovine keratoconjunctivitis.
52.5 Squamous cell carcinoma.
52.6 Anterior uveitis secondary to septicaemia of undetermined aetiology.
52.7 Congenital cataract.
52.8 Lens disision.
52.9 Papillary coloboma.
52.10 Normal bovine fundus.
52.11 Severe papilloedema with disc haemorrhages.
65.1 Acupuncture to treat anoestrus.
65.2 Stomach 36 acupuncture point.

Preface

It is now about ten years since the first edition of *Bovine Medicine* was published. While it was originally anticipated that it would be used mainly in Britain and Europe, it is pleasing to note that a good proportion of the sales have been in other parts of the world. In recognition of this, more emphasis has been placed on conditions and their treatment in areas other than temperate regions. Additionally, a new section gives an insight to the differences in bovine medicine as practised in various parts of the world.

Almost all parts of the book have been updated or completely rewritten. There are some new chapters, including one which integrates the various problems which occur in cattle, another on basic surgical techniques and others on artificial insemination and embryo transfer. An effort has been made to encompass all the main subjects which occur in the husbandry and diseases of cattle.

I wish to thank all the authors and co-editors for their hard work. Roger Blowey, Hugh Boyd and Roger Eddy have provided advice and assistance despite their many commitments. I would also like to thank John Sproat for supplying the photographs of cattle used on the end papers.

Every effort has been made to identify copyright holders of material reproduced in this book. Any inad-

vertent omissions will be rectified in any future reprint or edition of this work.

I hope that everyone reading the new edition will find it to be an interesting source of information.

Readers' note

Inevitably, when it comes to therapies, medicines and vaccines, each country has different needs and requirements. The laws concerning the use of particular therapeutic and preventative agents may vary and the reader is reminded that it is his or her duty to ensure that any preparation prescribed conforms with all relevant national legislation where the preparation is to be used. It is also essential to ensure that dosages and routes of administration are determined according to any national or local directions and other product information which has been provided with the medicine. While every effort has been made to ensure that the uses suggested and doses recommended are correct they should always be checked with currently available information. It must also be remembered that any meat withdrawal time or milk withholding time for drugs should follow the guidelines of the country in which a drug is used.

A.H. Andrews

Preface to the First Edition

Bovine Medicine aims to provide, within the covers of one book, much of the practical information available on cattle disease and production. Such an objective is admirable in sentiment but very difficult to achieve in practice. It involves the concentration of effort by a large number of different, and often very busy, experts into one volume. For the present part it is hoped that what we have produced will not only be a source of information but, in many areas, it will be an enjoyable, educational read. It is hoped that it will be used as a working guide rather than a reference book and that it will be of particular help to those at the 'sharp end' of the veterinary profession, i.e. in practice. Bearing this in mind, this work does not contain every detail concerning each disease, organism or clinical entity.

Inevitably there are some areas of subject overlap as might be expected with skin conditions and ectoparasites and 'downer cow', etc. Where possible each author has provided his or her own perspective on the subject.

In addition, references have been kept to a minimum to ensure a less disjointed read. In consequence, we

would be pleased to receive comments from readers on any deficiencies or difficulties encountered in presentation or content.

It has taken approximately 2 years to complete a work of this magnitude. The continual expansion in veterinary knowledge and expertise may well mean that in certain areas some recent developments have been omitted. Again, we would be pleased for any such deficiencies to be pointed out to us.

There has been considerable recent interest in alternative medicine for animals. Mindful of this, a section is included on the subject to help readers make up their own minds on its relevance to cattle therapy.

I must thank Blackwell Science, and particularly Peter Saugman for his patience during the production of this book. Much work has also fallen on my coeditors Hugh Boyd, Roger Blowey and Roger Eddy. However, the book would not have been completed but for the dedicated secretarial and managerial help of Mrs Rosemary Forster.

A.H. Andrews

Introduction

Whether calves from the dairy herd are being reared as dairy herd replacements or for beef production, a good start in life is essential. Calves of subnormal weight at three months of age tend to lag behind throughout the growing period.

The starting point for good calf rearing is the consumption of at least 2 litres of colostrum by suckling or bucket feeding within the first six hours of life and a further 2 litres within 12 hours. The passive immunity conferred on the calves by the immune lactoglobulin in colostrum is vital to disease resistance, especially if calves are transferred to another farm for rearing, probably via a collection centre or auction. Mortality among calves deprived of colostrum is high. Therefore, it is advisable to keep some colostrum in a freezer in case of emergencies.

Colostrum is a rich feed and a good source of the fat soluble vitamins A, D and E. Therefore it is sensible to feed all available colostrum even to calves that are beyond the stage when they can gain passive immunity.

Calf reception

Dairy-bred calves for beef rearing are usually purchased at about two weeks of age, often from a calf group or dealer. When they arrive at the farm, calves should be inspected individually and any showing signs of ill health returned to the supplier or isolated. Navel should be dipped in a concentrated iodine or phenol solution to guard against navel ill and joint ill. Any

calves with signs of lice should be treated with an approved ectoparasite product. A multivitamin injection containing vitamins A, D and E is good value for money.

The calves should be housed in pens bedded liberally with dry straw and clean, fresh water should be made available. Milk is best withheld for a few hours after arrival but any calves that appear stressed may be given a warm drink of 1 litre of a proprietary electrolyte solution.

If calves are housed individually, which is permissible up to eight weeks of age, pens should be at least 1.8×1.0 metres and should permit visual and physical contact with at least one other calf. Group-housed calves up to 150kg liveweight need a minimum space allowance of 1.5m^2 , rising to 2.0m^2 at 150–200kg. Pen floors should have a slope from back to front of at least 1 in 20 to permit good drainage.

Calves do not mind cold weather but need good ventilation without drafts. The modern trend in temperate climates is to erect simple monopitch buildings in which calves can be housed until they are 12 weeks or older. In the coldest weather straw bales or wooden sheets can be placed above the rear half of pens to provide more insulation. Where calves are single-penned, the pens are dismantled at weaning and the calves left where they are as a rearing group. If buildings and pens are used continuously for calf rearing, after each batch they should be power washed or steam cleaned, disinfected and left empty for at least two weeks before restocking.

Rearing systems

In high yielding dairy herds, calves are weaned off their dams as soon as possible after they have received colostrum and are reared by the early weaning system pioneered in the UK but also applicable worldwide. Calves can be weaned off milk replacer after five to seven weeks, which makes the system convenient and saves money compared to weaning at an older age. The secret of success is to ensure that individual calves are eating at least 1kg per day of a palatable early weaning concentrate before they are weaned.

The commonest rearing system is a twice daily bucket feed of milk replacer, but some rearers use computer-controlled machines that mix milk replacer and provide it to the calves via teats from which they suckle.

In the EU, where milk production is subject to milk quotas, milk produced over the quota has no market value so it is sensible to feed it to calves rather than purchase a milk replacer. However, if milk production is at or under quota, a milk replacer should be used. Feeding whole milk needs just the same attention to temperature and feeding level as milk replacer.

The high cost of dried skimmed milk on which milk replacers used to be based has led to the development of so-called 'zero' milk replacers. These are based on dried whey supplemented with fats and lactose to equate as closely as possible to cow's milk. Whey-based replacers are up to 25 per cent cheaper than skimmed milk products but can give equally good results.

For bucket feeding, replacers are mixed at 125–150 g/l, according to the manufacturer's recommendation. The mix is made up with water at 45–50°C so that the temperature at feeding is 42°C. Automatic feeding machines mix replacer at 100–125 g/l but can be set to vary reconstitution rates according to the stage of rearing. It is essential to keep all feeding equipment scrupulously clean.

Scouring and pneumonia are the twin scourges of calf rearing. Typically, calf mortality is 5 per cent, mainly due to these two causes, but it can rise to 10 per cent. The target in a well-managed calf rearing unit should be to keep mortality below 3 per cent.

Scouring is most likely in the first two weeks following removal from the dam and may be simply because the calf has been overfed or the milk replacer is at the wrong temperature. However, it may also be caused by pathogenic organisms. *E. coli* is the classic cause but a survey of calf units by practising veterinarians identified a number of other pathogens responsible for scouring. The immediate reaction to scouring is to take the calf off milk and feed a warm electrolyte solution. If the scouring does not start to clear up within 24 hours veterinary advice should be sought. Antibiotics should only be used on veterinary prescription.

If salmonella infection is suspected, veterinary advice should be sought straight away and rectal swabs taken for laboratory analysis so that the appropriate antibiotic can be prescribed. Infected calves should be isolated. Many *Salmonella* species are transmissible to humans so during an outbreak special attention needs to be paid to personal hygiene. Salmonellosis usually occurs in the first two or three weeks of life but can occur later, even beyond the milk feeding period (Chapter 15).

Pneumonia can occur at any time but is most prevalent in still, damp winter weather and is exacerbated if

calves are moved at this time. Frequent observation is needed to identify the early symptoms of pneumonia – listlessness, holding back at feeding time, a runny nose, rapid breathing or coughing. Veterinary advice should be sought straight away. Not only is pneumonia a major cause of calf mortality but also infected calves that recover often fail to thrive due to lung damage.

Dehorning and castration are stressful and so should not be done together, nor should they coincide with the stress of weaning. Healthy calves can be dehorned three weeks into the rearing period using a hot air or hot iron disbudder, with castration at four weeks.

Early weaning: bucket feeding

The commonest early weaning rearing method is twice daily bucket feeding with weaning at five to seven weeks. With milk replacer mixed at 125 g/l, the first full feed for a purchased calf is 1 litre. Home-bred calves are fed this level twice daily until they are about five days old, then the feeding level per feed is increased by 0.25 litres every other day up to a maximum of 2 litres per feed, that is 4 litres per day.

Some expert calf rearers have found a useful saving in labour, without detriment to calf performance, by feeding the calves milk replacer once daily after the first seven to ten days. In this case the feeding level is built up gradually to 3 litres per day. However, the saving in labour should not compromise calf inspection, which should continue frequently to detect health problems.

From the start calves are fed an early weaning concentrate containing 18 per cent crude protein and with a good amino acid profile, since the calf needs some of its protein intake to escape fermentation and degradation in the forestomachs. The energy value should be at least 12.5 MJ ME/kg DM.

Even the youngest calves crave some roughage in their diet and, rather than letting them pick up straw from the bedding, it is better to feed hay or straw from a rack. Hay is rarely of good enough quality for calves and, even if it is, they eat too much of it at the expense of concentrates and become pot-bellied. Instead, feed bright, dry barley or oat straw.

As previously mentioned, calves must be eating at least 1 kg concentrate per day before they can be weaned. Weaning may be abrupt after about 35 days, or a gradual weaning procedure may be used in which the level of milk replacer is reduced gradually over an additional 5–10 days to encourage concentrate consumption. Gradual weaning avoids the check to growth that accompanies abrupt weaning.

The early weaning concentrate should be fed *ad libitum* until it is replaced by a cheaper follow-on concentrate, or until it is rationed as forage feeds are introduced (p. 5).

The consumption of milk powder is 15–20kg and the target daily gain to weaning is 0.5–0.6kg/day, depending on breed type and sex.

Early weaning: machine feeding

Feeding milk *ad libitum* to group-housed calves can be the preferred choice where the buildings used for calf rearing do not lend themselves to the erection of individual pens or, as in dairy herds, where calves are born over a long period.

The saving in labour is not as great as might be supposed because, although mixing is automatic and cleaning is quicker, handling the calves is more time consuming, especially teaching them to suckle.

The most sophisticated machines are computer controlled and recognize individual calves fitted with an electronic tag. So mixing rates and feeding levels can be varied from calf to calf, including a gradual weaning procedure. Some machines can feed whole milk as well as milk replacer and even dispense a small quantity of concentrates to encourage calves to eat dry feed immediately after suckling. Of course these machines are expensive but the cost is spread over up to 80 calves that can be reared at a time, so the annual depreciation per calf may be reasonable.

A cheaper approach to *ad libitum* feeding held sway for a time but is little used now. This was to feed cold acidified milk which stays fresh for two to three days stored in a simple plastic bin and is led to a teat through a tube fitted with a non-return valve. The equipment is cheap but lacks the sophisticated control of individual calves achieved by computer-controlled feeders.

Calves are trained to suckle about 1 litre of milk replacer and then the milk supply is removed until the next feed. The procedure is repeated twice in the next 24 hours and then calves are allowed to suckle *ad libitum*, with not more than six calves per teat. Intake may be depressed in the coldest winter weather and then it is advisable to use an immersion heater to take the chill off the milk replacer. The feeding equipment should be cleaned thoroughly between mixes.

A trough containing early weaning concentrates should be placed near the teats, but far enough away to avoid spoilage by saliva or spilt milk.

Calves fed *ad libitum* consume more milk replacer than restricted bucket-fed calves. This manifests itself as rather loose faeces that must be differentiated from scouring. The high replacer intake inhibits early concentrate consumption and may delay weaning. Therefore, it is important to employ a gradual weaning programme to allow weaning at five to seven weeks. Even at these high intakes of milk replacer, it is essential that fresh water should always be available.

Consumption of milk replacer powder is 25–30kg and the target daily gain to weaning is 0.6–0.7kg/day, depending on breed type and sex.

Follow-on rearing

When calves are weaned at five to seven weeks the early weaning concentrate must continue to be fed *ad libitum*. In the case of calves going into intensive beef systems, concentrate feeding continues to appetite through to 12 weeks, although the finishing diet is introduced gradually from eight to ten weeks.

Where calves are designated for forage-based beef systems, forage is introduced by the tenth week and the early weaning concentrate is replaced by a cheaper mix. When calves reared through the winter are to be grazed in the next summer, it is important to hold gains at 0.6–0.8kg/day until turnout in the spring or the ability of the calves to exhibit extra rapid compensatory growth on high quality grazed grass will be inhibited. To achieve this the follow-on concentrate needs to be rationed at about 2½kg/day with forage fed to appetite.

Performance targets

Performance targets for early weaned bull calves fed concentrates *ad libitum* to three months are shown in Table 1.1.

Veal production

Veal production is a specialized system of calf rearing designed to produce a white meat that is especially popular in Italy and Germany. Traditionally, calves were housed in narrow crates and fed milk only until slaughter at 14–16 weeks, producing a carcass of 100–110kg. Subsequently the feeding period was extended to 22 weeks or more to produce a carcass of 160+ kg.

Consumer revulsion at the unnatural production method has brought about considerable changes in the way veal is produced, sanctioned by EU and national legislation. For example, veal crates have been banned in Britain since 1990, although EU legislation does not ban existing crated housing in continental Europe until 2006. Similarly, legislation stipulates a minimum iron content for calf milks and insists that calves over two weeks of age have access to digestible solid food. The effect has been to promote the production of veal that is pink in colour rather than white.

A welfare-friendly veal production system has been demonstrated experimentally in Britain with group-housed calves fed milk replacer from a machine and

supplemented with barley straw as a source of roughage. Carcasses were acceptable to the veal trade but variability of performance was an unsolved problem.

In the Netherlands, the main EU veal producer, there are now two approaches to veal production. First there is a white veal system in which group-housed calves are fed largely on milk replacer but with limited access to maize silage (which does not affect meat colour). The calves are slaughtered at about six months of age at around 285 kg liveweight. A pink veal system is also employed by some producers in which calves are fed about 40 kg milk replacer powder plus 500 kg concentrates and 500 kg maize silage. The calves are slaughtered at about 32 weeks at a weight of around 320 kg.

Calf identification

A beneficial consequence of the BSE crisis and subsequent foot-and-mouth disease epidemic is a realization

that being able to trace the whereabouts of cattle throughout their lives is an essential requirement of food safety for people and disease control in cattle.

Traceability is subject to EU legislation. The British Cattle Tracing System (CTS) is administered by the British Cattle Movement Service (BCMS) that commenced operations in September 1998. This fully computerized system was preceded by a paper passport system that started in July 1996. A one-off survey was undertaken of all cattle in 2000, including older cows and bulls which did not have passports, so that all cattle could be included in the BCMS database.

Calves must be double tagged within 36 hours of birth unless they are being sent for immediate slaughter. An application for a passport must normally be made within seven days of tagging but calves can be moved twice during the first 28 days of life, using the reverse of the cattle passport application form as a temporary passport. An all-numeric numbering system has replaced the former alpha numeric identity.

Introduction

The key indicator of profitability and technical efficiency in suckler herds is the calf output produced annually from each cow that is bulled. The most profitable herds owe their success to producing a large number of live calves per 100 cows bulled, with low calf mortality, rapid growth to weaning and a high sale value per kg for well-reared calves. This is as true under dry range conditions as it is on productive temperate grassland.

Suckler herd management is not the simple matter it may seem at first sight, with a cow suckling a single calf. The linked components are reproductive efficiency, milk production and growth. However, in practice the body condition of cows is a simple and sensitive barometer of their nutritional status and potential performance. Controlling body condition through the year is the key to high herd output at low cost.

Most beef suckler cows are kept on marginal land in upland or range areas where winter (or dry season) feeds are scarce. So it is common for calves to be sold at weaning, or after a period of further feeding, to finishers on better land. However, increasingly in UK upland herds where suitable buildings are available, male calves are finished as bull beef on purchased concentrates.

Planning the suckler herd

Fitting a suckler enterprise into farm resources is as important to profitable production as herd manage-

ment. Can the herd be integrated with a sheep flock? Are there arable crop residues that can be used to cheapen cow feeding? Are buildings and feeds available to add value to calves by feeding them beyond weaning? The answers to these and other relevant questions provide the framework on which a profitable enterprise can be built.

Particularly important is the choice of season of calving. Most herds calve in the spring or at the start of the rainy season because this minimizes cow feeding costs. The cow is working hardest suckling her calf on low cost, high quality grazed forage. On productive grassland autumn calving is an option, the extra cost of winter feeding cows suckling calves being offset by greater calf weaning weight. Autumn calving usually achieves the highest financial gross margin per cow, but spring calving rivals its gross margin per hectare. The need to reduce production costs has forced many former autumn-calving herds to change to spring calving.

The decision on calving season may be forced by the availability of housing and labour, regardless of feed availability. Housing allows a choice of calving season and avoids poaching of land by outwintered stock. However, the provision of housing increases fixed costs on the farm.

Choice of bull

The bull contributes half the genes of all the calves sired by him and so choice of breed and individual bull are both critical to herd performance. Even at weaning, when maternal effects are expressed at their maximum, sire breed has a greater effect on weaning weight than dam type.

Heavy breeds such as Charolais and Simmental are generally used as terminal sires, that is to produce the slaughter generation. They sire calves with the highest weaning weights (Table 2.1) and the rapid gains are carried through into the post-weaning period. However, the cost of this extra growth performance is a higher proportion of assisted calvings and greater neonatal calf mortality (Table 2.2). Overall, nevertheless, calves sired

by heavier breeds produce the greatest annual output of weaning weight per cow.

It is several years since these survey data were collected and there may have been subsequent changes in the relative performance of breeds. Also, breeds such as the double-muscled Belgian Blue are now available to commercial producers in the UK. This breed is just below the Charolais in growth performance but has greater dystokia. Belgian Blue crosses have exceptional carcass characteristics with high killing out and meat yield percentages. Limousin crosses are also outstanding for these characteristics.

Most commercial suckler herds in Britain have opted for continental terminal sire breeds, especially Charolais, Limousin and Simmental. However, some producers prefer local breeds or use Angus bulls to gain quality premiums that offset poorer growth performance. Easy care Angus and Herefords are often selected in pastoral and range countries where large numbers of cattle are managed by a single stockworker. Breed choice would

also be affected if herd replacements are home bred. Then easy calving breeds with good maternal abilities would be preferred (see p. 9).

The selection of an individual bull within a breed is just as important as breed choice. In recent years bull selection has been transformed by the development of a sophisticated statistical method of analysing breeding records from pedigree herds, known by its acronym BLUP (best linear unbiased predictor). The analysis of records from all related cattle, whatever herd they are in, effectively disentangles management and genetic effects on performance to calculate estimated breeding values (EBVs) that can be used with confidence to select bulls of above average genetic merit.

In Britain the recording agency Signet combines EBVs for selected performance characters into selection indices of overall genetic merit. There are two such indices. The calving value is used where ease of calving is paramount, for example for heifer matings and in the selection of bulls to breed female replacements. The beef index is used for bull selection when growth rate and carcass quality are the objectives, for example for terminal sires in suckler herds. Signet publishes EBVs and selection indices for participating breeds. A maternal index is under development.

Choice of cow breed type

In range countries the tradition was to keep purebred herds of Angus, Hereford, Shorthorn or local breed cattle. To some extent that tradition still exists. For example, French suckler cows are still largely purebred. However, crossbred cows have a considerable advantage over purebreds due to hybrid vigour (or heterosis), which is most pronounced for improved reproductive efficiency. The outcome is that the weaning weight of calves from crossbred cows is 15–25 per cent above the average of the parent breeds. Add to this an

Table 2.1 Effects of sire breed on calf 200-day weights. Source: Meat and Livestock Commission (MLC).

| Sire breed | Type of farm | | |

| Hereford | 4.0 | 1.6 | 372 | 189 |
| Aberdeen Angus | 2.4 | 1.3 | 370 | 179 |

improvement in longevity and the lifetime advantage to crossbreds is considerable.

Recognition of the benefits of crossbreeding in Britain is as old as the development of breeds themselves. Traditional crossbreds include the celebrated Blue Grey (White Shorthorn bull × Galloway cow), Shorthorn × Highland and Irish-bred Blue Grey (Angus × Dairy Shorthorn). As supplies of these traditional crosses started to become scarce some 30 years ago, beef breed × dairy cows started to be used as suckler cows, notably Hereford × Friesian and Angus × Friesian. It was later still that US ranchers discovered the heterosis advantage of Hereford × Angus and the reciprocal cross over either of the pure breeds.

The Hereford × Friesian was, and still is, widely used as a suckler cow. It produces more milk than the Blue Grey and weans a heavier calf; however, the Blue Grey has better reproductive efficiency and, overall, performance of the two crosses is similar. Both crosses share the advantage of medium body size. Heavy cows such as Charolais × Friesian need more feed but are unable to translate enough of their greater weight into heavier calf weaning weight to rival the efficiency of a lighter breed type. Nonetheless, many British suckled calf producers use these heavier cows and are prepared to trade a theoretical reduction in efficiency (that may not be apparent at farm level) for the improved conformation of calves which commands a premium at the calf sales and later in carcass value.

The penetration of the Friesian breed by extreme dairy Holstein genes from North America has caused such a deterioration in beef breed × Friesian cow conformation that it shows through in the calf. This has sparked off a search for alternative suckler herd replacements that are crossbred with good maternal qualities and have acceptable conformation. Moreover, in the wake of the BSE crisis many herd owners wish to breed their own replacements so that they can maintain a closed cow herd.

Merely saving heifer calves from terminal sire breeds such as Charolais increases cow size progressively and reduces maternal performance – the worst of all worlds. The simplest planned approach to breeding replacements is to breed about half the herd to a sire breed of medium size with good maternal qualities, for example Angus or Salers. In smaller herds this is best done by artificial insemination (AI). In the next generation, Angus cross females, for example, might be mated to Salers whose female progeny are in turn mated back to Angus. This two-breed rotation is known as criss-crossing. The other half of the herd would usually be mated to terminal sire breeds.

Bulls for breeding herd replacements should be selected to have a good calving value index (which incorporates EBVs for calf birth weight, ease of calving

score and gestation length) and a high EBV for 200-day milk (an estimate of the genetic merit for milk production that the sire passes to his female offspring).

In some parts of the world, notably the US, sophisticated breeding programmes have been used to create composite breeds combining the best features of three or four foundation breeds. A composite may be bred to feature maternal qualities, terminal sire qualities, heat tolerance and so on. A four-breed composite is effectively a purpose-bred pure breeding population that retains up to 75 per cent of the hybrid vigour of the initial first (F1) crosses between the original four breeds.

The creation of composite breeds needs very large numbers of cattle. However, commercial suckled calf producers with relatively small herds will have access to composites from international genetics companies with large-scale breeding operations involving thousands of cattle. The main demand will be for purpose-bred suckler herd replacements of good maternal ability.

Rearing replacement heifers

The replacement policy in a suckler herd should involve culling cows that are persistently barren, calve unacceptably late or are on the verge of the emaciation commonly associated with old age. A typical replacement rate is 16 per cent which indicates an average herd life of seven years.

In the UK, culling policies have been disrupted in the wake of the BSE crisis by the Over Thirty Month Scheme (OTMS) in which the carcasses of cattle over 30 months old are removed from human consumption. Compensation payments for culls are much lower than cull cow values before the BSE crisis and this will continue to inhibit planned culling until the scheme is eventually wound down.

Replacements may be purchased as calves from dairy herds, as bulling heifers or, less frequently nowadays, as heifers on the point of calving. With calves and bulling heifers it is prudent to purchase a surplus of 15–20 per cent to allow selection. Heifers that prove unsuitable as replacements are slaughtered for beef.

In most situations heifers should be calved for the first time at two years of age to optimise lifetime performance. However, autumn-born calves from the dairy herd would usually be calved at 2½ years in a spring-calving suckler herd. In either case, good management is necessary to achieve target mating and post calving weights (Table 2.3).

Heifers are best calved at the start of the herd calving period to allow for an almost inevitable slippage in time to the second calving. Also, since dystokia is worst in

Table 2.3 Rearing targets for replacement heifers.

| | Mating weight (kg) | Post calving weight (kg) |
|---------------------------|--------------------|--------------------------|
| Two-year calving | | |
| British breed crosses | 325 | 510 |
| Continental breed crosses | 350 | 550 |
| Calving at 2½ years | | |
| British breed crosses | 400 | 540 |
| Continental breed crosses | 435 | 575 |

heifers, it is desirable to mate them to an easy calving breed such as Angus or Hereford. Difficult calving is a cause of delayed rebreeding.

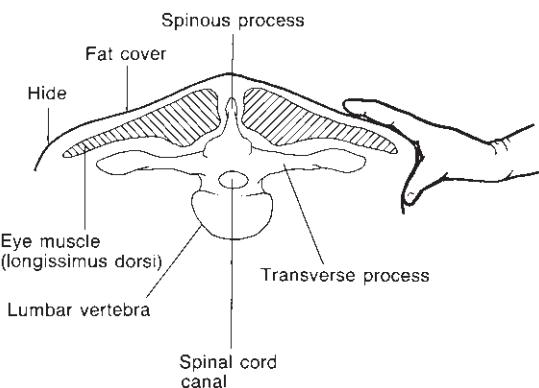

Suckler herd management

Suckler herd management aims for a high proportion of cows producing live calves in a calving period of 12 weeks or less. The advantages of a compact calving period are, firstly, that herd rationing matches closely the nutritional needs of individual cows, saving feed costs. Secondly, calvings can be supervised closely to provide assistance when needed, reducing calf mortality. Finally, calf performance is uniform with few of the late-born calves that are so difficult to utilize profitably.

Generally, a long drawn out calving period is a sure sign of low herd conception rate. Late calvers have too little time to rebreed by the end of the mating season and get later and later, eventually failing to get in calf altogether. The only solutions to an over-long calving period are to cull late calvers or switch them between spring- and autumn-calving herds so that they calve on time. The danger of the latter strategy is that cows shuttle from one herd to the other without the underlying causes of low conception rate being tackled.

The main reason why cows fail to conceive is that they are too thin. Under UK conditions, body condition at mating, scored on a scale from 0 (emaciated) to 5 (grossly overfat), needs to be 2½ in winter but can be as low as 2 if cows are grazing high quality forage and current nutrient intake is high. The key targets that achieve the necessary body condition at mating are a score of 3 in the autumn and 2 at turnout to grazing in the spring. The time to carry out condition scoring is in mid pregnancy, while there is still time to adjust feeding management before calving.

The method of condition scoring (Fig. 2.1) is to grip the loin between the thumb and forefinger mid-way between the hip (hook) bone and the last rib on the left

**Fig. 2.1** Technique for condition scoring.

side of the cow. The thumb curls over the ledge formed by the transverse processes of the spine to feel the overlying fat cover. It is best to handle cows until experience of the technique has been gained but, thereafter, a skilled stockworker can use close visual inspection to obtain a working guide to condition.

Descriptions of condition score classes are presented in Table 2.4. One possible confusion is with continental crosses of good conformation. Their thick muscling may overhang the transverse processes of the spine and confuse handling or visual assessments. If this is the case, condition should also be assessed by handling the ribs with the flat of the hand. If the score is above 3 in the autumn, autumn-calving cows are put at the risk of a difficult calving. If spring calvers score less than 3 in the autumn, the permissible winter weight loss is reduced and feed costs increase.

Feeding spring-calving cows through the winter that are at target condition score 3 in the autumn allows the loss of one unit of condition score, which equates to about 100kg liveweight or 0.5kg daily. Autumn calvers, on the other hand, must be fed through the winter for the additional strain of lactation and must be at condition score 2½ when mated in mid-winter. Therefore, in cows at condition score 3 in the autumn a weight loss of only 0.25kg/day is permissible until they are safely in calf. If there is a time to feed suckler cows generously, this is it. Thereafter, the rate of weight loss can increase to 0.5kg/day. Autumn-calved heifers are still growing as well as milking and should not be allowed to lose weight through the winter.

These guidelines are translated into daily metabolizable energy (ME) allowances expressed as megajoules (MJ) for cows fed a typical moderate quality ration in Table 2.5.

It is all too easy during the grazing season to concentrate on calf performance and forget that cows at target condition score 2 in the spring need to gain

Table 2.4 Condition scoring of suckler cows.

| Condition score | Description |
|-----------------|---|
| 0 | Spine very prominent with no detectable fat cover over the sharp transverse processes of the spine |
| 1 | Spine still prominent but transverse processes no longer sharp |
| 2 | Transverse processes can still be felt, but now rounded with a thin covering of fat |
| 3 | Individual transverse processes can now only be felt with firm pressure by the thumb |
| 4 | Transverse processes can hardly be felt, even with firm pressure |
| 5 | Transverse processes completely obscured with a thick layer of soft fat and puffy fat deposits around the tail head |

100 kg liveweight by the autumn. If by mid-season there is any doubt that the whole herd or individual cows may not attain the required total gain, action must be taken to rectify the situation. The provision of more selective grazing of fresh pasture may suffice. Alternatively, it may be necessary to take more drastic action with autumn calvers and wean calves early to remove the strain of lactation.

Suckled calf management

If cow performance is good, calf performance is usually also good. This is not to say that calf performance looks

after itself. Nevertheless, a compact calving means fewer of the late-born calves have subnormal weaning weights. In addition, achieving target body condition scores in cows is conducive to high milk yield.

In most situations the cow is capable of producing as much milk as the calf can suckle. This can lead to problems early in the suckling period, especially with spring-calving beef × dairy cows of high milk potential, when calves consume too much milk and scour. If the cause of scouring is viral or bacterial it is worth considering an appropriate scour vaccine.

Milk consumption increases quickly during the first month of suckling and, although calves pick at solid food early in life, milk intake dominates calf performance in the first three months. With a cow type of moderate yield potential, milk still accounts for half the calf gain in the third month and in higher yielding beef breed × Friesians this balance is not reached until the fourth month. Nevertheless, by this time the intake of solid food by the calf is increasing rapidly.

Milk intake is especially important to the spring-born calf that has a relatively short suckling period of six to seven months. The nutritional requirements of the calf and seasonal grass growth are well matched, although supplementary feeding helps to sustain daily gain from late summer onwards as grass growth and quality decline.

Management of the autumn-born calf is more complicated because the suckling period is longer and peak milk yield must be supported on winter rations. The most cost-effective approach over the winter is to feed the cow well in the early months until she is safely in calf and then to rely increasingly on creep feeding calves concentrates and the highest quality conserved forage available. It is energetically much more efficient to feed the calf directly than to increase cow feeding to stimulate milk yield.

When autumn-calved cows are turned out to grass in the spring there is a boost to milk yield, but by late summer calves require creep feeding to sustain daily gains. It is wise to wean the calves sooner rather than

^a Mated to suckler cows of average weight 550–600 kg.

later so that they can be managed separately and the cows left to gain condition before housing. The least stressful way of breaking the bond between calf and dam at weaning is to house the calves. An alternative approach is to put the cows and calves in well-fenced adjacent fields within sight and sound of each other.

In most ranching and pastoral countries bull calves are castrated for the convenience of herd management and a preference for steer beef over bull beef. However, in France, Italy and Spain it has become the custom to rear male calves entire because they grow faster and leaner than steers and are more profitable. In the UK, suckler bull beef is increasing and finds a ready market. The most common approach is to wean spring-born bulls in late summer and transfer them gradually over a period of about three weeks to an all-concentrate diet (Chapter 3).

For the system to be successful it is a considerable advantage to have a compact calving period so that older bull calves do not pester late-calving cows when they are in oestrus. In any case, cows with bull calves need to be separated from those with heifers by six months of age or there is a risk of premature pregnancy in the heifer calves. For this reason the system works best in spring-calving herds because there is no need to split the herd.

Grassland management

Grazed grass is the cheapest and one of the most nutritious feeds available on the farm. With financial margins under pressure, the key to profitable production is to utilize grazing to the full. This involves good grazing management and extending the grazing season where practicable.

Grassland management for suckler herds does not necessarily mean using the levels of nitrogen fertilizer employed by dairy farmers, although this may be the right policy on some productive lowland farms. In practice, especially on the upland farms where most suckler cows are kept in the UK, farmers use only moderate levels of nitrogen fertilizer and rely more on clover to increase sward productivity. Moreover, extensive grassland management is encouraged in the EU by the payment of extensification premiums for stocking lightly.

Whatever the type of sward, grazing management should aim to control the average sward height of grazed and ungrazed areas. Cows gain most weight early in the grazing season when average sward height is maintained at 8–10 cm. However, they graze selectively leaving patches that go to seed and are of poor nutritional quality when they have to be grazed later on. So until mid season it is necessary to graze swards more tightly at an average sward height of 6–8 cm to inhibit seed heading. Thereafter, when the risk of seed heading is less and there is an inevitable build-up of dead herbage in the base of the sward, average sward height can be relaxed to 8–10 cm to allow selective grazing.

In the period of peak grass growth in early summer, high stocking rates of three autumn calving cows per hectare or four spring calvers are needed to exert the necessary control of sward height. At these relatively high stocking rates it is important to have a reserve grazing buffer in case of reduced grass growth in dry weather. This can be achieved by setting aside an additional 25 per cent of grassland that is conserved as silage if possible, but grazed if necessary.

As the season progresses beyond mid season the grazing area needs to increase and this is achieved by grazing aftermaths on fields cut previously for silage or hay.

Parasitic worms causing gastroenteritis and bronchitis are less of a problem in suckled calves than in young dairy-bred calves in their first grazing season. Nevertheless, it is advisable to treat autumn-born calves at weaning. In any case, both autumn- and spring-born calves should be treated at yarding to guard against winter scour (Chapter 19).

With silage making the priority is a feed with high intake characteristics rather than the highest possible ME per kg dry matter (DM). Cutting can be delayed for a week or so to await dry sunny weather that allows an effective 24-hour wilt for clamp silage, longer for big bales, and produces silage with the best fermentation quality.

Targets of performance

The objectives of suckler herd management outlined in this chapter have been compiled into suckler herd

targets appropriate to lowland and upland herds in the UK and other European countries with similar climatic conditions (Table 2.6). For the predominant spring-calving herds targets are shown for herds both on grass farms, where silage is the basic winter feed, and on arable farms, where winter diets are based on straw and concentrates. Achieving the physical targets is a prerequisite of profitable production.

Introduction

A whole range of overlapping beef finishing systems is applicable to cattle bred in suckler and dairy herds. The higher the lifetime daily gain of the beef system, the younger is the slaughter age and the lighter the slaughter weight at a stated carcass fat cover. Also, within a given beef system, bulls grow faster and are leaner than steers which, in turn, grow faster and are leaner than heifers.

These characteristics of beef systems make it possible to chart average relationships between slaughter age and slaughter weight, illustrated in Fig. 3.1 for Charolais crosses. It is possible to construct similar graphs for other breed types and to predict the likely slaughter weight of cattle slaughtered at a particular age and vice versa. Note that as long as the Over Thirty Month Scheme (OTMS) is in place as a BSE control measure in the UK, beef from cattle over 30 months old at slaughter is destroyed, although this will change from 2004 onwards.

Cattle remain in an EU fat class for several weeks. The main EU fat class for bull carcasses is 3 on a five-point scale from 1 (ultra lean) to 5 (grossly overfat) and 4L for steers and heifers, which is the average fat class for all carcasses in Britain.

Calves from beef suckler herds on marginal land usually have to be sold in the autumn for finishing on farms with more productive land. However, spring-born calves may be overwintered for sale in spring, if buildings and feed are available, and bull calves may be finished on purchased concentrates as suckler bull beef.

The heaviest yearling steer calves purchased by fin-

ishers in the autumn may be finished through the ensuing winter for sale at 16–18 months old. Heifers and lighter steer calves are fed a store ration over the winter in preparation for grazing the following summer. Any that fail to finish off grass are yarded for a further winter finishing period.

Still, all too many cattle are managed aimlessly with no particular finishing system in mind and are sold finished or in store condition when prices seem favourable. This approach leads to a good deal of trading in suckled calves and stores, some of which may change ownership three or four times in their lifetime. Farm assurance schemes now limit the number of times an animal can be traded within the scheme.

Under range conditions in the USA, the growth rate of suckled calves is poorer than on European grass farms. However, feed grains are cheap and a special approach to finishing has been adopted in beef feed lots. Weaned calves from range herds are sold to 'back grounding' farms where they are grown on forage at moderate store rates of gain as feeder cattle. They then enter feed lots at 12–18 months of age for rapid finishing over a five-month period on a 'hot' high-grain ration.

In the case of dairy-bred calves, several distinctive beef systems have been developed. At one extreme is cereal (barley) beef in which bulls fed an all-concentrate diet grow rapidly to slaughter at 11–13 months of age. At the other extreme are forage-based systems in which steers and heifers are either winter finished off silage supplemented with concentrates for slaughter at 16–20 months of age or grass finished in summer at 20–24 months old.

In reality, cattle passport statistics indicate that more than a third of steers do not follow any of the production systems described here and are slaughtered at 24–30 months of age. The reason is thought to be that farmers delay slaughter until after they have obtained the second beef subsidy (p. 15), paid from 22 months of age. It demonstrates how subsidy rules manipulate production and marketing decisions.

Planning and budgeting

The fall in market prices for beef cattle in the aftermath of the BSE crisis has focused attention on beef system

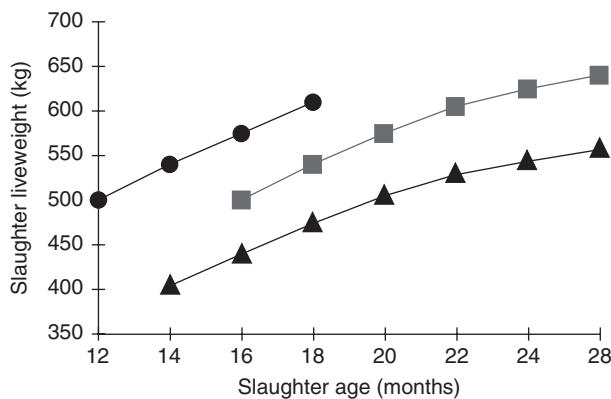

Fig. 3.1 Average relationships between slaughter age and slaughter weight for Charolais cross cattle. (Bulls were slaughtered at EU fat class 3, steers and heifers at EU fat class 4L.)
● = Bulls; ■ = steers; ▲ = heifers.

plans and budgets. Formerly, too many beef farmers were preoccupied by the margin between buying and selling prices, or even just the sale price achieved regardless of cost. Now controlling costs, whilst achieving performance targets, is very important. Also essential is maximizing eligibility for EU subsidies, without which profitable production is difficult.

The EU beef regime that came into effect in January 2000 is more complex than previous schemes. As before, bulls may qualify for a single Bull Premium and steers for one or both Beef Special Premiums (BSP), the first of which is paid at 9–20 months of age and the second at over 22 months. There is no upper limit on the number of claims provided the stocking rate does not exceed 1.8 Livestock Units (LU) per forage hectare, otherwise claims are scaled back. If a national ceiling of claims is exceeded, payments are also scaled back. Cattle must be retained for at least 2 months after the claim is made. All slaughter cattle, including cull cows, qualify for a slaughter premium provided they have been on the farm for at least two months. Suckler Cow Premiums are paid up to a farm quota and a minimum of 5 per cent and maximum of 40 per cent of claims can be made on heifers over 8 months of age. Complex rules apply to Extensification Premiums paid on farms practising extensive production methods. Detailed rules and rates of payment can be found in official publications. In 2003 discussions were in progress to alter fundamentally the basis of subsidy payments with headage subsidies replaced by area payments.

The starting point for planning is a decision on which beef system fits farm resources best, setting performance targets and drawing up a budget to evaluate margin potential. Figure 3.2 presents a budget format that can be used to evaluate finishing systems and shows as an example cereal bull beef from purebred Holstein–Friesian bulls.

If production is based on borrowed capital, it is important to calculate the interest on working capital that must be paid. The conventional method of calculation is the cost of the calf or store plus half the variable costs multiplied by the monthly bank interest rate for the number of months cattle are fed.

Sale returns are highly dependent on the quality of cattle produced, especially their conformation. Figure 3.3 illustrates differentials for steer carcasses classified by the EU method, in a conformation range from E (excellent), U+, –U, R (average), O+, –O and P (very poor). Note the severe discount for poor –O conformation, especially for carcasses that stray into what is regarded by most buyers as overfat class 4H. Holstein–Friesian carcasses fall into the poorest conformation classes –O and P and a high proportion of the beef is used for manufacturing. Good conformation classes –U and better contain mainly continental breed crosses.

Generally, young bulls sell for the same price per kg carcass or slightly less than steers in deadweight sales, but command a premium at selected live auction markets. Heifers usually sell at a small discount. There is a steady move towards deadweight selling under pressure from supermarket buying specifications.

Finishing suckled calves and stores

At the start of a winter feeding period there are two options for steers and heifers. Either the cattle are fed to gain at least 0.9 kg/day, often higher, for finishing that winter. Or they are fed a store ration to gain 0.6–0.8 kg/day in preparation for grazing the following summer.

It is generally held that the profitability of finishing depends mainly on buying and selling skills. It is perfectly true that the feeder's margin – the difference between the purchase and sale price – determines the average gross margin. However, finishers with the best margins owe much of their success to achieving high standards of cattle performance.

Winter finishing

Winter finishing has a feeding period of four to eight months, depending on breed, sex category and individual performance. At the start of the winter the cattle may be yearling suckled calves or older store cattle. Commonly, they are fed rationed concentrates with silage to appetite, but on arable farms arable byproducts may partly or wholly replace grass silage.

Steers of all breed types are well suited to winter finishing. Early maturing heifers are less suitable because they finish too quickly at light weights. Nevertheless, continental cross heifers can be winter finished at around 0.9 kg/day on a high forage diet.

| | Budget (£/head) | Example: cereal beef ^a (£/head @ 2003 prices) |

Fig. 3.2 Budget format for beef finishing systems.

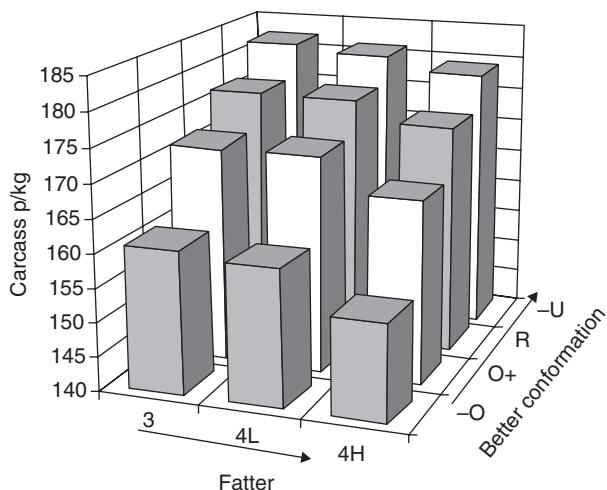

Fig. 3.3 Price differentials for steer carcasses of different EU conformation and fat classes. Source: Meat and Livestock Commission price report 1999.

Standards for winter finishing suckled calves and stores are shown in Table 3.1. Continental cross steers slaughtered at two years old or more may be too heavy for some buyers.

Suckler bull beef is still relatively new to the UK, but has been commonplace in France for many years. Production is expanding in the UK but demand is limited and it is important to secure a market before commencing production. The system is simplest for spring-born calves which are weaned in the autumn and transferred gradually over about three weeks to an all-concentrate diet containing 16 per cent crude protein. However, autumn-born calves weaned in the spring can also be used. The British safety code for bull beef production recommends no more than 20 bulls to a pen but much larger groups are housed in continental Europe.

Maize silage is short of protein but has good feed intake characteristics and is an excellent source of energy. In continental Europe maize silage is widely

used as the forage base for intensive bull beef production. The medium-sized feed lots of the Po valley in northern Italy with a few hundred to a few thousand cattle are a good example. In these maize silage comprises 30–50 per cent of ration DM.

Maize silage has not been used much for bull beef production in Britain but there is potential for systems in which maize silage forms up to 30 per cent of the dry matter of the diet, producing daily gains not far short of all-concentrate diets. Where suckled calf producers on marginal land have suitable buildings available, bull beef fed purchased concentrates can be a useful way of adding value to herd output.

Standards for suckler bull beef are shown in Table 3.2. Achieving the target daily gains is a prerequisite of profitable production. In practice many producers extend the feeding period and take bulls to slaughter weights in excess of 600 kg. At these high slaughter weights there is a danger of feed cost exceeding the

value of daily gain and carcasses being too heavy for buyers.

Grass finishing

Grazed grass is the cheapest and potentially the highest quality home grown feed. There is a growing realization of the need to exploit grass better by managing swards to maximize daily gains and, where practicable, to extend the grazing season.

In grass finishing systems, achieving high daily gains is especially important so that marketing begins in mid-season and reduces cattle numbers in step with declining grass production and quality.

Two aspects of management are crucial. Firstly, in the winter preceding grass finishing, gains are held down at a store level so that cattle exhibit rapid compensatory growth when they are turned out onto spring grass. Secondly, grazing should be managed to get the best

Table 3.3 Specimen winter store rations.

| 400 | 28 | 5.0 + 4.0 | 23 + 2 | 5.0 + 4.5 |

combination of daily gains in cattle and regrowth of high quality grass.

Grass finishing may commence with stores purchased in the spring or with suckled calves or stores purchased in the autumn that are overwintered before grass finishing. Specimen low cost rations for overwintering cattle are shown in Table 3.3. The lower gain of 0.6kg/day is optimum for British cross steers and heifers of all breed types. The higher gain of 0.8kg/day is suitable for continental cross steers.

During the grazing season on set stocked pastures, the provision of a continuous supply of nutritious grass is achieved by controlling sward height (the average of grazed and ungrazed grass). In the first half of the season sward height is controlled at 6–8cm to inhibit seed heading. Then in the second half of the season, when there is less risk of seed heading and dead herbage begins to accumulate in the base of the sward, grazing height is relaxed to 8–10cm to allow more selective grazing.

The confidence to manage cattle at the high early summer stocking rates needed to achieve this degree of control is helped by adding 25 per cent to the main grazing area as a buffer that can be grazed if grass runs short but is conserved if not needed. From mid-season grazing needs to expand onto aftermath regrowths on areas previously cut for silage or hay.

Grazing performance is undermined if cattle, especially those in their first season of independent grazing, become infected with parasitic worms that cause gastro-enteritis and bronchitis. Effective control programmes include early season treatment to inhibit the build-up of infective larvae on the sward, mid-season treatment accompanied by a move to fresh aftermaths on fields previously conserved or mid-season treatment with a long-acting bolus to control infection even though pastures carry infective larvae. The choice depends on farm circumstances (Chapter 19).

Standards for an overwintering and grass finishing system are presented in Table 3.4. Because the second

BSP is paid from 22 months of age, steers that are close to this age at the end of the grazing season are often yarded for winter finishing just to claim the subsidy. It is a strategy that needs to be costed carefully.

Dairy beef systems

In the UK the main dairy herd calving season is in late summer and autumn, which contrasts with many other countries where cows calve in the spring. It reflects the high proportion of milk produced used for year-round liquid consumption.

Intensive indoor dairy beef systems can utilize calves born at any time of year. However, grass-based systems work best utilizing calves from the main calving season. At turn-out in the spring these calves are old enough to make effective use of grazed grass.

Cereal (barley) beef

Cereal beef is a housed bull beef system feeding an all-concentrate diet to slaughter at 11–13 months of age. Carcasses have a creamy white fat which is popular with some supermarkets and independent butchers. However, it is advisable to secure market outlets before commencing production, especially if poor conformation Holstein–Friesians are reared. The system is at its most profitable when it adds value to home-grown grain or home-bred calves.

Profitable production is heavily dependent on achieving high target daily gains. The protein content of the diet is reduced progressively from 18 per cent crude protein in the calf ration to 14 per cent in the final finishing ration. From six months of age part of the protein can be supplied by urea. Rumen enhancers such as monensin sodium improve feed conversion efficiency by about 10 per cent, but their continued use in the EU is controversial.

Standards for cereal beef are shown in Table 3.5.

Grass and maize silage beef

Grass silage bull beef was popular in the 1980s as a beef system that made very intensive use of grass, all of which was made into silage. Its flaw was that it was a system designed for its production capabilities rather than market demand. In the original system bulls were 16–18 months old at slaughter, by which time the carcasses were too heavy for many buyers and the fat was coloured by carotene. There are also question marks over the eating quality of beef from bulls over 14 months of age.

There is still a place for grass silage bull beef up to 14 months of age and the standards in Table 3.6 are for slaughter at this age. The system could also be used for steers and heifers but, for reasons that have been enumerated already, grass-based systems now place emphasis on the utilization of grazed grass.

The section on winter finishing (see p. 15) has already discussed the potential for maize silage in beef production. With up to 30 per cent of the ration DM as maize

silage there is little decline in daily gain from cereal beef levels. Experience of the system is limited and so the bull beef system presented in Table 3.7 is somewhat speculative. It is based on 25 per cent of the ration DM as maize silage supplemented with a protein concentrate and cereal. Profitable production is heavily dependent on a high yield of good quality maize silage and achieving target daily gains. Continental × Friesian heifers may be suitable for maize silage beef fed to gain about 1.0kg/day and slaughtered at 435–450kg liveweight.

Eighteen-month beef

Eighteen-month beef is a grass-based system that utilizes dairy-bred steers born in the autumn. It is the original planned system of production in the UK. Calves are reared through their first winter, grazed from six to twelve months of age and then finished in their second winter on rationed concentrates with silage to appetite. Heifers may be used for eighteen-month beef, but are better suited to grass finishing.

Profitability depends heavily on achieving good grazing performance. In farm practice this has taken second priority to making a large tonnage of first-cut silage. This partly explains the poor financial margins achieved in recent years. In addition, the system has a relatively high concentrate requirement, a high silage requirement and, at best, steers only qualify for a single BSP payment.

The principles of good grazing management described for grass finishing (see p. 17) apply equally to eighteen-month beef. The cattle graze for the full season and so, from mid-season, there is a need to expand onto fresh aftermath grazing on areas previously cut for silage as the cattle grow heavier, but grass

production and quality decline. In addition, there is a strong case for supplementing calves with about 1kg concentrate daily for two or three weeks after turn-out in the spring until they become accustomed to grazing. Also, supplementation should be reintroduced in late summer to counter rapidly declining grass quality, starting at 1kg daily and building up to 2kg daily for a month before housing.

Standards for the system are shown in Table 3.8. The overall daily gain of 0.9kg for Limousin × Friesian steers is made up of 0.8kg/day through the rearing winter, 0.8kg/day during grazing and 1.1kg/day in the finishing winter. The finishing gain would be achieved at an average concentrate consumption of about 2.5kg cereal or concentrate with good quality grass silage to appetite. Limousin × Friesian heifers would be managed at an overall daily gain of 0.8kg/day to a slaughter weight of 450kg.

Grass beef

Grass beef is the most extensive of the planned dairy beef systems. Farmers see it as a low cost system that maximizes subsidy income. At best, steers qualify for both BSP payments, an extensification premium and the slaughter premium. Carcasses from continental cross steers may be too heavy for some buyers. Heifers are well suited to the system and can be more profitable than unsubsidized steers.

Good grazing gains are essential for profitable production. If first season gains are below target, winter store feeding costs are increased to catch up lost ground. Ideally, winter gains should be 0.5–0.6kg/day for heifers and early maturing Hereford × Friesian steers and 0.7–0.8kg/day for continental cross steers.

Table 3.8 Standards for steers in eighteen-month beef.

^a From 3 months of age.

In the second grazing season steers need to be marketed as soon as possible after they qualify for the second BSP to reduce stocking rate as the season progresses. Marketing of heifers should start in mid-season. This need to reduce stock numbers from mid-season in step with declining grass production favours early maturing types of cattle. So early maturing Hereford × Friesian steers fit the system better than late maturing Holstein–Friesians or Charolais × Friesians that may fail to finish off grass and have to be housed for a period of winter finishing. Similarly, early maturing heifers have advantages over later maturing steers. Nonetheless, all the breed types, steers and heifers can be utilized in the system provided their performance characteristics are understood and managed accordingly.

Grazing management is complicated by the fact that there are two age groups of cattle on the farm. A

complex leader–follower grazing system was developed in which the younger cattle graze selectively ahead of the older age group. Despite its merits, it is rarely adopted by farmers who prefer to keep the two age groups separate.

The principles of good grazing management described for grass finishing (see p. 17) are applicable to grass beef. As with eighteen-month beef there is a strong case for supplementing calves with about 1 kg concentrate daily for two or three weeks after turn-out in the spring and reintroducing supplementation in late summer to counter declining grass production and quality.

Standards for steers in the system are presented in Table 3.9. As an example of standards for heifers, Limousin × Friesians would have a lifetime gain of around 0.6 kg/day to slaughter at 20 months of age weighing 500 kg.

Structure in Europe and the world

Dairy farming in Europe and elsewhere is a very diverse industry and ranges from high-yielding cows in Israel, the USA and Canada as well as within European countries such as the Netherlands, Denmark and the UK to the small, low-yielding herds of Greece, Portugal, Spain and Italy. In many parts of the world milking

herds consist of a single cow, often with a calf at foot, or very small numbers of low-yielding cows. This occurs in many parts of Africa and Asia, and in Europe smallish herds are seen in countries such as Greece, Portugal, Spain and Italy. While there have been very gradual changes in the last half-century in Europe and the United Kingdom, the introduction of milk quotas in 1984 accelerated these. In the last decade since the first edition of *Bovine Medicine* was published the changes have been faster and at the start of the new twenty-first century they have become very rapid indeed. There are increasing trends towards a so-called 'global market' with a lowering of tariff barriers. If this continues this will mean that many areas where milk price is directly or indirectly subsidized will have to deal with lowered price for the product. Many areas with low labour costs and good weather to grow crops are starting to gear themselves up to the challenge of producing low cost milk for export to other parts of the world. This is at present particularly occurring in North and South America.

Over the past few years much thought has been invested by the World Trade Organization, among others, about increasing the flow of milk and dairy products across the globe. However, the dairy markets are some of the most protected of agricultural products and the Organization for Economic Co-operation and Development estimated in the late 1990s that member states producer support arrangements were, in absolute terms, higher than for all other commodities. It is this background which is causing international trade organizations to find ways to reduce export subsidies paid by countries and to alter tariff quotas for imported products.

The introduction of milk production quotas had a very profound effect on the European milk industry. Its aim was to reduce overall European milk production and the changes undertaken by producers to accommodate this altered many milk parameters. The structure in 1983 prior to the change is given in Table 4.1a and the present situation within the enlarged EU is shown in Table 4.1b. The position presented in Table 4.1a was reached over the previous 23 years by each country expanding its milk production through an expanded herd size and increased yield per cow. Total

cow population did not increase to the same extent as the number of dairy producers gradually declined. The reasons for this were due to both individual national policies and the then EC requirements.

The Common Agricultural Policy (CAP) set out to increase food production, maintain farm incomes and prevent rural depopulation. This encouraged the very small farms of much of Europe to survive and expand,

while for the larger producers, financial help made dairy farming relatively profitable compared with other sectors of agriculture. Thus total milk production for the 10 members of the EC at that time rose from 87.5 million tonnes in 1965 to 120.7 million tonnes in 1983. The success of the EU milk quota in controlling production is demonstrated by the fact that even in the expanded Union total milk production was 120.9 million tonnes in 1998.

While the CAP was proving very satisfactory for dairy farmers, the financial support they were receiving was increasingly threatening the whole EU budget. Most of this aid was provided through intervention buying of surplus products. In fact, sale into intervention became the accepted market rather than the market of last resort. Thus by 1983, self-sufficiency levels rose within the EC to 125 per cent for butterfat (BF) and 166 per cent for solids-not-fats (SNF) (Table 4.1a) and the cost of dairy support made up one quarter of the whole EC agricultural budget. Thus at this stage, milk quotas were imposed to control milk production and each member country had to take a cut of varying proportions (Table 4.2).

If national production exceeded the allocated quota then a super-levy was imposed. This super-levy was to be calculated either on a dairy basis or on an on-farm basis. On a dairy basis, if national production and the supplying dairy were over quota, then levy was imposed on the dairy and hence back to the individual over-

quota producers at a rate of 100 per cent of the target price for milk. On an on-farm basis, provided national production exceeded quota, each farm paid super-levy on excess production above its individual quota at a rate of 75 per cent of the target price for milk. In 1987–88 further changes to the means of determining super-levy liability were made so that those producers most over quota paid the highest proportion of the levy, again provided the national quota was exceeded.

Quota has been transferable between individual farmers within a member state, either on a sale (attached to land or without, but both are complex) or lease basis (a much simpler procedure) or else on an administratively based system where unused quota reverts to an authority and is re-allocated. Further regulation in 1987 imposed a butterfat ceiling on quotas, thereby giving a reduction in national quota if the average butterfat of 1985–86 was exceeded. Also in 1987 further quota cuts were announced, resulting in a further fall by 1989 of 8 per cent. The calculation of any liability for excess production for a farmer is extremely complex. It depends on the amount of milk over quota and on the average butterfat content of the milk. Each producer has a butterfat reference figure. If a levy is to be charged then the farmer's production volume will be adjusted up or down by the amount that the butterfat average differs from his/her reference figure. Again levies only arise when national production is too high.

The objective of reducing milk production has been achieved. Initially it was envisaged that milk quotas would be phased out in the early 2000s. However, this has not been the case and the CAP reform has extended milk quota until 2006. Special increases in quota were allocated to Italy, Spain, Greece, Ireland and Northern Ireland in 2000 and 2001 in addition to the increase of 1.5 per cent given to all countries in three stages from 2005. The intervention price will be gradually cut from 2005 and it is expected that the system will have been re-examined in detail by then.

Trends of structure in the United Kingdom

Changes to the structure in dairy farming in the United Kingdom have mirrored the trends over the last 25 years in Europe. Thus there are fewer producers and slightly fewer cows, but in larger herds and with a higher yield per cow (Table 4.3). This has been brought about by the virtual elimination of the small herd. In 1972, 20 per cent of cows were in herds of less than 30 cows, but by 1997 it was about 5 per cent. This acceleration has increased at the beginning of the new century as milk prices dropped, causing most farms either just to break even or to lose money. The foot and mouth disease outbreak of 2001 has caused more producers to cease milk

production, and present numbers of herds are likely to decrease sharply.

The December 2001 census showed UK dairy cows down to 2.203 million with in-calf heifers down to 0.442 million. While beef cows were down to 1.673 million, in-calf beef heifer numbers rose.

The changes to larger herds have been facilitated by new technology and mechanization and a consequent loss of labour. In 1972, 67 per cent of farms milked through a cowshed, with only 28 per cent in 1990.

Source: Milk Marketing Board, 1990; National Dairy Council, 2001.

Herringbone parlours accounted for only 11 per cent of milking installations in 1972, but made up over 45 per cent in 1990 (Fig. 4.1), and are the main system today.

The increased yields have been realized by improved feeding (see Chapter 9), breeding and management techniques. The breed of cow in the UK has altered, 64 per cent Friesian in 1965 moving to over 91 per cent Holstein–Friesian by 1990, which has also made a major contribution.

Milk purchase has also undergone some very fundamental changes in the last century. Initially farmers sold direct to dairy companies. However, as the latter became larger the individual farmer had problems in obtaining a fair price. This resulted in Agricultural Marketing Acts in 1931 and 1933, which set up a framework whereby all the milk produced was taken by the Milk Marketing Boards who then had to sell it on the producer's behalf. The Agricultural Act of 1993 allowed the abolition of the Milk Marketing Boards in Great Britain and from 1 November 1994 the Milk Marketing Scheme was revoked (Northern Ireland from 1 March 1995). In the deregulated market, producers are free to sell their milk wherever they choose including direct to dairy companies, or via intermediary organizations managed jointly by the dairy company and producers, or independent producer groups, usually co-operatives, who either then sell to the dairy companies or process the milk themselves. Many sold milk via Milk Marque, which was considered in 1999 to be a monopoly, resulting in its division into three new regionally based co-operatives, namely Axis, Milklink and Zenith, which

began to operate as fully independent businesses from 1 April 2000. There has since been more rationalization and mergers, with one group involved in milk purchase in Scotland, England and Wales becoming known as British Milk. Some milk purchasers now have their headquarters outside the UK.

The last few years have seen many milk purchasers buying milk from individual farmers or small groups or farmer clubs. In the early part of the twenty-first century the number of purchasers has been reducing and farmers are starting to combine in co-operatives to provide more negotiating power with the purchasers. Milk is now purchased in varying ways, but is usually paid for according to its composition, cell count and bacterial count (undertaken in the UK by a Bactoscan, see Chapter 25). There are also seasonality payments.

Milk utilization

While milk production has increased over the last 25 years, milk consumption has slightly reduced. The amount used as liquid milk has declined from 73 to 45 per cent. However, because of quotas this percentage has increased again (Table 4.4). Self-sufficiency in 1999 compared with 1996 in the UK was 74 per cent (68 per cent) for butter, 64 per cent (69 per cent) for cheese, 128 per cent (129 per cent) for condensed milk, 147 per cent (147 per cent) for cream and 187 per cent (112 per cent) for skim milk powder.

Prior to the EU, the UK was mainly concerned with supplying the liquid market, with Commonwealth countries supplying butter and cheese requirements.

Fig. 4.2 A modern butter-making creamery produces and packs 5 tonnes of butter an hour.

This changed with increasing amounts of milk being used for manufacturing. At one stage (Table 4.4) butter manufacture increased (Fig. 4.2) with much intervention producing the so-called ‘butter mountain’. With liquid milk sales realizing the highest return to the producer, the producers in England and Wales should be in a more favourable position than the rest of the EU, as shown in Table 4.5. The large quantities of other uses constitute mainly milk powder and milk fed to livestock, which is common practice in some countries.

Sources: various, including National Dairy Council (2001).

While this table relates to the 1980s, proportions are relatively similar today. The surplus situation in Europe was at one time exacerbated by much of the liquid milk consumed being skimmed milk, or semi-skimmed milk, allowing the release of milk for butter production. The last 20 years have also seen a similar trend in the UK, with about 20 per cent of liquid milk consumed as skim or semi-skim in the 1980s, 55 per cent in 1994 and 62 per cent in 1998. The further quota restrictions have taken this into account.

Dairy breeds

The principal dairy breeds of the United Kingdom are given in Table 4.6. These breeds or their local variations

are now becoming very similar in many other parts of the world. While every breed has its enthusiasts, the vast majority of herds are mainly Holstein–Friesian type (Fig. 4.3). These black and white cows are renowned for their high yields of average quality milk. As they become more extreme, the surplus males are of less use for beef. Recently the input costs have been examined by some farmers and there is a slight tendency for those who wish low input production to favour animals of a less extreme Holstein type. These animals are also often favoured by the organic milk producers. However, those aiming at the very high yielding herd are still pursuing a Holstein type of animal. The main drawback of such animals is that any surplus calves produced are of limited use in beef production. Such problems in the future may be overcome by the use of sexed semen and then possibly by the one of embryo transfer in those

Fig. 4.3 (a) A Friesian cow, (b) a Guernsey cow, (c) a Jersey cow, (d) an Ayrshire cow.

cows not required to produce dairy herd replacements. The increased interest in organic farming and sustainable agriculture is likely to be reflected in an increase in usage of Friesian-type animals, which are more adjusted to such production systems than the Holstein.

The Channel Island breeds, Guernseys and Jerseys, are still popular with a minority of breeders. They are docile cows producing lower yields of very high quality 'gold top' milk. This sells at a premium to the liquid milk or cream markets. The milk is now often sold homogenized. The breed does produce very efficiently on the basis of weight of milk constituents produced. The beefing qualities are low and the fat tends to be yellow, but the meat can be acceptable when crossed with one of the continental beef breeds such as Charolais, Limousin, Simmental or Belgian Blue. Dys-tokia problems in the Channel Island breeds are few because of a broad and pliable pelvis that allows delivery of viable live calves when crossed with the large beef breeds.

The Ayrshire is still regionally very popular in a few parts of its native Scotland. While its numbers have

decreased, the breed has currently been given a boost as its milk is being specifically retailed by some chain food stores. A smaller cow than the Friesian, it produces lower milk yields but of higher quality. It is a breed renowned for the dairy type and so is not very suitable for beef.

The Dairy Shorthorn has suffered from the demise of being the major breed pre World War II, now slipping to almost insignificance. With good beefing qualities, it tended to fall between two stools, with neither the milk quantity of the Friesian nor the quality of the Channel Island breeds. Types of the breed are used in some countries. Its use may also increase on farms practising sustainable or organic agriculture.

The beefing characteristics of the dairy breeds are of importance in England and Wales as the majority of the beef produced originates from the dairy herd. Until March 1996, the origin of British beef was as in Fig. 4.4. The Over Thirty Month Scheme (OTMS), which prevented the sale of older animals for human consumption, plus the Calf Processing Aid Scheme (CPAS), which paid a premium for calves slaughtered before 20

days of age, payable from May 1996 until 31 July 1999, altered these proportions so that in the early twenty-first century the origins are as in Table 4.7. These are likely to alter with an increase in the amount of beef

derived from the dairy herd. Recent BSE problems in other parts of Europe are also altering the types of animal which are entering the meat industry for use both directly and in manufacturing. In Britain, should the OTMS be removed, it will cause another alteration in the constituents of beef which is consumed. At present, increased proportions of total beef production are being used for manufacturing and catering and so if human consumption of over thirty-month-old beef is again allowed, there should be a market for the product.

The Friesian breed has played an important part in beef production with most farmers producing sufficient of their cows pure to provide the heifer replacements for the dairy herd, with the remainder being bred to a beef bull to maximize calf returns. Figure 4.5 shows that, in most years, 60–70 per cent of inseminations have been to a dairy bull, with the remainder to beef breeds. These data cannot at present be updated, but the most numerous breeds of bull used for artificial insemination (AI) in 1986 are shown in Table 4.8. While the dairy inseminations follow the pattern of breed distribution,

with beef the continental breeds are replacing the traditional British beef breeds, especially the Hereford. The Belgian Blue is more widely used in the UK than shown in Table 4.8, but again recent figures are unobtainable. The Aberdeen Angus continues to enjoy some support because of the ease of calving, particularly when used on maiden heifers or small cows. It also has some marketing advantages in that Angus beef can demand a premium.

While there is an increasing amount of embryo transfer occurring and costs have reduced, it is still an uncommon procedure. However, the possible use of sexed semen does appear to offer considerable possibilities over the next few years. Its uptake will be very

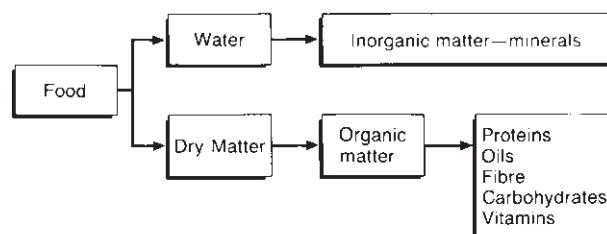

Fig. 4.6 Food components.

dependent on the price and the quality of the bulls offered.

Feeding dairy cows (see also Chapter 9)

A vital feature of dairy cow management is correct feeding. Food, either purchased or home produced, amounts to 60 per cent of the variable costs of production so the efficiency of feed use is extremely important. In the past, most high-energy feeds were purchased as concentrates from feed manufacturing companies. The onset of bigger herds, access to machinery to mix up feeds and the ability to buy feed constituents at competitive prices have meant that many dairy and beef farmers now produce their own rations, often feeding them as complete feeds or total mixed rations (TMR).

The main components of feed are shown in Fig. 4.6. All feeds contain water in varying amounts. Dry feeds such as cereals will only have about 14 per cent water, while other feeds such as mangels and other root crops will be up to 90 per cent water. While all cows require water it is the dry matter proportion of the total food that supplies the nutrients for maintenance and production. In general, the higher the dry matter of the overall diet, the higher will be the dry matter intake (DMI). Apart from the need for minerals and vitamins, the main aspects to consider in dairy cow feeding are DMI and energy and protein levels.

Dry matter intake

Dry matter intake (DMI) is affected by the liveweight of the cow, stage of lactation, milk yield, type of feed and frequency of feeding. As a guide for estimating DMI the following equation is used:

$$\text{DMI (kg/day)} = 0.025 \times \text{liveweight (kg)} + 0.1 \times \text{milk yield (kg/day)}$$

At calving DMI will be 2–3 kg/day lower than calculated, but it will then increase to peak at three to five

Table 4.9 Energy requirements of dairy cows.

| Breed | Liveweight (kg) | Maintenance (MJ/day) | Production (MJ/kg milk) | Liveweight gain (MJ/kg gain) | Pregnancy (MJ/day) |
|-----------|-----------------|----------------------|-------------------------|------------------------------|--------------------|
| Ayrshire | 500 | 54 | 5.3 | 34 | 23 |
| Friesian | 600 | 63 | 5.2 | 34 | 23 |
| Guernsey | 450 | 49 | 5.8 | 34 | 23 |
| Jersey | 350 | 40 | 5.9 | 34 | 23 |
| Shorthorn | 550 | 59 | 5.1 | 34 | 23 |

Table 4.10 Digestible crude protein requirements of dairy cows.

| Breed | Liveweight (kg) | Maintenance (g/day) | Production (g/kg milk) | Pregnancy (g/day) |
|-----------|-----------------|---------------------|------------------------|-------------------|
| Ayrshire | 500 | 300 | 60 | 150 |
| Friesian | 600 | 350 | 55 | 150 |
| Guernsey | 450 | 275 | 70 | 150 |
| Jersey | 350 | 225 | 70 | 150 |
| Shorthorn | 550 | 325 | 55 | 150 |

months after calving. After peak milk production, intake decreases slowly through lactation and is lower during the dry period. DMI can be increased by feeding highly or more digestible feeds such as maize silage. Thus cows will eat greater quantities of a 70 per cent digestibility (D) silage than one of 64 D. Also succulent feeds such as brewers' grains, kale and roots considerably enhance intakes in an otherwise dry diet of hay or silage with concentrates. When feeding large quantities of concentrates, splitting the feed into three or four feeds rather than the conventional two in the parlour will also increase intake and reduce rumen acidity. This is also why TMR can work well and again it will increase feed intake.

Energy (see Chapter 9)

The energy requirements of a dairy cow depend on her needs for maintenance, lactation, pregnancy and whether she is increasing or decreasing weight (Table 4.9). Energy in diets in Britain is measured as metabolizable energy (ME) and the units are megajoules (MJ) per kilogramme dry matter (DM). If dairy cows are in energy deficit then body fat will be mobilized, causing liveweight loss to make up for some or all of the deficit. This will contribute about 28MJ of ME per kg liveweight loss. Estimated energy requirements are shown in Table 4.9. Thus, for example, a 600kg Friesian cow producing 20kg/day of milk, in calf and gaining 0.5kg/day liveweight would require:

| | |
|-------------------------------------|-------------------|
| Maintenance | 63 MJ |
| Production (20×5.2) | 104 MJ |
| Liveweight gain (0.5×34) | 17 MJ |
| Pregnancy | 23 MJ |
| <i>Total energy required</i> | <i>207 MJ/day</i> |

Protein (see Chapter 9)

Protein is required for both maintenance and production. In contrast to the case for energy, body tissues cannot be used to make up a shortfall in protein and so milk yields will suffer if protein is in deficit, especially in early lactation. Protein is often measured as crude protein (CP) and is given as percentage of dry matter. In rations it used to be measured in grammes of digestible crude protein (DCP) per kilogram DM. Requirements for maintenance and production are shown in Table 4.10.

A refinement of the DCP system is the division of rumen degradable protein (RDP) and rumen undegradable protein (UDP). A dairy cow has a need for both types of protein. The system has been further refined into the metabolizable protein (MP) system. This looks at the rate at which protein becomes available within the rumen and is given as quickly degradable protein (QDP) and slowly degradable protein (SDP). These two (QDP + SDP) form what is known as the effective rumen degradable protein (ERDP). A cow has a need for both rumen degradable protein (both quick and slow) and rumen undegradable protein.

Different feeds contain different proportions or ratings of these. Thus silage is about 80 per cent degradable and soya is about 60 per cent degradable. Also, degradability does depend on the form of the feed, thus heating or formalin treatment reduces rumen degradability. The rate of passage out of the rumen also has an effect, with higher passage rates increasing the UDP.

In many instances, although the protein supplied may be sufficient in terms of its CP or DCP basis, it may still be deficient in either RDP or UDP. In early lactation on a predominantly grass silage diet, any shortfall is likely to be in UDP; this explains the observed good response when fishmeal or soya was added. Meat and bone meal are also a good source of UDP but were banned in Great Britain in 1988 for ruminants and in the rest of the EU finally in 2001. The EU also decided to ban the use of fishmeal in ruminant diets from 1 January 2001, resulting in the loss of a major practical source of UDP. However, it may return.

Feeding strategies

Many textbooks have been written on strategies for feeding dairy cows. The main principles are (i) to maximize DMI and (ii) to provide the cow's requirements as cheaply as possible. These two requirements are associated as the higher the DMI then the lower the energy concentration in the diet and hence the cheaper the production of the ration.

In early lactation of high-yielding cows, it will be difficult to satisfy their requirements within appetite. This will result in a loss of bodyweight, perhaps 0.5kg/day,

for the first 120 days of lactation. As yield declines and appetite increases then balance should be reached and then any liveweight loss in early lactation can be replaced in mid to late lactation (see Fig. 4.7 and Chapter 9). As will be discussed later, a compromise has to be achieved between biological efficiency and economic efficiency.

Very approximately, the most common feeds for dairy cows (grazing grass, grass silage and concentrates) have a relative cost of 1:2:3. Therefore, greater profits will be shown as the proportion of grass and silage in the total diet increases provided performance does not suffer (see Fig. 4.8).

While flat rate feeding of concentrates is popular, particularly with total mixed rations (TMR), most farmers feed at least partly to yield. In most instances

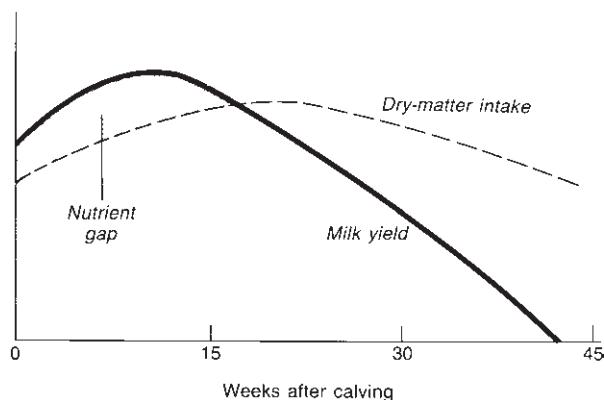

Fig. 4.7 Nutrient gap.

Fig. 4.8 Feeding silage at a barrier.

Table 4.11 Examples of possible cow diets.

| | Stage of lactation | | |
|--------------------------|--------------------|-----|------|
| | Early | Mid | Late |
| Concentrates (kg DM/day) | 8 | 6 | 2 |
| Silage (kg DM/day) | 8 | 12 | 12 |
| Total DMI (kg/day) | 16 | 18 | 14 |
| Energy supplied (MJ/day) | 180 | 195 | 145 |
| Energy required (MJ/day) | 195 | 186 | 133 |

this is important as dairy cows are not similar enough in their genetic make-up to allow feeding as if a single animal. It also cannot work unless cows are all at the same stage of lactation rather than calving over widespread periods or all the year round. Thus most farmers do to a certain extent 'feed to yield' or requirements, whereby concentrates are allocated on an individual basis depending on the yield attained and/or condition loss. In consequence, more concentrates are fed early on in lactation and are reduced as lactation progresses. Appetite is dependent on DMI so as concentrate consumption increases, forage intake reduces. This has the effect of limiting forage intake in early lactation as concentrates are normally eaten in preference to forages. Table 4.11 shows the effect of this on the cow's diet. For correct digestion the dry matter ratio between concentrates and forage should be in the range 70:30 to 30:70 in early to mid lactation. Any lower and performance will suffer, any higher and digestion will suffer (see pages 829–32).

Minerals and vitamins

The daily requirements for these must be adequately met if the dairy cow is to remain healthy and produce effectively. The major essential elements are calcium, phosphorus, magnesium, sodium, potassium, chlorine and sulphur. Table 4.12 gives the daily requirements for four minerals. The main vitamins required are A, D and E. As milk yields increase the mineral and vitamin requirements become more critical. They should always form an integral part of the ration. When proprietary concentrates are fed these will usually produce sufficient of these nutrients for the productive cow. However, where rations are all or nearly all TMR then addition of adequate amounts of vitamins and minerals is essential.

Grassland farming

Grass and its derivatives, hay and silage, form an important part of dairy farming. The two major aspects to

Table 4.12 Main mineral requirement of dairy cows.

| 5.0 | 30 | 17 | 6 | 6 |

consider are grassland production and grassland utilization.

Grassland production

To get optimum production from grassland the basics must be correct. These include climate and soil type about which little can be done. Grass grows best on a medium loam soil with adequate summer rainfall. These conditions are most often found in the west of England and Wales. Where soil is heavy and waterlogged, then drainage can give good results. Conversely, in dry areas, irrigation has a part to play, although the economics of grassland irrigation in Britain are questionable on all except the driest farms. Soil acidity should be corrected to a pH of 5.5–6.5.

Having achieved as near optimum as possible with the basics the next area to consider is grass varieties. For grazing, most seed mixtures are based on varieties of perennial ryegrass (Fig. 4.9). There are many recommended varieties in the National Institute of Agricultural Botany (NIAB) lists. Timothy is often sown, which adds some palatability and midsummer growth. Older grass varieties such as meadow fescue and cocks-foot are not often sown now. Most mixtures will also include some white clover. This provides nutrients by fixing atmospheric nitrogen and also increases intake by improving the palatability of the sward. But clover is difficult to establish and maintain in grassland receiving high levels of fertilizer nitrogen.

Once established, and with good management, a grazing sward should remain highly productive for 10 years or more. The main enemy to this is grazing in too wet conditions, when treading and poaching will quickly destroy a sward and allow weed grasses to establish. Swards mainly for cutting are usually based on a shorter term perennial ryegrass or Italian ryegrass. These have a more erect growth habit and are easier to cut but are

Fig. 4.9 Cow set stocking, grazing a rye-grass sward.

Fig. 4.10 A good response is shown from nitrogen fertilizer.

not so persistent. They are often grown as a grass break in an arable rotation for two to three years. Often the species are sown pure. If clover is required then red clover is more suited to a cutting regimen than white clover. In between these extremes are many dual purpose mixtures that are both grazed and cut during a season.

The best time to sow grass is in August–September. This gives it a chance to establish before winter and to be in full production the following spring. A spring reseed in April–May will lose much of the first year's production and can be vulnerable to summer drought.

Having established the grass the fertilizer requirement must be satisfied. Normal recommendations for grazing would be an annual application of 300kg/ha nitrogen, 40kg/ha phosphate and 40kg/ha potash. Under a cutting regimen the nitrogen and potash would be increased to 350 and 150kg respectively. Whilst phosphate and potash are essential for grass growth the main response is shown to nitrogen. Much trial work has been undertaken showing a good response up to 400kg/ha, but the average nitrogen use is still under 200kg/ha (Fig. 4.10). Researchers have defined a target nitrogen use as being the point in the response curve where 10kg of grass dry

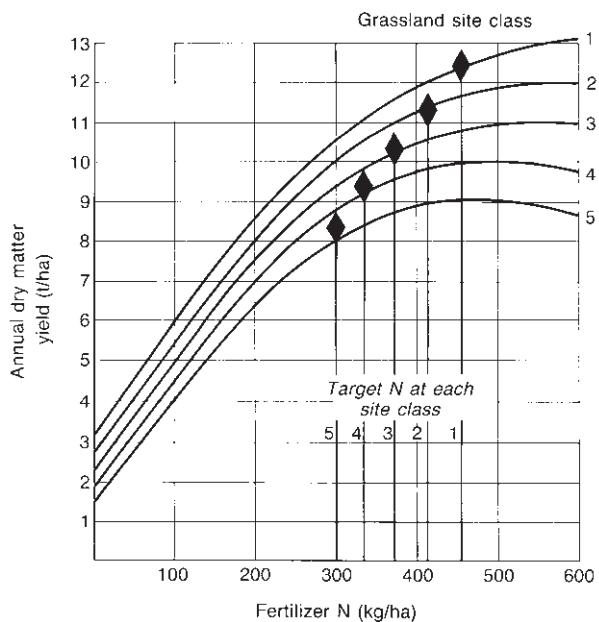

Fig. 4.11 Target nitrogen on five site classes. Source: *Milk from Grass* (GRI and ICI).

matter are produced for each 1kg of fertilizer nitrogen. Nitrogen use is now controlled in many areas.

Figure 4.11 shows the target point for five site classes, class 1 being the most suited to grass growth and class 5 the least suitable.

Grassland utilization

Grass growth is uneven through the year with a peak in the spring and then falling away through the growing season (Fig. 4.12). Grass growth will also vary greatly between seasons depending mainly on the summer rainfall. Nor are the animal requirements even over the season. For all these reasons any system of grassland utilization must be flexible and adaptable to cover any situation.

The overall aim is to provide the cow with her maintenance requirement and as much of her production as possible for each day of the year. This will be achieved with an integrated grazing and cutting system whereby in early season about one-third of the grass area is grazed and two-thirds is cut. This is reversed in mid season and then the whole farm is grazed in the autumn.

The most common systems of grazing management are either continuous grazing or rotational grazing with paddocks or strip grazing. There is little to choose between systems in terms of output so choice is down to personal preference and ease of management.

Under any system, cows should be stocked at a heavy density (6–8/ha) in the spring, which will allow a

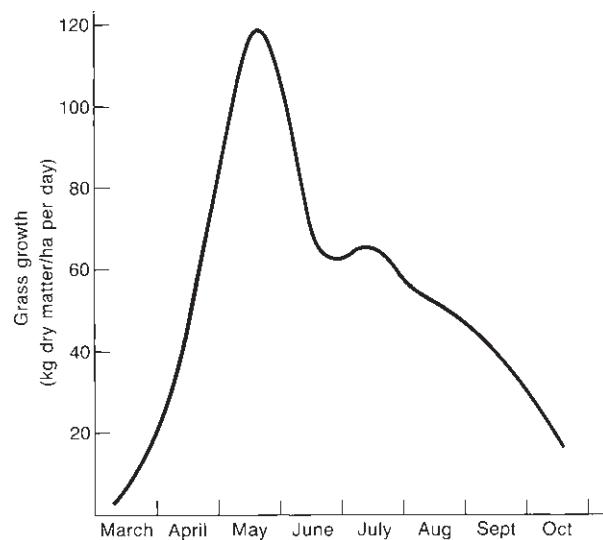

Fig. 4.12 Seasonal pattern of grass growth. Source: *Milk from Grass* (GRI and ICI).

maximum area to be cut without affecting milk production. Maintenance plus 20–25l/day of milk can easily be obtained from spring grass. For an autumn-calving cow, as grass declines so milk yield declines and there should be no need to introduce supplementary feeding. Spring-calving cows may need supplementary feeding to sustain yields in the summer. This may be concentrates or forage crops such as rape or stubble turnips.

Efficient conservation is a vital part of grassland management. It both provides a feed for winter use by the cows and aids grassland management by utilizing grass surplus to the grazing requirement. The main options for conservation are either hay or silage. There is a continuing move away from hay towards silage on dairy farms because:

- it is more flexible and integrates better with grazing;
- silage is a better feed for dairy cows;
- silage can be made in poorer (not poor) weather conditions; and
- silage can respond to higher levels of fertilizer nitrogen use.

However, silage making does require a higher capital investment in both machinery and storage areas (Fig. 4.13). Much of this criticism has now been overcome by the use of contractors and with the advent of big bale silage. These have given even the smallest dairy farm the opportunity to improve grassland utilization and profitability by changing to silage making.

Whilst grass is the most important forage crop, reference must be made to other forage crops that may have

Fig. 4.13 Silage making with a precision chop forage harvester.

a place on dairy farms by producing heavier yields than grass or producing feed in a season when grass is not available. The most popular forage crops are maize, fodder beet, kale, lucerne, and stubble turnips and rape.

Maize

This is increasing in popularity in southern England and is normally made into silage but can be fed green. To be successful it requires high summer temperatures so even in southern England a sheltered field should be used. It produces a similar or heavier yield per hectare than grass and has the advantage of being harvested in one cut. The resultant silage is a very palatable, high energy, low protein feed that improves a winter ration. It is often mixed with grass silage in the proportion 1:1 to 1:4 maize: grass but can successfully be fed on its own.

Fodder beet

This has about the highest yield of dry matter per unit area of any fodder crop. It can be grown successfully anywhere but prefers a heavier soil. It is an arable crop and the farmer needs arable techniques to grow it successfully, especially for establishment, weed control and harvesting. It is harvested in October/November and stored for winter use. It provides a palatable high energy feed, which helps butterfat percentages.

Kale

This is a high protein green feed grown mainly for grazing in the autumn and early winter. It produces a high yield of succulent feed that stimulates milk production. It can be cut and fed to dairy cows in the yards but is more commonly grazed, which means that it should be grown in dry fields with good access. Mud, dirty cows and bad feet can be a problem. However, some have successfully made silage.

Lucerne

This is a drought-resistant legume that grows well on light chalky soils. Being a legume it fixes atmospheric nitrogen and hence is cheap to grow once established. Cut four or five times during the season it provides good yields of high protein silage, but it can be difficult to get a good fermentation in the silage. A useful crop for organic farms with suitable soils.

Stubble turnips and rape

Although these are not the same they are used for the same purpose – to provide a succulent green feed either in the summer or autumn. For summer use they need sowing in the spring but autumn grazing can be achieved by drilling after harvesting an early cereal crop. They both provide grazing when feed might otherwise be short.

Fig. 4.14 Self-feeding silage.

Winter feeding systems

A winter feeding system will be partially dictated by the objectives, high or low milk yields, and by the facilities available.

In all cases the first requirement is to know the quantity of bulk feeds available. Over a 200-day winter a Friesian cow may well consume about 3.5t of dry matter. If there are 2.2t of silage dry matter per cow then this will leave 1.3t to be made up with concentrates or other purchased feed. Provided there are about 1.8t of forage dry matter for a 200-day winter then a reasonable feeding system can be devised. This equates to about 7t/cow of fresh weight silage. Anything much less than this will create problems, not so much from the cow's point of view but from the economic side as it will tend to be an unprofitable winter. Anything more than this will be a bonus and an asset to the farm especially if of a high D value.

All feed changes should be done gradually to prevent digestive upsets. Thus silage should be gradually introduced on a limited access basis from calving or by mid-September, whichever is the earlier. The herd should be housed at night by some time in October depending on conditions and then housed continually from mid-October onwards, again depending on weather conditions. Over this period silage consumption will increase and other feeds can be gradually introduced. The same principle applies in the spring, when ideally the herd should be kept inside at night on silage for seven to ten days after turning out with grazing time gradually increased.

Silage will either be self-fed (Fig. 4.14) or fed mechanically behind a barrier or in a trough. Self-feeding works well for low yields, provided that the

silage quality is even throughout the clamp, that the face is not more than 2m high and that there is enough space at the face, 24 hour access of at least 40cm/cow.

To avoid secondary fermentation the silage face needs to move back by at least 150cm/day. Self-feeding is labour saving and requires no machinery. It is better but not essential to have a roof over the silo and intakes will improve if a light is left on at night. Keep cows back from the silage face with a barrier, either a solid rail or an electric wire. The latter, however, can often reduce intake. To prevent waste the face must be kept tidy and waste silage removed.

Mechanical feeding of silage will either involve putting the silage in a trough or behind a barrier with a tractor and fore-loader/blockcutter or else loading the silage into a forage wagon that will spread it behind the barrier. Many people claim that this will increase intake compared with self-feeding by 10 per cent or more. Two simple barrier designs are shown in Fig. 4.15.

For 24-hour access the herd will need a minimum feed space of 40cm/cow, but space of up to 75cm is now often recommended for best intakes. Again cleanliness is important and waste silage should be removed on a regular basis, preferably at least once daily. It is important to ensure that silage is always available *ad libitum*. Leaving the trough empty for two to three hours before feeding will suppress intake and can cause digestive problems. It is a tremendous advantage to a winter feeding system to have a trough or barrier available as almost any feed can be fed behind it, from silage to hay, roots, brewers grains, sugar beet pulp or concentrates. This gives a great flexibility. When feeds such as dried beet pulp or concentrates are fed it is essential to have at least 60cm/cow of trough space to ensure a reasonably even intake among cows.

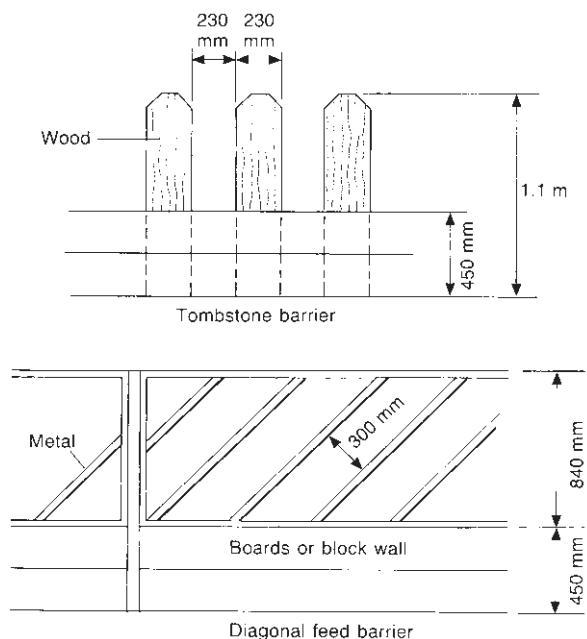

Fig. 4.15 Two types of feed barrier.

A sophistication of this system is complete diet feeding or total mixed rations (TMR). Here all the feeds are placed in a mixer wagon, which mixes them together and delivers the diet behind a feeding barrier. Because of the degree of mixing the cow is unable to separate out, say, barley from silage and so eats the whole mixture uniformly. Ideally the wagon has weigh cells so giving a very accurate measurement of feeds. Use of a mixer wagon allows the feeding of a wide range of feeds that may represent a very economical buy, but which are normally either difficult to feed or unpalatable, e.g. molasses and rapeseed meal. It also allows much more satisfactory feed digestion within the rumen and further down the alimentary tract. Some farmers are now buying straights and producing their own complete diets, usually with the help of a nutritionist. Attention is being focused on straights and ensuring that they are stored in satisfactory containers which allow the feed to be kept dry, vermin and bird proof. The introduction of herd health and quality assurance schemes has drawn attention to how feeds are stored. On some farms forage boxes are used instead of mixer wagons, but these do not really mix up the feed.

Most milking parlours have facilities to feed concentrates and it is usual to feed these twice per day at milking time. A limit to be fed during each milking would be 4–5 kg. If anything above this is needed then an out-of-parlour feed at the barrier is beneficial. This not only splits the feeds, which helps digestion, but also allows a proportion of the concentrate to be replaced

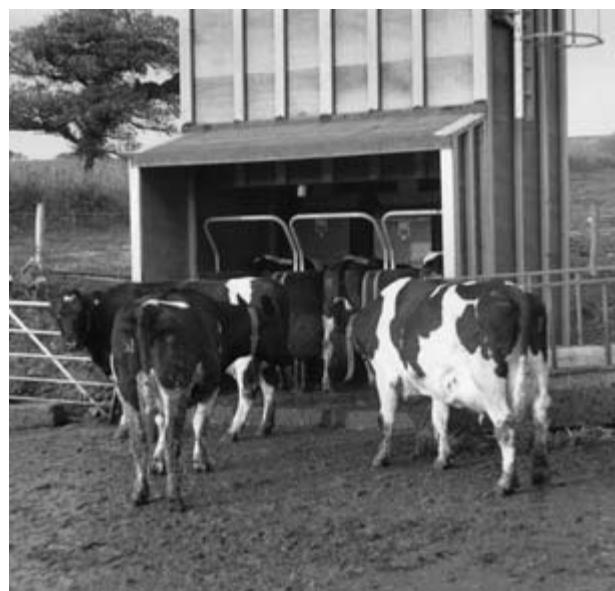

Fig. 4.16 Cows at a computerized out-of-parlour feed station.

with alternative feeds such as cereals, maize gluten or sugar beet pulp.

A sophistication of this system is with computerized out-of-parlour feeders (Fig. 4.16). Each cow has a transponder identifying her to a feeder station. This is then programmed to allow a specified amount of feed per day in a number of feeds. The cow can then eat up to her allowance but no more. Although the capital cost of these installations is high they make for very accurate feeding, based on the sound principle of 'little and often'. They perhaps demonstrate the way dairying will go in the future. Printouts can be obtained for cows not consuming their allocated amounts.

In all feeding systems water must not be overlooked. With milk being 86 per cent water any shortage of water will quickly limit milk production. A dairy cow will need 60–100 kg of water per day and being creatures of habit tend to all want to drink at the same time, especially late afternoon. This makes a large reservoir and fast flow of water essential. The volume drunk will increase as milk yield increases and in dry hot weather, so that 120 litres or more is not uncommon.

Dairy farm buildings

Because of the diverse nature of dairy farming there are almost as many different designs of dairy building units as there are dairy farmers.

However, if starting from scratch the main needs are for a milking parlour and dairy, winter housing and

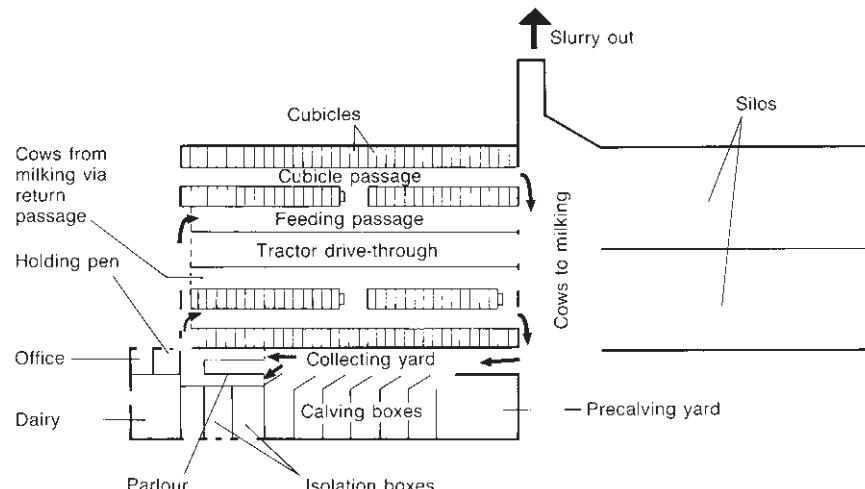

Fig. 4.17 Typical layout of a dairy unit.

feeding barn, food storage area, calving and isolation boxes, slurry handling area and various collecting yards and access concrete. A typical set of dairy buildings is shown in Fig. 4.17.

Important considerations when designing a dairy unit include the following.

- Cow-free access for the milk tanker so that collection can be made at any time.
- Good cow flow so that cows come from the bedded area through the parlour and back with a minimum of narrow passages and sharp corners.
- Good feeding access so that cows can be fed without having to work amongst them.
- Access to silage storage areas away from the cows so that silage making can take place while the cows are in the yards or in for milking.
- Good handling arrangements for veterinary treatment and AI.
- Adequate slurry storage as spreading may be restricted in nitrogen vulnerable zones.
- Thought should be given to the way the buildings blend in with the surroundings. Choice of materials and site are important.
- Adequate loose boxes for calving, sick animals, etc.

Parlour and dairy

This is the key to the whole dairy unit, being used twice (or three times) a day 365 days of the year. Cowsheds are very labour intensive and outdated while rotary parlours in the past have proved unreliable, with no benefits over a static parlour but are now becoming more common again. Automatic (robotic) parlours are also now being introduced. Figure 4.18 shows the most common parlours used, an abreast and a herringbone parlour.

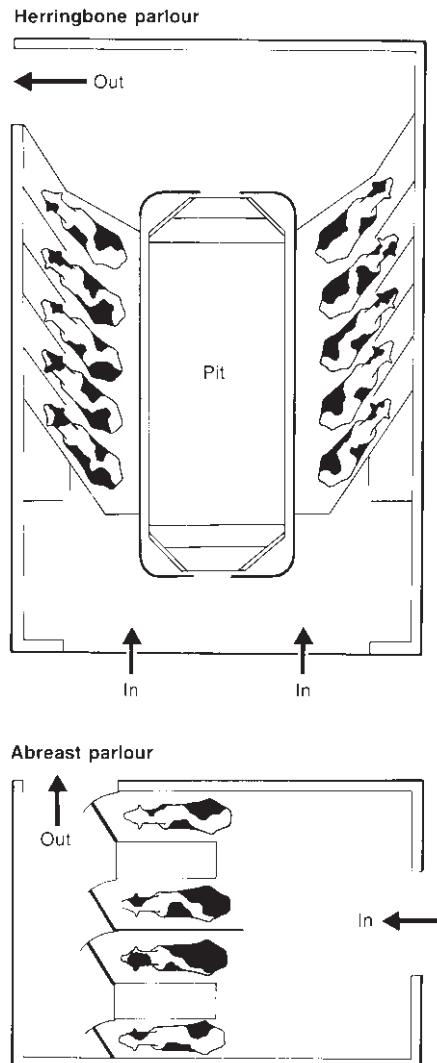

Fig. 4.18 An abreast and a herringbone parlour.

The most simple parlour is the abreast, which is particularly suitable for herds of up to 80 cows with one man milking either with three milking units and six standings or six units and six standings. The cows enter and leave one at a time so a degree of individual treatment for a slow milker or slow eater is possible. The parlour should have a loft above to hold the concentrates, which fall by gravity to the feeder situated between each pair of cows. Milking rate will be about 30–40 cows/hour.

In a herringbone parlour, by far the most common, the milker stands in a pit, which removes most of the bending required. The cows come in and out of the parlour in batches and stand at an angle to the pit on either side. A herringbone parlour is suitable for any sized herd and one man could comfortably milk 100 cows in two hours with a 10:10 herringbone, i.e. 10 milking units, 10 standings. For 300 cows or more larger herringbones with two or three milkers are common. A loft above the parlour will hold the concentrates and each standing will have a feeder. In some parlours feeding has been discontinued.

Automatic cluster removers (ACRs) are now available that make it possible for one man to handle more machines without the danger of overmilking.

In any parlour the work routine is to let the cow or group of cows in, feed them, dry wipe the udder or wash and dry if dirty, wash the udder, test the foremilk, attach the cluster, remove the cluster, teat dip or spray, transfer the milk and let the cows out. Pre-milking teat dipping is practised in some herds, especially those with high levels of environmental mastitis.

The dairy should be adjacent to the parlour and will contain some dairy equipment such as the vacuum regulator, milk pump, water heater and washing equipment. The bulk milk tank will also be situated here. The capacity of the bulk tank is important and must be sufficient to hold the likely peak milk production. Except in a herd with a very compact calving pattern about 30–35 litres/cow capacity is normally sufficient.

Both the parlour and dairy must be kept scrupulously clean and in Britain will be inspected regularly by the authorities. The motors and refrigeration unit should be housed separately in an engine house. It is also useful to have a small area near the parlour where the cowman can keep the records necessary for herd management.

Cow housing and feeding barn (Chapter 56)

The choice for cow housing will rest between housing in straw yards and cubicles.

Cows often appear more comfortable in a straw yard but if they are to keep clean they need about $6\text{ m}^2/\text{cow}$. They also use a lot of straw over a winter (about 2.5–

Fig. 4.19 A feed/sleep arrangement with metal cubicles.

3 tonnes per cow), which creates work to cart in and take out each day. But straw yards do help to alleviate a problem by reducing the volume of slurry produced.

Cubicles (see p. 422) have gained in popularity and, well designed, can be a very trouble-free system with a low demand on labour (Fig. 4.19). The main requirement for comfort is to make the cubicle large enough, about 1.2m wide and 2.2m long, with a good lying surface. They can be made of metal or timber and a typical design is shown in Fig. 4.20. This design is for Friesian cows and does not offer sufficient flexibility for many high-yielding cows and so ones such as in Figs 4.21 and 4.22 are used. Other new models are also available. The measurements of an ideal cubicle are given in Table 4.13.

The cubicle should slope from the head to tail end and the best surface is concrete with mattresses, mats or sand as a bed. A strategically placed headrail is essential to ensure the cow dungs in the scraper passageway. Passageways should be at least 2.4m (8ft) wide to allow for good cow flow and sufficient width for the scraper.

The whole cubicle and scraper passageway can either be situated within an open span building or be part of a purpose-built cubicle building. For all situations it is important to have a draught-free environment with plenty of ventilation. This is normally achieved by the use of Yorkshire boarding (vertical boarding with gaps

to allow free movement of air) or with an open ridge to the building or kennel.

With either straw yards or cubicle beds, the feeding areas can be either inside or outside the building. An inside area is preferable but will add to the cost. An example of an arrangement with a centre feed passage is shown in Fig. 4.23.

The advantages of this type of arrangement are that the cows can be shut in the feed area while the cubicles are scraped and vice versa. Feed can be put out without driving through the cows and it is also possible to split

the whole herd into groups, by milk yield or calving date, which can assist management.

There has been increasing emphasis on cow comfort, particularly from the point of view of preventing lameness and providing suitable conditions to ensure that cows lie down for similar lengths of time as they do when at grass. This is difficult or impossible to achieve with cubicles and so some farms have altered accommodation to straw yards (see Figs 4.24, 4.25 and 4.26). Such alterations do require sufficient space for each cow (see Table 4.14). They can result in rapid improvement of locomotion scores, and considerably reduce lameness due to white line disease and solar ulceration (Hughes, 2000). However, mastitis levels can rapidly increase, particularly due to *Strep. uberis* and *E. coli*, unless great care is taken in producing a satisfactory straw bed. The keys to success include making available a large quantity of straw for each cow (about 2.5–3 tonnes) and ensuring that it is kept dry when stored and the bed remains dry. Regular cleaning out every 4–6 weeks may help prevent mastitis problems, but this is possibly less important than the quality of the straw used. Good ventilation is also required to help keep the straw bed dry.

Feed storage area

The major item here is the silage storage facility. This can range from a tower silo to a simple hardcore pad.

Construction of a simple silo is worthwhile to make handling easier and to prevent waste. Clamp silos are the most common and are usually constructed with a concrete base and walls of earth, sleepers or concrete. Safety is essential and in Britain walls must be up to DEFRA (Department for the Environment, Food and Rural Affairs) standards bearing in mind the walls have to contain not only the weight of the silage but also pressure from the tractor when consolidating the clamp. For open silos, guide rails must be provided 900 mm above the wall and for roofed silos sufficient height (5.5 m) must be allowed for tractor clearance. All effluent must be contained in a sealed tank that can be pumped out.

For self-feeding of silage the height of clamp must not be more than 2 m and capacity will need to be about 12–15 m³ per cow for a winter's storage. If other feeds

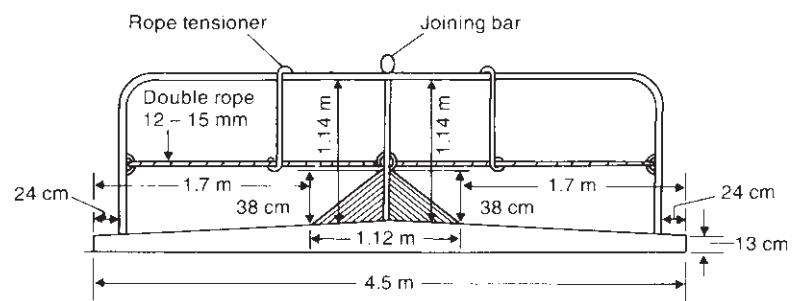

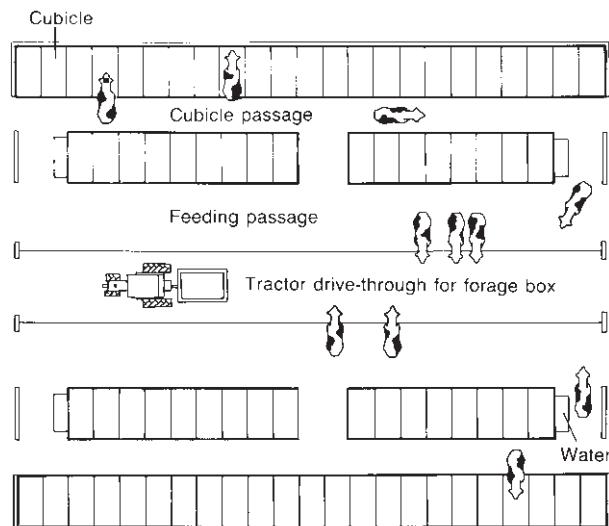

Fig. 4.22 A double fronted cubicle suitable for Holstein cows (courtesy of J. Hughes).

Table 4.13 Measurements of cubicles suitable for high yielding Holstein cattle as determined in Britain (adapted from Hughes, 2000).

| Measurement | Metric (Imperial) |
|---|--|
| Length | 2.4 m (8ft) <i>If double fronted cubicles with concrete fillet so maximum forward lungeing space length can be reduced to 2.28m (7ft 6inches)</i> |
| Width | 1.2m (4ft) <i>If width 1.14m (3ft 9in) there must be a flexible lower barrier</i> |
| Rear step | <150 mm (6 inches or less) |
| Fall (front to rear) | 100–125 mm (4–5 inches) |
| Division height | 1.14 m (3ft 9 inches) |
| Lower division rail (flexible) | 400 mm (1ft 4 inches) |
| Barrier thickness ideally flexible – at least | 19 mm ($\frac{3}{4}$ inch) |
| Brisket board | 100 mm (4 inches) |
| Brisket board from front | 0.75m (2ft 6 inches) |
| Brisket board from rear | 1.7 m (5ft 8 inches) |
| Sloped concrete fillet (instead of brisket board) height | 38cm (1 ft 3 inches) |
| Concrete fillet from heel stone | 1.7 m (5ft 8 inches) |
| Barrier (above fillet) if head to head cubicles | 76 cm (2ft 6 inches) |
| Head rail (below average wither height) $\frac{1}{5}$ cubicle length from front | 150–250 mm (6–10 inches) |

**Fig. 4.23** Sleep and feed arrangements.

are to be stored they must be kept in buildings which can be made vermin-free so that the feed remains clean and dry.

Calving and isolation boxes

These need siting in a convenient position to allow for ease of entry and exit for cows. The area would also probably include a cow handling area where

cows can be restrained for veterinary treatment or insemination. They require a separate air space.

Boxes should be reasonably spacious and must have a tying-up ring or some other method to aid cow restraint. Walls must be rendered so that disinfection can take place. It is also useful to have a water bowl and feed rack, tractor access for cleaning out and, maybe, a milking point so that cows can be milked in the box. Sick cows may die or have to be destroyed in the boxes so good access for the slaughterer's lorry is essential.

For a herd with spread calving pattern, one box for every 40–50 cows should suffice. Placing hinges and a swinging gate against a wall with the fixed end about 0.5 m (2ft) from a corner is a useful method of restraint. It allows the gate to be swung round to restrain a cow between the gate and the wall.

Slurry

With more and more farmers using a loose housing and cubicle system, disposal of slurry is becoming an increasing problem. Also, water authorities are rightly demanding more control of pollution. A dairy cow will produce about 7000–8000l (7–8m³) of slurry over a winter. This has quite a high fertilizer value (10000l will contain 25kg N, 10kg P₂O₅, 45kg K₂O) but much of this will be lost by leaching if it is spread during the winter when the soil is saturated. Also, the pollution risk is much increased. In the UK there are laws concerning application in nitrogen vulnerable zones (NVZs). Therefore, winter storage becomes almost essential.

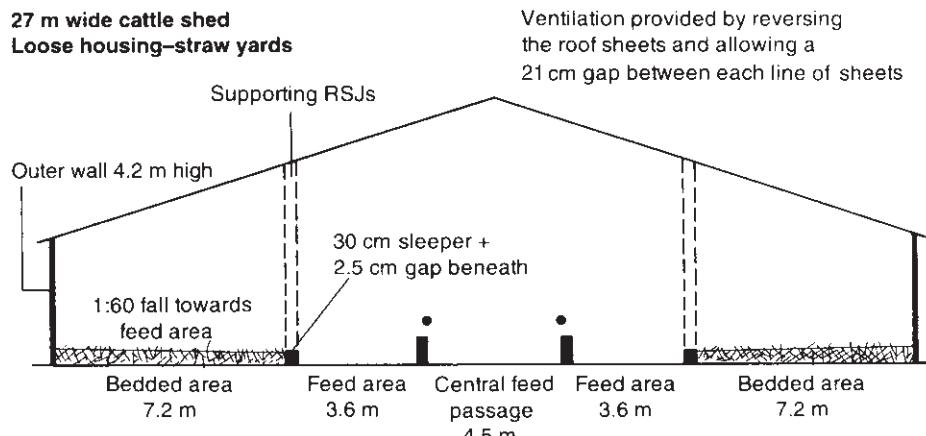

Fig. 4.24 A 27.5 m (90 ft) wide cattle shed with loose housing (reprinted from Hughes, 2000).

NB: The base of the feed manger should be made 62.5 cm high and the top rail fitted 65 cm above and inset 5 cm towards the forage

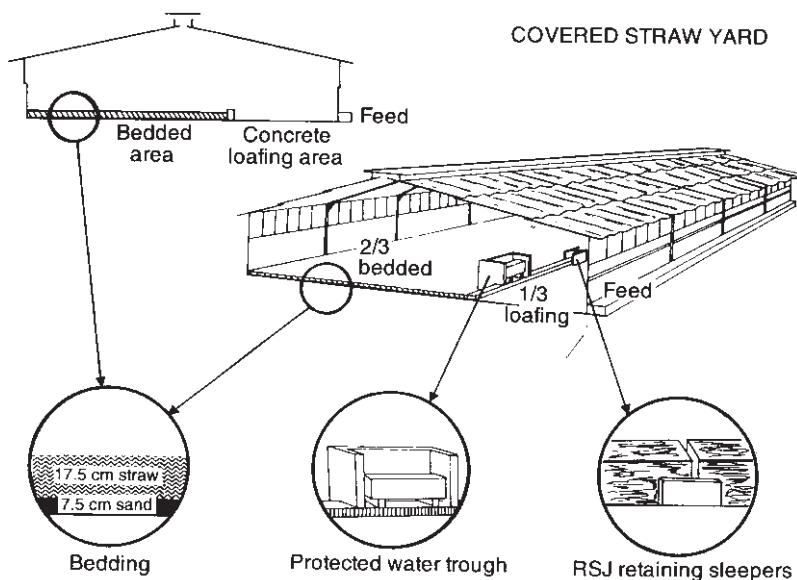

Fig. 4.25 Structures within a covered straw yard (reprinted from Hughes, 2000).

Slurry is usually scraped with a tractor-mounted squeegee to the store. The store must be able to cope with slurry, water, waste feed and bedding. It will reduce the volume considerably if clean water from roofs is diverted to a separate soak-away or drain.

Long-term storage can be provided in a sealed tower or a storage compound. With a slurry tower, the slurry is scraped into a reception pit and then pumped into the sealed tower. This is kept agitated to prevent settling or crusting of material. For emptying, the slurry runs back by gravity to the reception pit and is then pumped into the slurry spreader. It provides a good pollution-free system but is expensive to install and can create problems if management is not good leading to crusting and blockage of pumps.

By contrast the storage compound, although not cheap to construct, provides a simple-to-manage system with very few problems. The compound should be large

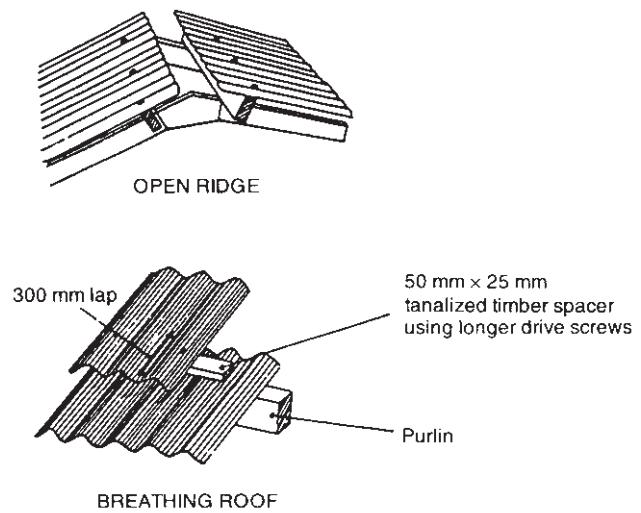

Fig. 4.26 Ventilation for a covered straw yard (reprinted from Hughes, 2000).

enough to hold a winter's slurry, have a concrete or hard base to facilitate emptying and a shallow ramp to push the slurry up for filling. Slurry is pushed in all winter and then at a suitable time emptying takes place with a tractor and fore-loader direct into spreaders. A sophistication is a 'weepy wall' silo with walls constructed of timber or concrete sleepers with gaps between the

Table 4.14 Space allowances for straw yards suitable for high yielding Holstein cattle as determined in Britain (adapted from Hughes, 2000).

| Space allocation | Metric |
|--|---|
| <i>Strawed area</i> | |
| Freshly calved cow | 6.5 m ² (70 ft ²) |
| Mid lactation cow | 5.6 m ² (60 ft ²) |
| Dry cow | 4.6 m ² (50 ft ²) |
| Plus | |
| <i>Loafing area</i> | |
| All production stages minimum | 2.3 m ² (25 ft ²) |
| Thus total minimum | |
| Freshly calved cow | 8.8 m ² (95 ft ²) |
| Mid lactation cow | 7.9 m ² (85 ft ²) |
| Dry cow | 6.9 m ² (75 ft ²) |
| Optimum number per pen = 40 cows | |
| <i>Area per pen of 40 cows</i> | |
| Freshly calved cows | 350 m ² (450 yd ²) |
| Mid lactation cows | 320 m ² (380 yd ²) |
| Dry cow | 275 m ² (335 yd ²) |
| • Maximum per pen with sufficient space = 60 | |
| • Drainage in feeding area = 1 in 60 | |
| • Straw usage = 2.5 t per cow | |
| • Feeding passage never less than 3.7 m (12 ft) wide | |
| • Easy access from bedded area | |
| • Water – recess into bedded area but no access from bed | |
| • Ventilation must allow moisture to escape – roof open ridged, possibly breathing or gap roof | |

sleepers (Fig. 4.27). This allows water to drain from the slurry, which is collected and spread separately. This considerably reduces the volume of material needing to be stored for the winter and improves the handling of the remaining material.

Herd records

Herd records are essential for management of the herd but they must be simple to keep, understood by the farmer and his staff and of use in the herd management. Before records can be kept, cows must be individually identified. With herds becoming larger and to make identifying cows by relief staff possible, this identification must be permanent and clear.

Freeze branding with liquid nitrogen kills the pigment cells in hair and results in a clear white number on black cows but is not so successful with light coloured cows. Ear tags are also often used and can be very clear if large. However, there is always the possibility of losing tags. With the coming of new technology it is possible that most cow identification in the future will be by transponder, either implanted into the cow or worn on a collar or ear tag or placed in the rumen.

For short-term cow identification, e.g. for a cow needing treatment, etc., spray cans of different coloured paints or tail tape, sticky coloured tape, can be successfully used.

Computers are now used for keeping records for most large herds, but this is by no means essential and the capital cost will result in a place for manual recording in small herds for many years to come. Records kept will be either physical or financial. In many countries treatment records must also be kept.

Physical records

The notebook: The herdsman or farmer should always have a notebook in his pocket to record information

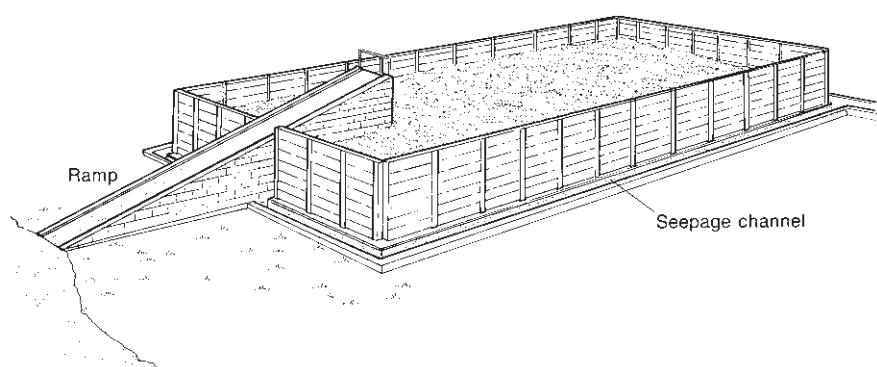

Fig. 4.27 A weeping-walled slurry compound.

| Cow record card | | | | | | | | | |
|-----------------|---------------|---------------------|-----------------------|------------|----------------------|----------------------|-----------|-----------|----------|
| Cow name _____ | | | Pedigree number _____ | | | Ear tag number _____ | | | |
| Sire _____ | | Date of birth _____ | | | | | | | |

| | Service dates | | | | Veterinary treatment | | | | |

Fig. 4.28 Cow record card.

such as bulling cows when the event is observed, before transferring this to more permanent records.

Cow record cards: This will be the cow's 'log book' and will give a concise picture of each cow's history. It must contain basic details such as name, pedigree number, ear tag number, herd number, date of birth, service dates, calving dates, sex and sire of calf data, production details, health records and details of veterinary treatment. An example is shown in Fig. 4.28. Much of this information can now be computerized. Today in the UK each animal also has a Cattle Passport.

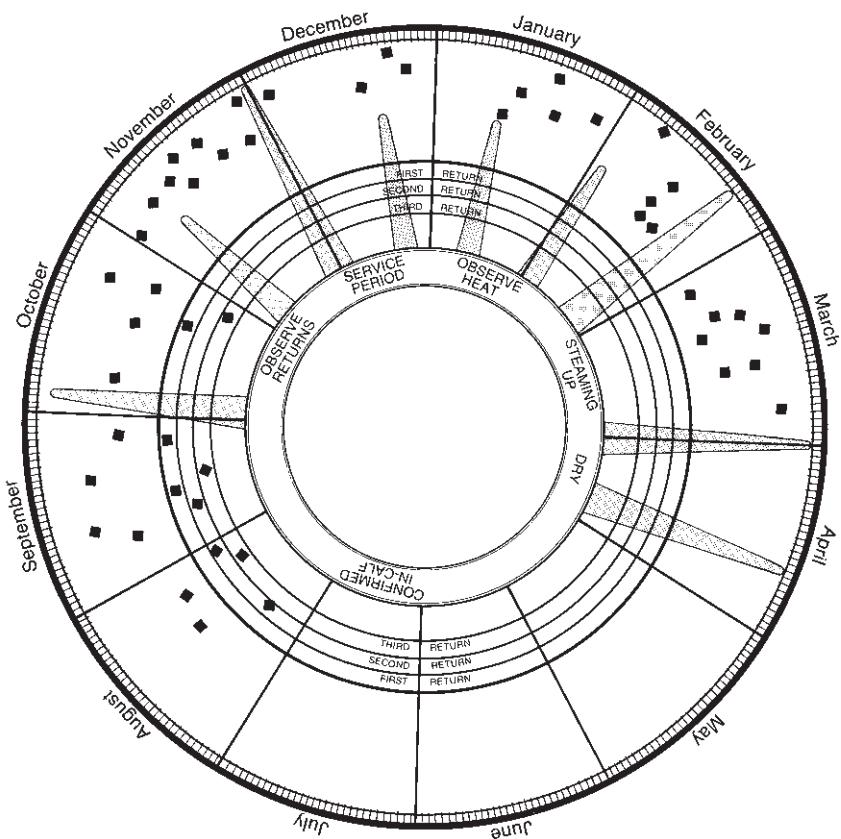

Breeding records

Apart from information kept on the cow record card a simple breeding record should be kept. This will be used to keep dates of calving, pre-service oestrus, services and identification of sire and expected calving dates. These records should allow the farmer or herdsman to quickly identify any problem cows, such as those not cycling or not holding to service, so that treatment can be carried out before the calving interval slips. These records can be

successfully maintained with written entries on a card but often a more visual record is kept. This is usually a rotary board with pins or magnetic blocks of different colours used to identify cows. These are placed on the board to record events so any cow 'out of line' is quickly obvious and can be investigated. If this method is used it is important to have a more permanent back-up in case the pins are accidentally removed. Figure 4.29 shows examples of these records. Several computerized systems are now available and they are being increasingly used in larger herds. These will usually allow the creation of various action lists such as those cows to separate out for routine veterinary examination, those due to come on heat that week, those due to be served, those due to be dried off, those due to calve, etc.

Milk records

Whilst it is possible to record milk yields from cows personally, most farmers who wish to record milk use National Milk Records. The scheme supplies a milk recorder to measure the milk and take a sample, which is then sent to a laboratory for testing for the percent-

**Fig. 4.29** Breeding board.**Fig. 4.30** The milk recorder sampling milk in the parlour.

age of butterfat, protein and lactose and cell count. The recorder also enters dates of calving, service, drying off and culling (Fig. 4.30). The results are sent back to the farmer within a week and contain records not only for that month but also on a cumulative basis from the

commencement of lactation. At the end of the lactation a cow record card is produced. From the dates provided an action list is produced for the next month with lists of cows due to calve, to dry off, to serve or to pregnancy diagnose.

Milk records are used for pedigree purposes, to provide information to prepare Improved Contemporary Comparisons (ICC) for bulls and to assist with cow selection for breeding purposes.

Apart from this, milk records can be used for management purposes for individually rationing cows or for use in a milk prediction scheme.

Financial records

Farmers keep many financial records with varying degrees of sophistication to assist with the management of the herd. Many farmers use a bureau service provided by a firm supplying the feed or use a service provided by agricultural organizations or consultants. All of these measure the main output from the dairy herd, milk income, and relate this to the main variable cost of production, namely feed. This then gives a margin over feed analysis, expressed on the basis of per herd, per hectare, per cow or per litre. For example, the gross margin per litre in England and Wales in 1995–96 was 15.34 p/litre and 13.24 p/litre in 1997–98; and that per cow was £897/cow in 1995–96 and £809/cow in 1997–98. Margins in some of the next few years were considerably lower (e.g. £807 per cow and 14 pence per litre in November 2002, taking into account inflation).

These services are all computerized and rely on the farmer supplying information monthly on cow numbers, milk quantity and quality, feed used and price, fertilizer used and price, and land area used.

The farmer then has the results returned to him and often has a league table comparing his results with other farmers or comparing his results for this year with the previous year or budget.

Differences between the various schemes are small but some form of financial monitoring provides an essential part of the dairy herd management.

Management

Labour

No dairy system will work efficiently without good labour. In many cases this is supplied by the farmer and his family but for larger herds employing a herdsman is common. In the milk costs survey for 1986–87, 63 per cent of herds only used family labour. From the same survey there was an average labour use of 35 hours/cow per year. This ranged from 79 hours/cow for herds of below 30 cows to 27 hours/cow for those above 100 cows. About half of this time was spent milking the cows and the other half tending them. Labour costs will vary depending on factors such as herd size, facilities available and type of person employed but will range between £250 and £300/cow or about 4 pence per litre.

A herdsman will be one of the most skilled workers employed on the farm. He must enjoy working with cows and be prepared to work the long hours made necessary by milking twice a day, seven days a week. He must be observant to see signs of unhealthy cows, to see cows in oestrus or about to calve and to see signs of under- or overfeeding. He must be capable of keeping records accurately.

He must be clean, to produce high quality milk and to prevent a dirty environment. He must be strong as there is still considerable physical work involved in cow feeding and calving especially. Fortunately, the herdsman's job provides a high degree of job satisfaction and interest for a dedicated man.

Most herdsmen are paid a fixed wage for the job but may also have bonus schemes related to such things as milk yield per cow (less common since quotas), margin over feed costs, calving percentage or calves sold.

Apart from the main herdsman, relief will be needed for weekends, holidays and sickness. Often this relief will be provided by the farmer or another farm worker. Failing this, relief agencies exist which can provide a herdsman often at short notice. At present numbers of farm workers are decreasing rapidly, resulting in increased numbers of animals being cared for by each individual stock person.

Breeding

The aim of a breeding policy must be to get the cows in calf regularly and to provide sufficient replacements of high genetic potential to maintain the herd size at the optimum level. This will depend on the culling rate, the age at first calving, the breed of sire used and the genetic worth of that sire.

Culling

Studies have shown that the majority of culls are sold for reasons such as poor breeding, mastitis, bad feet, injury, etc. (Table 4.15). These might be termed

Table 4.15 Reasons for culling (%). Sources: Cull cow surveys 1984 – FMS Information Unit; Milk Development Council, 2000.

| | 1984 | 2000 |
|---------------------|-------------|-------------|
| Poor yield/quality | 12 | 10 |
| Poor breeder | 21 | 28 |
| Bad legs or feet | 9 | 7 |
| Mastitis/cell count | 15 | 18 |
| Udder | 8 | 6 |
| Old age | 10 | 5 |
| Injury | 5 | 4 |
| Others | 20 | 22 |

unplanned reasons and will not lead to overall herd improvement.

With good management it should be possible to keep the annual culling rate to 20 per cent. But the national average is about 25 per cent. Also, because so much of that culling is for the unplanned reasons outlined above, the rate of genetic progress is considerably slowed. In some countries such as North America culling percentages tend to be higher, while in others such as New Zealand they are lower.

Age at first calving (see Chapter 5)

This is very much linked with culling rate. Table 4.16 shows the effect of three culling rates and three different ages of first calving. The number of heifer replacements needed more than doubles between options. Although heifers need a higher plane of nutrition to reach sufficient weight to calve at two years old their lifetime yield will exceed those calving at three years (Table 4.17).

Breed of sire used

Most dairy farmers breed sufficient cows pure to get the desired number of replacements, the remainder being put to a beef sire to maximize the value of the calf. Depending on the factors outlined above this can mean between 40 and 80 per cent of the herd will need to be bred pure.

Table 4.16 Number of replacement heifers needed per 100 cows.

| Culling rate (%) | Age at first calving (years) | | |
|------------------|------------------------------|----|----|
| | 2 | 2½ | 3 |
| 15 | 30 | 38 | 45 |
| 20 | 40 | 50 | 60 |
| 25 | 50 | 63 | 75 |

| Yield/day in herd (kg) | 13.1 | 13.2 | 13.1 | 13.1 | 13.2 |
| Yield/day of life (kg) | 8.8 | 8.4 | 7.9 | 7.5 | 7.3 |

With many first calf heifers still being bred to a beef bull this gives very limited scope to do other than breed pure with the dairy cows especially if management is below average. However, where choice is available then cows with the highest cow genetic index (CGI) should be used to breed replacements.

As pre-sexed semen becomes more available and affordable it will become increasingly possible to produce all high genetic merit heifers from those cows chosen to breed replacements. The remainder can then be bred to a beef bull and again it will be possible to choose the calf's sex. Otherwise embryo transfer can be used to solve both these management problems.

Genetic worth of the sire

The choice here will rest between using natural service and AI. The chances of being able to use a bull of high genetic merit which was referred to as 'ICC' for natural service are very remote, so AI is to be recommended. Also, AI gives choice for traits other than production such as ease of calving, conformation or size. Within the overall traits desired, bulls with the highest ICCs for weight of fat plus protein should be used. Also, it is important to choose bulls with a reliable proof, i.e. with a weighting of +40 or above, with daughters in over 20 herds and with less than 25 per cent of daughters in the two herds with most daughters. A wide selection of bulls are available meeting these requirements (Fig. 4.31) (see also Chapters 5, 12). Genetic merit has been converted into various numbers such as the production index number (PIN), which is a comparison of milk volume and weight of the milk constituents, and index of total economic merit (ITEM), which includes both production and conformation parameters.

It has always been difficult for farmers to assess a high genetic merit (HGM) bull in terms of their own herds. The advent of a large number of companies selling semen and the different methods used to express genetic merit in various countries have also not helped. It has resulted in the production of conversion formulae to predict performance. Production information is

Fig. 4.31 Peckforton Citation River ET—a high ICC Friesian bull.

expressed as predicted transmitting abilities (PTAs). In the UK, production (profit) index number (PIN) has been used for several years, but was biased towards milk quantity and constituents. This was superseded by the index of total economic merit (ITEM) for a time, which included conformation traits as well as those of production. More recently the PLI (production plus lifespan index) has also been included to provide an indication of production and lifetime performance. Other indices have been introduced including mastitis and calving interval.

In 2001 a new genetic evaluation system was introduced for Holstein cattle in the UK. The system is based on the Swedish interbull evaluations for production and conformation. The procedure, developed in 1995, is known as the multiple trait across country evaluations (MACE) and involves the incorporation of data on a particular bull from its own country and also from anywhere else it has been used plus parent information from the home country and abroad. As a bull is used in different countries it reduces the evaluation contribution of the parents to the overall genetic levels such as PIN. This parental contribution can initially be up to a third when the bull has not produced daughters in another country, but reduces to about 1 per cent when it has been widely used in that country and two or more others. The information will still be expressed in PIN and PLI values.

The other objective of obtaining a calf per year will largely depend on herd management. Very few cows are infertile but many fail to breed regularly. Key management times are as follows:

- (1) Post calving: ensure the cow is clean, has no discharges and is cycling regularly.

- (2) At service: ensure the cow is on a rising plane of nutrition and not losing weight. Oestrous detection is a skill found in a good herdsman. Four observation periods during the day of at least 20 minutes each will aid oestrous detection. Oestrous detectors such as tail paint, dyes or vasectomized bulls can be used to help detection.
- (3) Post service: cows should still be closely observed for repeat heats. Cows apparently in calf should be pregnancy tested at 24 days after service with a milk progesterone test or at six to eight weeks after service with a veterinary examination.

To achieve a regular 365-day calving interval, first service should be at 50–60 days from calving, which allows time for one repeat service before losing time.

An MMB report on Checkmate, the Board's fertility monitoring service, showed a wide difference between the top and bottom 10 per cent selected on the interval between calving and assumed conception (Table 4.18).

New techniques to improve the rate of genetic progress will doubtless be developed further over the next few years. These mainly revolve around embryo transplants and include possibilities with sexed embryos and super-ovulated cows producing many embryos for non-surgical transplants. As the cost comes down and the success rate improves these techniques will be used on more commercial farms.

Health

This subject will be dealt with very fully in the main text of the book. Suffice to say here that cow health is paramount to success in dairying.

| Direct overhead costs (ppl) | 8.01 | 7.23 | 6.87 |
| Rent, finance and quota (ppl) | 4.07 | 3.66 | 3.08 |
| Total overheads | 12.08 | 10.89 | 9.95 |
| Profit before drawings/tax (ppl) | 0.50 | 2.48 | 4.54 |
| Drawings/tax (ppl) | 2.90 | 2.58 | 2.45 |
| Retained profit/loss (ppl) | -2.40 | -0.09 | +2.45 |
| Total cost of production (ppl) | 22.71 | 20.64 | 18.81 |

Veterinary and medicine charges are usually between £35–80/cow or 0.4–0.8 p/litre and are made up of drugs, particularly anthelmintics and antibiotics, and veterinary charges. The main diseases that cause losses to the farmer through loss of production, cost of treatment or even death of the cow are mastitis (see Chapter 23), hypocalcaemia (see p. 781), hypomagnesaemia (see p. 787), lameness (see Chapter 32) and calving problems.

Economics of dairy farming

Measures of efficiency

The overall measure of efficiency on any dairy farm is profit. Profit is calculated by deducting from the whole farm gross margin the overhead costs of the business. The gross margin (GM) is the output of milk, calves and cull cows less the herd replacement charge to give the gross output. From this are deducted the variable costs, of production, purchased feed, forage costs, veterinary costs, and medicine and sundry costs. The overhead

costs are paid wages, power and machinery, sundries, property charges, interest and depreciation.

Each year various farm advisory services produce reports looking at the economics of specialist dairy farms. These analyse the average as well as the top and bottom 25% of farms selected by profit/hectare. The results in Table 4.19 are an example and highlight the differences. The system is now known as benchmarking, which compares or measures a level of achievement which is seen as the target for that individual or business.

For all the major factors those in the top group outperform the others showing the enormous range of results found on fairly similar farms. However, on very many farms full records are not available to carry out this type of analysis and simpler records must be used. There are many, such as margin over concentrates, margin over all purchased feed (MOPF) or gross margin, all per litre, per cow or per hectare. Statistical analysis shows none of these measures to be closely correlated to profit. The best measures are those where land area, and hence intensity of farming, are taken into

account. Provided the overhead costs are not exceptionally high, then margin over feed/ha (Table 4.22) will have a large influence on profit.

However, with the quota system now limiting production on farms, many people are now saying that margin per quota volume and hence margin per litre has become the most important measure (see Table 4.19). Tables 4.20–4.22 show that, depending on the criteria chosen, very different methods of production give the best results. These tables are based on the 1986–87

Milkminder report, which analysed data from 2459 herds, and *Genus Management Costed Dairy Farming 1989–90*.

A high margin per cow results from a high yield per cow with modest concentrate use. Stocking rate does not change substantially over the range of results. Farms with a high margin per litre had a lower milk yield per cow but with a much lower concentrate usage. Stocking rate also fell so there was little improvement in margin per hectare. Those with a high margin per

Table 4.23 Details of spring- and autumn-calving systems.

| | Spring | Autumn |
|--------------------------|---------------|---------------|
| Yield (l/cow) | 5228 | 5634 |
| Concentrate use (kg/cow) | 946 | 1409 |
| MOPF (p/l) | 13.0 | 12.4 |
| MOPF (£/cow) | 678 | 698 |
| Stocking rate (cows/ha) | 2.29 | 2.30 |
| MOPF (£/ha) | 1553 | 1605 |

hectare had a higher yield produced with increased concentrate usage and with a much higher stocking rate. The intensity of farming was much greater.

All these different systems of producing milk can lead to good profits if carried out efficiently. Therefore, depending on the farm situation and the circumstances appertaining, different systems can suit different farms.

A vigorous debate also ensues about the merits of seasonality of calving and its effect on profits. Both spring calving and autumn calving are very defined systems that can be successful and profitable if operated efficiently. Table 4.23 shows the differences between the systems.

A British spring-calving herd (calving February–April) produces a lower yield with less purchased feed than an autumn-calving herd (September–December). This gives a higher margin per litre but lower margin per cow and per hectare.

Both systems can be equally profitable but as the margin per cow is lower for the spring calver then the overhead costs must also be lower to show the same profit.

Thus the level of overhead costs goes a long way to determining the farm system. Where overhead costs are very low (i.e. an owner-occupied farm with no rent, no borrowed money, no paid labour and little machinery), then a very extensive system with low yields and low outputs can be practised and still show a good profit. However, if the overhead costs are high then the farm must be intensively run with high yields and high stocking rates, putting surplus land into arable crops to generate a high gross output. Only then will a satisfactory profit be generated.

There are many ways of making a profit in dairy farming. The skilled operator and the one making the greatest profit will be the one managing the resources of land, labour, capital, stock and quota most efficiently.

Farm assurance and herd health schemes

These are another initiative to ensure high management and health standards on dairy farms. They help provide

an audit and accountability trail from the animal to the end consumer. They will usually involve regular periodic inspections of the accommodation, management, health and record keeping of the farm. These visits may be undertaken by veterinary surgeons or other inspectors. The aim is to provide reports and, where necessary, to enforce improvements within given time periods. In Britain the schemes are mainly run or approved by the milk purchasers. While at present they are limited in their effectiveness they do provide the mechanisms to improve both animal health and welfare.

Organic farming

In the United Kingdom and other parts of Europe there has been rising interest in organic farming. At present in Great Britain only about 5 per cent of milk is produced in this way but the volume is growing. While there are strict criteria to follow, the farmer is at present rewarded with a higher milk price. However, as stocking rates are lower and also costs of organic feeds are high, margins tend not to be greater than in conventional farms.

This method of food production has been receiving increasing attention over the last 15 years. Its main aim is to ensure that production is undertaken in harmony with the environment and that as much is returned to the land as is removed from it. The system has been taken up in many countries especially those of Europe. Organic farming is defined in EU law under EU Regulation 1804/99. The system involves meeting various criteria before a farm can be defined as organic and this involves a conversion period which involves the land and, in Britain, usually takes about 2.5 years. The objectives of the system are to sustain the animals in good health by the use of effective management systems, good stockmanship and suitable diets and by preventing conditions where remedial treatments have previously been used. The use of alternative and complementary medicines is indirectly encouraged by the increase in stated withdrawal periods, usually by at least 100 per cent. The EU regulations only allow three ‘synthetic drug treatments’ a year (except for vaccines and antiparasitic preparations). At present a premium is paid for organic milk, which makes it an attractive proposition for some dairy farmers, but this is reducing.

The future

While milk quotas remain within the EU it is probable that they will be further reduced for most nations in the short term and then gradually or rapidly abandoned. The commodity price will eventually have to become

closer to world milk prices under the direction of various World Trade Organization initiatives. In several parts of the world cow numbers and milk production are being geared up to meet this. In most European countries there will be a reduction in dairy cow numbers as yields increase. There will also be fewer farms with larger numbers of cattle and proportionately fewer people employed. This will inevitably lead to more cows or animals per stock person and an increased requirement for mechanisation. Feeding practices will continue to change to allow the expression of genetic merit with its increased yields per cow. Sexed semen will facilitate a reduction in the number of cows made pregnant to produce herd replacements and will also then allow poorer producing cows to be bred to beef bulls again, often with sexed semen.

Increasing movement of animal products may lead to more interest being paid to the methods of production in those countries which are primarily exporters. The global transportation of food will probably also result in increased levels of disease in those which are major importers of animals and animal products. Unless disease levels in importing countries are allowed to rise, increased emphasis must be placed on health control and monitoring in the exporting regions.

Dairy farm incomes are likely to be further squeezed, resulting in the formation of various producer groups to give improved bargaining power with milk buyers. Such milk producer groups will also be able to purchase creameries and milk processing plants to improve integration of the supply chain. Much of the price structure will still depend on the prices which the main supermarkets are prepared to pay. However, as prosperity increases more people will eat less at home and more outside the home. This will allow the development of the catering market at all levels and again will provide marketing initiatives. There will be more niche marketing, either direct to the public via farm shops, farmer

markets and the internet, or indirectly via shops of all types.

Those doing the job well will survive although they will have to keep their eye very much on the various trends which develop concerning milk and its products. Whilst political decisions and the further reduction or demise of milk quotas will close many doors, it is probable that others will open and there will be good opportunities in dairy farming for many producers.

Introduction

Dairy heifer rearing is generally considered to be a non-intensive, low-profit enterprise. Indeed, few farmers would rear heifers at all if it were not for their interest in herd improvement and disease control. However, planned heifer rearing is the starting point for profitable dairying. An increasing number of farmers now realize the importance of this and are adopting

more intensive methods, particularly where the land involved could be used for alternative, more profitable, enterprises.

The low priority given to heifer rearing is supported by DAISY survey data (Kossaibati & Esslemont, 1996) which stated that in the average herd, 22 per cent of dairy heifers born were lost before they started their first lactation, with a further 14 per cent culled before they completed their first lactation, while in the worst herds, almost 60 per cent of heifers failed to calve for a second time.

Calving at two years is more profitable than calving at two and a half to three years as little over half the area of land is required, lifetime milk yield is greater and the amount of feed, housing, labour and working capital required for the rearing enterprise is reduced. A policy of calving at two years can only be achieved if the majority of cows calve within a relatively short period or a proportion of herd replacements are taken from heifers.

The management of a dairy heifer between 12 weeks old and calving has a considerable effect on her potential for milk yield, fertility, the incidence of dystokia and on longevity. Insufficient growth rates during the rearing period result in the production of small-framed heifers with disappointing milk yields due to their inability to compete with older cows during the first lactation. Poor growth rates at around the time of service result in low pregnancy rates and delayed entry into the herd.

The faster a heifer grows, the more efficient she is in converting feed into liveweight gain. This could suggest that heifers should be fed to grow as rapidly as possible, especially during the summer months when grass provides an abundant and relatively inexpensive source of feed. However, in some circumstances, high growth rates during the first year can result in lower milk yields due to the effect of rapid growth on the relative proportion of fat and milk secretory cells in the developing udder.

The potential of a heifer will only be maximized if she is reared to a plan with careful control over performance at all stages of the rearing period. Target growth rates and intermediate target weights should be set as soon as the predicted date of first calving has been

decided. Optimal growth rates will depend on age at calving, estimated mature body size, management after calving and average herd yield.

Dairy heifer rearing is a specific farm enterprise involving capital, land and labour. It should be managed and recorded with the same attention to detail as that given to the other enterprises on the farm, with preplanned target rates of growth being achieved throughout the rearing period.

A detailed description of the management and targets required for autumn-born heifers reared to calve at two years is given in this chapter. The pattern of growth and targets for weight-for-age for spring-born heifers calving at two years are similar. There is less pressure to maintain steady weight gains when the aim is to calve at an older age and there are periods when lower growth rates are acceptable.

Age at calving

The younger a heifer is at calving the less land, housing and capital are required during her rearing period but heifers should not calve at less than 23 months because a higher incidence of calving problems can be expected and subsequent milk yields are disappointing. With a high stocking rate of 0.4ha/livestock unit, the area of land required for each replacement unit is 0.4ha for heifers calving at two years, 0.5ha for heifers calving at two and a half years and 0.7ha for heifers calving at three years. When the stocking rate is 0.5ha/livestock unit the area required for heifers calving at three years is twice that required for heifers calving at two. The housing and capital required to sustain a two year system is also reduced. For instance, a 100 cow, autumn-calving herd calving at two years needs 40 replacements requiring accommodation for calves and yearling heifers. However, a similar herd calving at three years must maintain 60 heifers and house the third-year heifers during their third winter when space requirements are approaching those of adult cattle (Table 4.16).

The first lactation milk yields of heifers calving at two years are likely to be lower than if the age of first calving is delayed. Milk yields of two-year-old calving heifers at the ADAS Bridgets Research Centre averaged 4544kg milk as compared with a yield of 4980kg for heifers calving at three years (Furniss *et al.*, 1986). However, when differences in the mean calving interval are taken into account the effect on yield was marginal (Table 5.1). This is supported by more recent research (Pirlo *et al.*, 2000) which showed that as age of first calving increased there was generally an increase in milk yield and milk fat percentage, but at the same time rearing costs increased. The optimum age for first calving still appears to be approximately 23 to 24

Table 5.1 Effect of age at calving on first lactation milk yield.
Source: Furniss *et al.* (1986).

| | Age (years) | |
|----------------------------|-------------|------|
| | 2 | 3 |
| Milk yield (305 days) (kg) | 4544 | 4980 |
| Calving interval (days) | 386 | 401 |

months. It is known that the average life expectancy of two-year calvers is greater and the lifetime milk production higher than heifers calving at three years (Table 4.17).

There are a few circumstances when it is preferable to adopt a policy of calving heifers at two and a half to three years. Calving at an older age reduces the management pressures imposed by the two-year system and permits the utilization of marginal land unsuitable for cropping. It also enables replacements to be taken from cows of high genetic merit even if they calve later in the season. Calving at three years can only be justified when there is a large area of outlying rough grazing.

Month of calving

Most dairy farmers plan to calve their heifers in a batch at one season of the year. Autumn-calving herds find difficulty in maintaining this seasonality in the pattern of calving unless either herd fertility is high or a proportion of the calves reared for replacements are taken from heifers. The optimum month of calving varies with the relative prices of milk and compound feed and with the management pressures from other enterprises. Once the optimum month of calving for a herd has been established the heifers should be mated to calve at the same time or shortly before the earliest calving cows.

Calving heifers before the cows reduces the stress imposed following introduction to the herd and allows for a longer interval between calving and service. However, some farmers prefer to calve heifers at the same time as the early calving cows as they find that they are then easier to manage in the parlour.

Rearing management, 3–6 months

Management and housing

Heifers should be housed in semi-covered yards such as that shown in Fig. 5.1. The calves should be given as much fresh air as possible with a draught-free lying

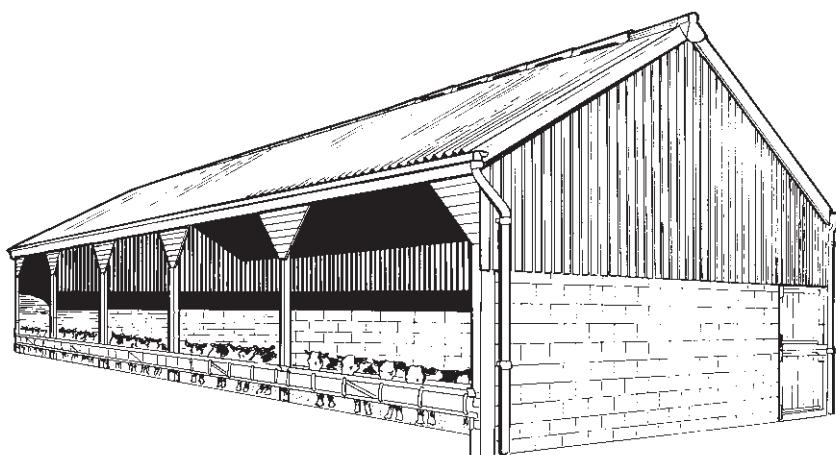

Fig. 5.1 Example of a well-ventilated calf house.

area. Autumn-born heifers should be housed throughout the period but spring-born heifers may be turned out towards the end of the period if afterbirths are available.

Feeding

Minimum target growth rates during the first year of life should be based on estimated mature body weight. A steady liveweight gain at a rate equivalent to the estimated mature body weight in g/day is required. Thus a Jersey heifer with a mature weight of 500kg should be predicted to grow at 500g/day (0.5kg) while a Holstein should be expected to grow at a minimum of 700g/day (0.7kg).

It is important to maintain a constant rate of gain. Poor growth rates, whether caused by an inadequate diet or disease, are likely to lead to compensatory gain at grass, which can have an adverse effect on subsequent milk yield.

From 12 weeks of age the calves should be fed to achieve target growth rates, with either a silage, hay or straw based diet offered, supplemented with concentrate feed as either a rearing nut or home mix. The total diet at this stage would typically be approximately 16 per cent crude protein. The amount of concentrate feed offered should be varied according to forage quality and the growth rates required. Forage should be of high quality, fresh and palatable. Calves should not be given forage that would be unacceptable to cows. Calves fed silage should also be offered clean barley straw and can be expected to take about 5 per cent of their roughage in this form. Regular monthly weighings are essential to monitor progress and adjust nutrition. On infected farms consideration should be given to vaccination against lungworm prior to turnout (see p. 274).

Rearing management, 6–12 months

Management at turnout

Autumn-born heifers should be turned out to pasture when weather and soil conditions permit. After turnout the winter ration should be continued until the forage intake declines, generally within one to two weeks. The compound can then be withdrawn. Spring-born heifers are normally housed until afterbirths become available.

Supplementary feeding

Following withdrawal of compound feed soon after turnout, no supplementary feed should be required until late August or early September. Attention should be given to mineral and trace element supplementation, especially in areas of known deficiency (see Chapter 21).

Optimum growth rates

Stocking rates should be adjusted to maintain a steady rate of liveweight gain over the summer. During May and June when grass is of high quality it is not unusual for heifers to grow at 0.8–1.0kg/day unless a tight stocking density is maintained. In the months leading up to puberty it is desirable to restrict daily liveweight gains to approximately 0.7kg/day for Holsteins or equivalent for smaller breeds based on the animals' predicted mature weight.

It is known that high growth rates in prepubertal heifers are detrimental to milk production (Little & Kay, 1979; Drew & Altman, 1982). A typical relationship between early liveweight gain and the first lactation milk yield of heifers is shown in Fig. 5.2. Mammary growth and development is under hormonal control and serum concentrations of some of the hormones

involved are affected by plane of nutrition (Sejrsen & Foldager, 1992; Sejrsen, 1994). It is likely that the negative influence of a high plane of nutrition on mammary growth is caused by changes in the secretion of

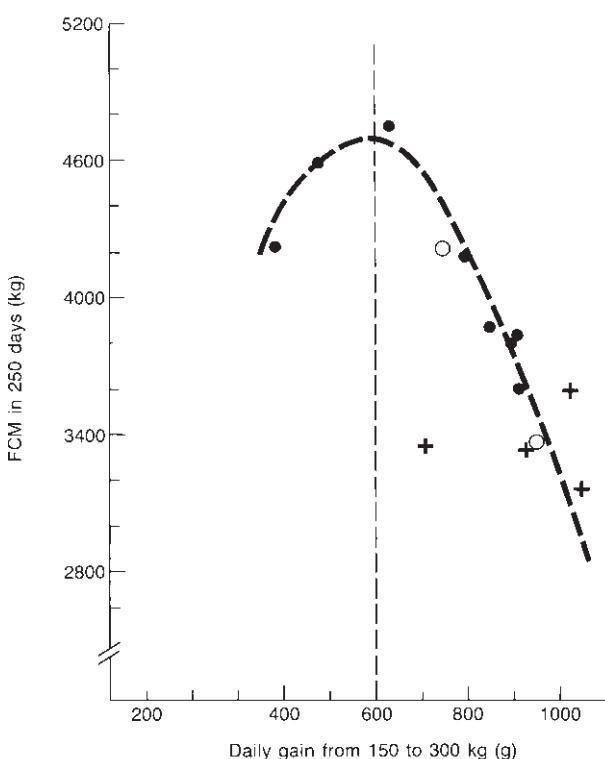

Fig. 5.2 First lactation milk production in relation to early life liveweight gain (after Foldager & Sejrsen, 1982).

these hormones. Rapid growth before puberty has been shown to coincide with impaired development of the mammary epithelium, decreased serum growth hormone and elevated serum prolactin concentrations (Foldager & Sejrsen, 1982). After puberty there is little or no effect (Fig. 5.3).

Summary evidence from recent studies at ADAS Bridgets suggests that there are production and economic benefits from restricting the rate of liveweight gain (to around 0.7 kg/day) in the prepubertal period, in terms of subsequent milk yield performance, with little or no loss in terms of onset of puberty or first calving age and weight. There is also a potential benefit to be gained from a period of cheaper feeding followed by compensatory growth.

Grazing systems

Ideally, calves should be turned out to pasture with a low level of parasite challenge. Up to late June this can be classified as land that falls into one of the following categories: new seeds after an arable rotation and grassland used only for conservation in the previous year. After mid July a pasture can be assumed clean if either it is an aftermath or not grazed by cattle earlier in the year (Chapters 19, 60).

If parasite-free calves are turned out to and remain on a clean pasture it should be safe to graze for the remainder of the season. Unfortunately, in intensive dairy systems it is seldom possible to provide clean grazing as such. On permanent pasture, helminth egg output can be suppressed by anthelmintic treatment.

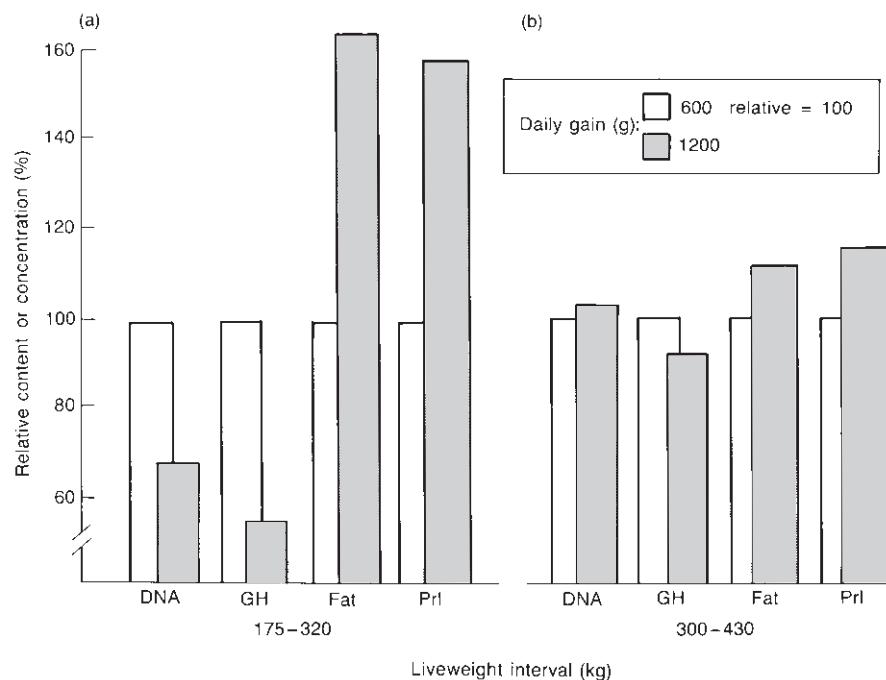

Fig. 5.3 Relative content of DNA and fat in mammary glands and serum growth hormone (GH) and prolactin (Prl) concentrations in (a) prepubertal and (b) post pubertal heifers raised on two planes of nutrition (after Foldager & Sejrsen, 1982).

Overall it is important to reduce parasitic challenge in the heifers' first grazing season whilst allowing sufficient challenge for them to build up natural immunity. Individual parasitic control programmes should be drawn up for each herd (Chapter 19).

In continuous grazing systems the stocking rate should be adjusted to match the grass available and the required growth rate, aiming for a sward height of 5–6 cm in spring, 7–8 cm in mid summer and 9–10 cm in autumn. In what is known as the '1–2–3' grazing system the grazing area dedicated to the heifers is divided into three blocks. In spring the heifers graze one area while the other two blocks are cut for silage. Later the heifers graze the two silage aftermaths while the grazed block is cut for silage. At the end of the season all three blocks can be used for grazing.

An alternative grazing system is described as the 'leader–follower' system. This is a rotational grazing system of eight to twelve paddocks where the youngest heifers graze each paddock ahead of older heifers (Kossaibati & Esslemont, 1986).

Grass growth and supply should be monitored throughout the summer to achieve the required growth targets. Concentrate supplementation should be provided if required.

Autumn management

During the period May–August target liveweight gains should be achieved without difficulty. At the end of this period the heifers should be well grown for their age and breed without any obvious fatness (Table 5.9).

Heifers calving at two years require supplementary feeding from late August or early September depending on grass growth, soil and weather conditions. Growth rates decline rapidly from this time and if additional energy is not supplied liveweight gains will be low. A compound feed or home mixed cereal ration supplemented with minerals and vitamins should be fed.

Regular weighings are essential at this time for both autumn- and spring-born heifers programmed for calving at two years. Heifers being reared to calve at three years can be allowed a store period.

Autumn-born heifers should be assessed for size and suitability for service. Actual weights should be compared with targets. If any animal is found to be below target but, with additional feeding, could attain the minimum service weight, she should be housed at the beginning of September and fed an appropriate ration.

Rearing management, 12–15 months

Housing and management

Heifers reared for two-year calving should be housed at least six weeks prior to service and given any routine

veterinary treatments required during the period. They should be housed in semi-covered yards with a total space allowance of approximately 6 m²/animal. A clean concrete loafing area should be included to encourage good hoof development. A special area of cubicles can be left to train the heifers.

Feeding for fertility

It is known that the level of nutrition over the service period is important in ensuring high pregnancy rates and entry into the herd at the optimum time. In a study undertaken on six commercial dairy farms, the fertility of heifers fed rations considered to be adequate by the farmers was compared with the fertility of heifers fed the same diets supplemented with cereal (Drew & Pointer, 1977). The supplemented diets were calculated to provide an additional 20 MJ/day metabolizable energy (ME) and were fed for a 12-week period commencing six weeks prior to service. Ovulation was controlled and the heifers were inseminated at a fixed time. Semen and inseminators were used equally over all groups.

The calving rates to fixed time insemination are shown in Table 5.2. There was a wide variation in fertility between farms, but on each farm a higher proportion of heifers fed the improved ration calved to the synchronized service. The calving rates to first service for the heifers on the farm ration ranged from 32 to 67 per cent and for the supplemented groups from 59 to 79 per cent. In this study, no significant relationship between body condition score and fertility was found. However, other workers have reported a relationship between body condition and fertility, with lower pregnancy rates occurring at each end of the score range.

It is likely that change in body condition score has a greater effect on fertility than the actual score at service. Holstein/Friesian heifers weighing 350 kg require to grow at a rate of approximately 0.8 kg/day in order to maintain body condition. As it has been shown

Table 5.2 The effect of level of nutrition on the fertility of dairy heifers.

| Farm | Number of heifers | Percentage calved to the synchronized insemination | |
|-------------|------------------------------|---|---------------------|
| | | Control | Supplemented |
| 1 | 62 | 40 | 67 |
| 2 | 58 | 59 | 75 |
| 3 | 56 | 32 | 59 |
| 4 | 37 | 67 | 79 |
| 5 | 78 | 54 | 69 |
| 6 | 73 | 53 | 67 |
| Mean | 61 | 50.0 | 68.9 |

that loss of body condition is associated with low pregnancy rates a ration calculated to provide for maintenance and at least 0.8kg/day liveweight gain should be provided to Holstein/Friesian heifers over the service period. Rations for other breeds should be adjusted according to relative body size.

Attempts to reduce the period of supplementary feeding to three weeks before and after service have been only partially successful. Reducing the period of supplementary feeding to three weeks prior to service should only be considered if Friesian heifers are in condition score 2.5–3.0 (Holstein and Jersey 2.0–2.5), or heifers are to be mated by natural service or observed oestrus artificial insemination (AI) and the reduced period of feeding does not affect the time of housing. The period of supplementary feeding after service should not be shortened as it is likely to increase the incidence of early embryonic loss.

In addition to providing a ration to satisfy the above standards it is important to avoid major changes to the composition of the diet during the ten days before and after service. Changes in diet are almost always associated with disappointing pregnancy rates.

Stress

Stress, such as that caused by noise, physical trauma, overcrowding or some routine veterinary treatments, can alter the concentration and pattern of secretion of the reproductive hormones and is, therefore, potentially detrimental to fertility. In intensive management systems it is difficult to eliminate the possibility of stress, but with careful planning it can be reduced to a level at which pregnancy rates are not likely to be affected.

Housing should be undertaken six weeks prior to service as oestrous behaviour is suppressed during the first oestrous cycle after housing. It is important to ensure that sufficient trough space is provided to avoid competition. There should be an adequate loafing area, the building should be well ventilated and the floor such that animals in oestrus will not slip. If AI is to be used, the handling facilities should be designed to allow for quiet and efficient movement of animals. The heifer should be presented standing at the same level as the inseminator and restrained from sideways movement.

Breeding policy

Some farmers consider oestrous detection in heifers to be too difficult and time consuming for AI to be practical. This is likely to be a problem when groups of heifers graze outlying fields away from satisfactory handling facilities. Synchronization offers a possible solution to this problem but the management standards on farms

Table 5.3 The effect of the parity of the dam on lactation performance of heifers.

| | Dam | |
|--------------------------------------|---------------|------------|
| | Heifer | Cow |
| Weight at first service (kg) | 370 | 360 |
| Weight at calving (kg) | 496 | 503 |
| First lactation yield (305-day) (kg) | 4977 | 4742 |
| Proportion rebred | 0.8 | 0.8 |

must be good to achieve acceptable results and avoid disappointment.

The cost of keeping a bull is often less than AI but the risk of disease and injury are greater. The increased cost of using AI can only be justified if a pure bred sire is used and the female calves reared for herd replacements. A few farmers are still reluctant to take replacements from heifers, preferring to use mature cows with a proven record of performance. The rate of genetic progress will be greater when replacements are taken from heifers, providing a sire of high genetic merit is used.

A study by Furniss *et al.* (1988) of the first lactation and breeding records of 569 heifers calving in a Friesian/Holstein-based herd showed that those heifers born to heifers yielded significantly more milk in 305-day lactation than those from cows (Table 5.3).

Rearing replacements from heifers and the earliest calving cows enables a two-year calving policy to be adopted, with herd replacements entering the herd at the optimum time. The management of the heifer rearing enterprise is simplified as it should only be necessary to rear calves born over a six to eight week period. It also assists in the maintenance of the optimum calving pattern as the later calving cows can be mated to a beef bull.

The incidence of dystokia need be no greater with a selected AI Holstein/Friesian bull, than a Hereford bull used in natural service. In a survey of 61 herds recording aspects of rearing and calving experience with heifer calvings, the incidence of dystokia associated with Hereford sires, averaged over all data, was almost identical to that associated with Friesians (Table 5.4). There was no difference between the breed in calf mortality rates. When using Holstein/Friesian AI bulls for heifer inseminations there is no need to restrict the selection to those noted to be easy calving although those recorded as having greater than average calving difficulties should generally be avoided. The most critical factor is overall heifer rearing management to ensure that they are large but not fat at the time of calving.

Sire selection: breeding replacements from heifers

A survey of farmers breeding replacements from heifers showed that the main selection criterion was 'ease of calving'. It would appear that it is not unusual for this issue completely to override all the principles taken into account when selecting replacements from cows. Any heifer mated to a pure-bred bull is potentially a dam of the next generation. The bull used must be at least as good as those used on the cows and should also be genetically superior to the sire of the heifer to which it is mated. Only by adopting these basic principles can genetic progress be made. When a bull is considered to be of sufficient merit to be a sire of the next generation, attention should be given to the effect that he may have on the incidence of dystokia.

Selecting a sire (see p. 48–9)

Genetic improvement has long-term effects on herd performance and profitability. The effect is cumulative, making the inclusion of heifers in the breeding of replacements important for maximizing genetic progress (Table 5.5). It is advisable to select a 'team' of several sires (typically three or four) for a herd, including two or more which are suitable for use on maiden heifers. Using several sires reduces risk, although too

many can lead to unnecessary complication and lack of uniformity in the herd. There are two key economic indices used to describe the overall production potential of sires in the UK: these are profitable life index (£PLI) and production index (£PIN). £PLI and £PIN are used to describe the average net margin per cow per year which the bull is likely to pass to his daughters and bulls can be ranked on these values for comparison. A short list of sires based on their £PLI and their overall type merit can be produced as a starting point. The cut-off point for this list is likely to vary depending on the genetic merit of the existing herd, with high genetic merit herds having to apply higher standards of selection to ensure progress continues to be made. It must be ensured that the average £PLI of the bulls selected is higher than the average £PLI of the cows/heifers to be mated. The predicted (production) transmission ability (PTA) indicates the relative production potential in terms of milk volume and composition. The reliability of PTAs should be considered: the higher the reliability, the greater the confidence in the predicted values. Generally, sires with a PTA reliability of 70 per cent or greater should be selected. Once a short list of top production bulls has been produced, the selection should be refined using factors such as milk composition and functional conformation traits including udders, legs and feet, SCC and calving difficulty.

Selecting for longevity

Few studies have been undertaken in this country on the relationship between conformation (type), production and longevity. Many studies of these relationships have been undertaken in the USA and show that first lactation yield is the best early indicator of longevity and lifetime yield of dairy cattle. Type scores may add a little to the accuracy of prediction, but not nearly as much as is commonly assumed by breeders. To a great extent, longevity in cows depends on the management

Table 5.4 Effect of breed of sire on dystokia in heifers.

| Breed of sire (No. of heifers) | Percentage of calvings | | |
|-----------------------------------|------------------------|----------|-----------|
| | Unassisted | Assisted | Difficult |
| Friesian (1181) | 63 | 25 | 12 |
| Hereford (753) | 63 | 24 | 13 |

Table 5.5 Example of accumulating genetic merit in younger animals.

| Lactation No. | No. of animals | Average £PIN ^a | Average PTA ^b | | | | | Average reliability |
|---------------|----------------|---------------------------|--------------------------|----------|-----------|---------|----------|---------------------|
| | | | Milk (kg) | Fat (kg) | Prot (kg) | Fat (%) | Prot (%) | |
| Young stock | 289 | 53 | 460 | 13.0 | 14.6 | -0.08 | -0.01 | 27 |
| 1 | 97 | 48 | 417 | 11.6 | 13.3 | -0.07 | -0.01 | 44 |
| 2 | 130 | 37 | 314 | 10.1 | 10.1 | -0.04 | 0.00 | 51 |
| 3 | 90 | 34 | 312 | 9.3 | 9.5 | -0.05 | -0.01 | 54 |
| 4 | 73 | 23 | 224 | 5.6 | 6.5 | -0.05 | -0.01 | 59 |
| 5 | 31 | 10 | 148 | 4.1 | 3.1 | -0.03 | -0.03 | 61 |

^a PIN, production (profit) index number.

^b PTA, predicted (production) transmission ability.

decisions of the farmer. However, differences in longevity between cows within the same herd are now believed to be heritable and factors thought to influence longevity are being included in genetic selection parameters.

Selecting for a low incidence of dystokia

The service sire has a considerable effect on dystokia. The results of a detailed analysis of 1485 heifer calvings to six Friesian/Holstein bulls used equally on 58 farms showed that the differences between the bulls used in the percentage of assisted and difficult calvings were statistically highly significant (Table 5.6). However, the effect of the bull was far less marked than the management on the farm on which the heifer calved. Of the 58 farms in the study, 18 reported mean calf mortality rates of 1.3 per cent born dead or died within 24 hours and recorded a low incidence of dystokia with all bulls. Twelve farms reported mean calf mortality rates of 26.9 per cent, which on some farms was associated with a high incidence of dystokia. On the farms with low mortality, none of the bulls was associated with an incidence of dystokia of more than 4 per cent, while on the high mortality farms no bulls resulted in an incidence of less than 20 per cent. In this study the bulls used were known to be breed average or less for both dystokia on cows (<2.7 per cent) and gestation length (<281 days).

In Table 5.6 only bulls 1 and 3 were specifically recommended for ease of calving. This highlights the importance of ensuring that if a recommendation is based on heifer calvings, that the bull has been used on sufficient farms for the data to be reliable.

In general, bulls with short gestation lengths give easier calvings. The mean gestation lengths of bulls in this study ranged from 273 to 279 days. Providing a bull is not known to be above breed average for dystokia on cows, he can be considered for use on heifers, especially if the gestation length is also less than the mean for the breed. However, some farmers reported dystokia with

bulls that were the easiest calving overall, while other farmers reported that heifers calved without assistance to bulls that caused the most problems generally. In view of the considerable variation between farms and farm/bull interactions it is not possible to be certain whether dystokia will occur on an individual farm.

Heifer calves are generally smaller than bull calves and with the advent of sexed semen it is now possible to inseminate maiden heifers with 'female' Holstein semen to ensure maximum genetic progress in the herd and at the same time reduce calving difficulties.

Other factors involved in dystokia are discussed in the section on 'Management at calving' (see p. 65).

Service management

Controlled breeding (see also Chapter 42)

The introduction of synchronization techniques in the mid 1970s offered farmers a unique opportunity to exploit the use of AI without the time consuming and difficult task of oestrous detection or the need to separate individuals from a group for service. The results of numerous studies have shown that the pregnancy rates following prostaglandin or progestagen treatment are similar to those obtained with untreated controls inseminated at observed oestrus. Despite these findings, the uptake of commercial techniques to control the bovine oestrous cycle have fallen well short of expectations, as in the field results can be disappointing where herd management or supervision of the breeding programme are not of a sufficiently high standard.

There are many reasons why group synchronization of heifers has failed to become a technique in widespread use. Initially, farmer expectation was too high. Many had been accustomed to running heifers with a natural service bull for perhaps nine to twelve weeks. By this time around 90 per cent should have become pregnant, even with modest levels of performance. Farmers have, therefore, become used to finding the majority of heifers confirmed in calf when manually examined as a group and tend to expect similar results from a single AI mating.

Compared with natural service, the cost of a controlled breeding programme with AI is likely to be at least £25–£35 if a double insemination is given. If only 40 per cent of served heifers produce a calf and 50 per cent of those are male the service cost per heifer calf born could easily be in excess of £100.

Although pregnancy rates of 40 per cent are not unusual, the management factors affecting fertility in dairy heifers are generally well understood. Providing the recommendations given in the section 'Rearing management, 12–15 months' (see p. 58) are followed,

Table 5.6 The effect of bull on dystokia in heifers.

| Bull (number of calvings) | Percentage calvings | | |
|---------------------------|---------------------|----------|-----------|
| | Normal | Assisted | Difficult |
| 1 (236) | 52 | 37 | 11 |
| 2 (231) | 70 | 25 | 5 |
| 3 (249) | 79 | 19 | 2 |
| 4 (221) | 71 | 24 | 5 |
| 5 (261) | 79 | 19 | 2 |
| 6 (263) | 63 | 31 | 6 |

pregnancy rates of 65–75 per cent should be achieved. At this level of fertility the use of synchronization becomes more attractive if used only for a proportion of the group.

Several synchronization techniques (p. 678) are now routinely used for controlled breeding of heifers, including the use of prostaglandins, progestagen and GnRH. The oestrous response following synchronization in heifers is generally precise and pregnancy rates to fixed time insemination satisfactory. However, a proportion of heifers do not show oestrus within the expected window after treatment and programmes may therefore recommend AI only at observed oestrus or AI at a fixed time followed by either AI at subsequent observed oestrus or natural service.

An example synchronization programme would be a system whereby the heifers are housed or moved to a field adjacent to the handling facilities six weeks before commencement of service. At the same time the heifers are weighed and the diet adjusted to ensure a minimum gain of 0.8kg/day with adequate mineral supplementation. Any routine veterinary treatments necessary are undertaken and a check made to ensure that the heifers can be clearly and easily identified. After a minimum of four weeks all heifers are injected with prostaglandin and observed closely for standing oestrus. Heifers not inseminated after the first injection are given a second injection and inseminated at a fixed time, either once at around 84 hours after treatment or twice at 72 and 96 hours after injection. Following the synchronized mating either the heifers are observed for repeat AI, or a bull of another breed is turned in as soon as the period of intense oestrous behaviour has subsided, which is usually on the fifth or sixth day after the second injection.

Rearing management, 15–18 months

Housed heifers should be allowed approximately 7m²/head from this age. The preservice ration should be maintained for at least six weeks. As soon as it is known that pregnancy has been established in the majority of heifers, decisions can be taken on the level of nutrition for the remainder of the period. Their weights should be recorded and compared with target (Table 5.9). They should be grouped according to size. Required growth rates should be calculated using the target calving weight and feed adjusted accordingly, with higher levels of supplementary concentrate feed offered to the smaller heifers. Growth rates of up to 1kg/day or more are not uncommon in Holstein heifers at this age. It is likely that, at this age, the variation in weights of heifers of similar age will be around 80–100kg. Adjusting feed

levels according to size at this time enables the heifer group to become more evenly matched. High-quality silage and barley straw without further supplementation should be sufficient for well-grown heifers. A mineral mix should be fed to heifers given silage and straw alone.

Rearing management, 18–22 months

Autumn-born heifers should be turned out as soon as soil and weather conditions permit. Nitrogenous fertilizer with phosphate and potash according to soil requirements should be applied. The sward height should be maintained at about 6–8cm. Target stocking rate at this stage should be six to seven livestock units/ha.

Rearing management, 22–24 months (2 months precalving)

In the two months before calving heifers should be housed or grazed with the dry cows of a similar stage of gestation as this reduces the stress of introducing them to the milking herd post calving. If heifers are to be managed and milked as a separate group during their first lactation, precalving heifers can be managed as a separate group. In the last two months of pregnancy the growth rate of heifers should be controlled to approximately 0.7kg/day.

Growth rates in pregnancy

Target growth rates between the third to eighth month of pregnancy should be approximately 0.8kg/day, but should be adjusted to ensure adequate calving weights. The target calving weight for a heifer depends on her estimated mature body size and the management routine during the first lactation. The target calving weight for a Holstein heifer is around 650kg precalving. In management systems where heifers are fed as a heifer group in the first lactation there is obviously less competition than where heifers are competing with older cows.

Two-year calving heifers competing with cows in self-fed silage systems are at the greatest risk as not only are they relatively small in weight and stature but they are also changing their teeth at this time.

In an investigation involving Friesian/Holstein heifers calving at two years, Keown (1986) showed that growth rate during pregnancy has a significant effect on milk production, with the heavier heifers at calving producing the most milk (Fig. 5.4).

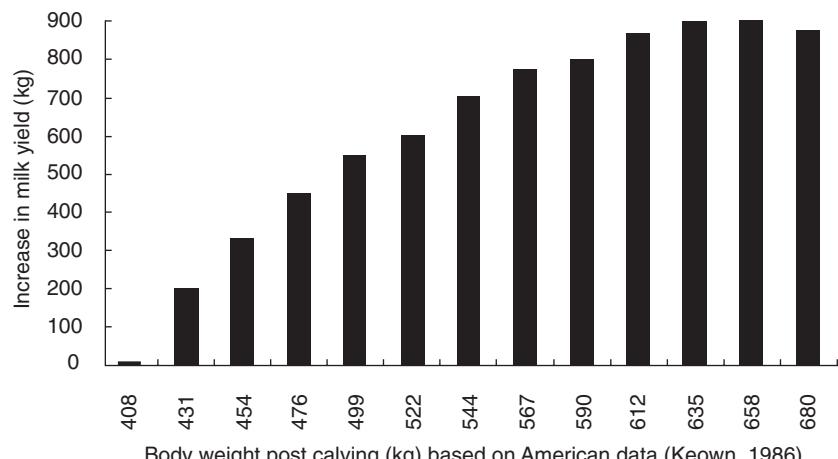

Fig. 5.4 The effect of weight at calving on first lactation yield (increase in first lactation milk yield). Data used with permission.

Weight, height and pelvic length at calving were found to affect milk yield. All these relationships were statistically significant and suggest that while rapid growth in the prepubertal heifer is detrimental to milk yield, the converse applies during pregnancy.

The initial results suggested that there is a positive relationship between body condition score and milk yield throughout the condition score range. However, a more detailed analysis showed that when heifers are fed adequately during the first lactation there is no beneficial effect on milk yield of feeding to calve them at body condition scores above 2.5 for Friesians or greater than 2.0 for Holsteins or the Channel Island breeds. This information is reassuring in view of the fact that an increased level of assistance at calving was required when heifers calved at condition scores of 3.0 or more (see pp. 10–11).

To a considerable extent, dystokia can be avoided by careful management in the ninth month of pregnancy. Growth rate should be restricted at this time.

Fly prevention

Summer mastitis can be a cause of loss in heifers (see Chapter 24). It is most likely to occur between the fifth and eighth month of pregnancy, usually in July, August and September. The incidence of summer mastitis can be reduced by grazing large open fields away from woods and streams and by the use of fly repellent measures. Impregnated ear tags, sprays and pour-ons have proved to be of benefit in preventing disturbance and irritation caused by flies and reducing the incidence of New Forest eye and summer mastitis. The incidence of the latter can also be reduced by regular (e.g. weekly) teat treatment with proprietary fly repellents.

Cubicle training

Some dairy heifers can show clinical signs of laminitis early in their first lactation. This is frequently a stress-related condition associated with changes in the environment, social grouping and feeding, which occur at the time of first calving. It has been shown that housing heifers for a few weeks during a period when cubicles are not occupied by cows has two advantages. Firstly, the heifers become accustomed to using cubicles and are less likely to reject them following introduction into the herd, and secondly, as one of the postparturient stresses is eliminated, the incidence of laminitis and other stress-related metabolic diseases is reduced. Providing a clean concrete loafing area whenever the animals are housed, throughout the heifer rearing phase, encourages better hoof formation and reduces problems when heifers move into cubicle yards post calving.

Minerals and trace elements

A detailed description of some of the minerals and trace elements of particular significance to the dairy heifer is given in Chapters 21, 46. In view of the fact that dairy heifers receive relatively little compound feed, deficiencies are more likely than with the milking herd. The advice given regarding minerals such as phosphorus, copper, cobalt, selenium and manganese fed to dairy cows applies equally to dairy heifers (Chapters 18, 21).

Although iodine deficiency may not be a widespread problem, it can be responsible for serious losses on individual farms (see pp. 253–60). If perinatal calf mortality in heifer calvings has exceeded 10 per cent in previous years an investigation into the iodine status of

the herd is recommended early in the season and treatment undertaken during the fifth to eighth months of pregnancy.

Magnesium supplementation is normally given to dairy cows prior to calving in order to reduce the incidence of hypocalcaemia. As heifers are less prone to this condition, supplementary magnesium is not always provided (see Chapter 46). Data from ADAS trials suggest that magnesium supplementation in the month prior to calving reduces the incidence of dystokia. As the energy intake should be restricted at this time it is usually most convenient to provide this via the water.

Management factors affecting dystokia and calf mortality

Management at around the time of calving has a major effect on dystokia and calf mortality. Management prior to service and during the first eight months of pregnancy is generally considered to have little effect, although opinion is divided. The results of a large-scale investigation into the factors affecting dystokia showed a tendency for calf mortality and dystokia to be greater at each end of the growth rate range (Table 5.7).

On the basis of this study, high weight gains during pregnancy should not result in unacceptable levels of dystokia, especially if liveweight gain is restricted during the final month of pregnancy. An analysis of the precalving weight and height records showed there to be no significant relationships with dystokia.

In order to study the effect of management on the factors affecting calving difficulty and calf mortality, the performance of the 18 farms with calf mortality rates below 5 per cent was compared with the performance of the 12 farms with calf mortality rates over 20 per cent. There was no difference between the groups in the growth rates of the heifers (Table 5.8).

These figures suggest that growth rate of the heifer has little effect on dystokia. Equally, there appeared to be no differences between the groups in the size of the calves born, farmers with both low and high mortality rates recording a similar proportion of small, medium and large calves. The high mortality rate farms assisted a greater proportion of heifers in all of the size group categories and classified 58 per cent of large calves as difficult calvings compared with only 8 per cent of the large calves on the low mortality rate farms.

There is no evidence from these data to suggest that the management of the heifer during pregnancy accounted for the differences obtained. The differences would, therefore, appear to be due mainly to factors

Table 5.7 Effect of weight gain during pregnancy on dystokia.

| Weight gain (kg/day) | Calf mortality (%) | Percentage calvings | | |
|-------------------------|--------------------------|---------------------|----------|-----------|
| | | Normal | Assisted | Difficult |
| <0.4 (49) | 19 | 61 | 35 | 7 |
| 0.41–0.60 (348) | 10 | 74 | 25 | 3 |
| 0.61–0.80 (854) | 11 | 69 | 26 | 5 |
| >8.0 (199) | 14 | 64 | 28 | 8 |

Number of cattle recorded at each weight gain is given in brackets.

Table 5.8 Farms with calf mortality rates below 5 per cent compared with farms with calf mortality rates above 20 per cent.

| Heifer measurements | Low mortality | High mortality |

relating to the management of the heifer at around the time of calving.

Management prior to calving

Providing weather conditions permit, it is preferable to graze heifers in a field or paddock adjacent to the dairy complex, where the forage is naturally sparse or can be deliberately restricted to ensure that the optimum body condition at calving is achieved. The heifers should have the opportunity for exercise. The diet offered should be a correctly formulated transition diet which introduces the heifer to the main forages and feeds which she will be fed post calving. Mineral supplementation remains as for dry cows. Supplementary magnesium should be provided.

The group should be observed at least four to five times daily from three weeks prior to the estimated date of the first calving. Care should be taken to adjust the 'due to calve' dates for the gestation length of the bulls used.

Management at calving

Grazed heifers should calve in their allotted field or paddock if possible; housed heifers should calve in buildings with which they are familiar.

There is evidence to suggest that moving a heifer to a calving box increases the risk of dystokia and therefore it is preferable to avoid movement unless this is essential for adequate assistance (Chapter 67). The field should be well fenced to avoid the possibility of heifers rolling into positions from where it would be difficult to assist. The herdsman should be trained to recognize fear, abnormal pain or distress and instructed on the correct use of calving aids.

Targets for growth for two-year calving

The targets shown in Table 5.9 refer to heifers calving at two years. The target growth rates for heifers calving at 2.5 or 3.0 years are less as they can grow at a slower rate overall and during growth they can be allowed a store period. The maximum growth rates suggested for the first year and the minimum growth rates during the immediate preservice period apply.

Management during the first lactation

Heifers fed in competition with cows during their first lactation are likely to give less milk in the first lactation and have less chance of surviving to calve for a second time than when fed in a heifer group.

Table 5.9 Growth targets for two-year calving of Holstein heifers.

| From | To | Daily liveweight gain (kg) | Target liveweight (kg) (at end of period) |
|-----------|-----------|----------------------------|---|
| Birth | Weaning | 0.50 | 65 |
| Weaning | 4 months | 0.90 | 150 |
| 4 months | 10 months | 0.65 | 280 |
| 10 months | 13 months | 0.80 | 350 |
| 13 months | 17 months | 0.90 | 460 |
| 17 months | 22 months | 0.90 | 595 |
| 22 months | Calving | 0.65 | 630 (pre calving) |

A study involving 179 small-framed Friesian heifers calving at two years, all the progeny of one sire, compared the milk yields and longevity of heifers fed with or without competition during their first lactation. The first lactation milk yields and survival rates to the end of the fifth lactation of heifers at a range of service weights are shown in Table 5.10.

On this farm no allowances were made for the size of heifer or the effect of competition on milk yield. A higher percentage of heifers in the group fed with cows were therefore culled on grounds of disappointing milk yields.

In a subsequent study, the lactation records of 1346 cows on 54 farms were examined to determine the extent to which heifers were affected by competition with cows. The farms were allocated to one of three groups according to the method of management during the first lactation:

Group 1: fed as a heifer group throughout the winter period.

Group 2: housed with cows. Fed a complete diet or manger fed.

Group 3: housed with cows. Fed on self-feed silage.

Heifers fed as a heifer group (group 1) gave more milk than those fed in competition with cows (Table 5.11).

Farmers electing to feed cows in groups are more likely to be aiming for high yields than those where the

| 1 (207) | 5200 | 209 | 170 | 5369 | 319 |
| 2 (580) | 4504 | 180 | 146 | 4641 | 308 |
| 3 (559) | 4274 | 174 | 140 | 4358 | 309 |

whole herd is managed as a single unit. When the milk yields are compared with the average herd yield it can be seen that the true effect in heifers between herds is some 5 per cent of mature potential (Table 5.12).

Although heifers fed in competition with cows during their first lactation are likely to yield less milk, it is not always possible, feasible or economic to manage, milk and feed them separately.

The effect of competition can be minimized by ensuring that heifers are well grown prior to calving. Size is important, but not the only factor determining the peck order within a group of cows.

Immediately after calving a heifer is maternally orientated and may be weakened by a prolonged and difficult calving. She is, therefore, least able to establish her place in the peck order. Bullying following introduction to the herd can be reduced by ensuring that the heifer has regained her strength after calving and by allowing her to join the herd in the late afternoon or early evening when there appears to be less aggressive behaviour. Competition for food can be reduced by providing access to 'easy'-feed silage in self-fed systems. It is as well to remember that heifers calving at two years of age are changing their teeth at this time and find difficulty in extracting silage from well-consolidated clamps. The problem is obviously most acute on farms where the width of the silage face is inadequate or where true 24-hour access is not provided. Silage or other forage should be fed in mangers or cut from clamps and fed behind an easy-feed barrier. The newly introduced heifers should be observed carefully to ensure that they are maximizing forage and concentrate intake. Sufficient loafing areas and loose housing or cubicles should be provided for all the cows in the herd. There is a tendency for farmers to provide 5 per cent fewer cubicles than cows in the group on the assumption that not all the animals will wish to lie down at the same time. Heifers will not always lie in empty cubicles between older cows and therefore it is recommended that one cubicle is provided for each cow and heifer in the group.

Table 5.12 Mean first lactation yields (kg) as percentage of mature yields in different management systems.

| Group | Mean heifer yield | Mean cow yield | Yield difference | Heifer yield as percentage of cow yield |
|-------|-------------------------|----------------------|---------------------|---|
| 1 | 5200 | 6265 | -1065 | 83 |
| 2 | 4504 | 5630 | -1126 | 80 |
| 3 | 4274 | 5479 | -1205 | 78 |

Survival rates

On average, cows in Britain fail to survive in the herd for sufficient time to fulfil their mature yield potential. The mean length of herd life is less than 3.5 lactations, while mature yields are not obtained until the fourth, fifth or even the sixth lactation. It is also estimated that some 40 per cent of all heifer calves born alive fail to calve for a second time. The main reasons for disposal are fertility and low milk production. It is evident that the rate of growth during the rearing period influences milk yield; the level of nutrition at around the time of service affects pregnancy rates and the management of the heifer at calving the incidence of dystokia and calf mortality. It must be emphasized that attention to detail and good management throughout the rearing period have a considerable effect on longevity and overall herd profitability.

Introduction

In the following sections an overview is given of tropical cattle management and the tropical production systems in which cattle are found. Attention is paid to the main differences between tropical and temperate production systems in order to introduce them to the unfamiliar reader. The majority of tropical cattle are kept in extensive subsistence systems that differ fundamentally in their management objectives from commercial temperate enterprises. The latter tend to be specialized single product units whilst in the tropics livestock units are usually multi-purpose with important social as well as commercial objectives.

Statistics

Asia, Africa and South America contain approximately 74 per cent of the world's cattle (Table 6.1) and if other tropical areas are taken into account such as Central America then over 78 per cent are found in the tropics and subtropics. The same tropics produce only 59 per cent of the world's beef and veal and 55 per cent of the world's milk (Tables 6.2 and 6.3).

This discrepancy represents a challenge for those involved in tropical cattle management, since the tropics have many advantages for bovine production. These include: a potential year-round growing season in

the absence of very low temperatures; grass species capable of greater energy capture and dry matter yields than temperate grasses; vast land areas un-utilized or underutilized; labour availability, much with strong animal keeping traditions; and many locally adapted breeds that have been selected for production in adverse environments.

Counteracting these advantages are several constraints, which include: high temperatures which depress production and food intake; long periods without rain when grass growth is impossible; animal diseases, such as trypanosomiasis and those transmitted by ticks; communal grazing systems that inhibit investment and the use of improved management techniques; and a lack of effective local demand and infrastructure to stimulate and support production. These advantages and constraints are discussed in greater detail in the subsequent sections.

The productivity of tropical cattle

The productivity of tropical cattle is sometimes said to be low. This is often untrue when total output is considered. Absolute production levels of milk or meat are usually low compared with temperate cattle, but capital inputs are also usually low. Productivity levels, in terms of use of capital as opposed to production levels, may therefore be relatively high.

The multiple outputs of tropical cattle systems include milk, meat, dung, hides and draught power (Fig. 6.1). Additional functions include acting as a saving mechanism, as a means of realizing emergency cash, as a means of fulfilling social obligations and as a symbol of wealth and status within the community. These outputs are not reflected in commonly used measurements of performance such as offtake, which refer only to products and animals that are sold. Social offtake, barter offtake, subsistence offtake, increases in herd size and the use of animals for draught power are not reflected in normal offtake measurements. The difference between the number of animals sold each year from subsistence systems and from commercial ranches of 8–10 per cent and 18–20 per cent respectively may be explained largely by these differences in objectives and products.

Production strategy

Some people have argued that the tropics are suited to multipurpose low input/low output systems. The environmental constraints on high producing animals and the lower quality forages and byproducts of the tropics

support this view. Intensification and specialization are certainly inhibited by the need for multi-purpose production. However, as development evolves it will probably promote the type of specialization that has taken place in temperate areas. The speed of this evolution will be determined by our ability to counteract the direct and indirect negative environmental effects on the production systems and to capitalize on the positive ones.

Calf management

In traditional cattle systems, such as pastoralism and settled extensive systems, reproductive cycles follow seasonal climatic variation. The peak of calving often occurs in the early wet season. In Sudan, in southern Darfur, most calvings occur in April, May and June. South of the Equator in Zambia the corresponding peak occurs in October and November. In humid areas where there is less seasonal nutritional stress, calvings occur throughout the year.

Fig. 6.1 Draught cows in Guadaloupe.

Preweaning management

In pastoral systems, young calves are separated from the grazing herd during the day and kept in special calf areas. After evening suckling cows and calves may again be separated. In Nigeria, Fulani pastoralists allow calves to suckle briefly in the morning to induce milk let-down and then tether them until milking is completed. After milking the calves suckle until the herds move off for grazing. Calves seldom receive supplements and may not even receive adequate milk due to overmilking for human consumption. This is typical of pastoralism in Africa and the Middle East.

Calf management inputs in these systems are minimal and this is reflected in the levels of production. In arid areas gains may be as low as 200 g/day with liveweights of 60 kg and 150 kg at 6 and 18 months respectively. Calf mortality rates of 15–20 per cent in pastoral herds and of up to 40 per cent in sedentary herds are normally encountered.

Environmental stress, principally due to high ambient temperatures, is best minimized through correct time of grazing, use or planting of shade trees and provision of simple open houses that offer protection from the direct rays of the sun, but ensure maximum air flow.

As production systems improve indoor rearing systems may be adopted. Semi-intensive and intensive calf rearing systems found in the tropics include the following.

- Single suckling for beef calves where the objective is to achieve greatest calf growth rates and conversion of milk to meat.
- Dairy ranching where calves are separated at night and the cows are milked once in the morning and limited or restricted suckling is allowed throughout the day. If management will allow evening milking, suckling all night and separating the cow and calf during the day is a better option, as carried out by some pastoralists.

In the tropics calves may be reared inside, outside or a combination of both. Calves can be reared outside all year, though a number of disadvantages are associated with outside rearing on grass paddocks.

- It is difficult to keep grass sufficiently young and nutritious for calves.
- It is difficult to keep calves free from internal parasites if they are grazing in small enclosed areas.
- Environmental stress (temperature and radiation) can be high, even if good shading is available.

The combination of poor nutrition, parasites and climatic stress is a major constraint to calf rearing. Adequate nutrition is the key to success and to enabling a stable host-parasite relationship to be established.

For the first two months the calf should ideally be kept in an individual stall measuring about 2 × 1.5 m. In warmer areas, portable calf pens may be used. The most practical indoor system is a shed sited in a gravel or concrete yard where the calves may exercise. The house must provide shelter, be easily cleaned and should keep calves warm in cool weather and cool in warm weather. It may be no more than a simple roof over a concrete base. Slatted-floor houses have advantages, but are more expensive (Fig. 6.2). No walls are necessary in the humid tropics, but adequate overhangs are required in high rainfall areas.

Housed calves, if properly managed, tend to perform better than calves on pasture. A typical home mixed ration to accompany whole milk is a mixture of 50 per cent ground guinea corn and 50 per cent groundnut cake from two to three weeks of age.

The calf cannot utilize average quality tropical forage successfully until it is four or five months old. Consequently, it is desirable to suckle or bucket feed for as many months as possible and to feed concentrates and high-quality roughage. In intensive systems, the provision of some good quality forage is beneficial to stimulate rumen development.

Major calf diseases in intensive systems include scouring (gastroenteritis) (see Chapter 14), pneumonia (see Chapter 17) and worms (roundworms,

Fig. 6.2 Australian dairy Zebu calves in Malaysia.

thread-worms, hookworms, lungworms and tapeworms) (see Chapter 19). Suckling systems tend to have lower mortality rates than bucket feeding systems. The advantage is due to the avoidance of disease caused by incomplete sterilization of buckets and equipment, and suckled calves may receive more milk at more frequent intervals. In herds with many calves to be fed twice a day, maintenance of sanitation is difficult and the incidence of gastrointestinal disorders and indigestion in bucket-fed calves is often high (Chapter 16).

Restricted suckling can overcome many problems and is the system commonly practised in pastoral and semi-intensive systems. It is also widely used in the dairy ranching systems of South America. Calves are housed separately, either at night or during the day, and are then allowed to suckle for one minute to achieve let-down before the cows are milked in the morning or evening. The cows are fully milked-out and the calves then run with the cows for the rest of the day or night. When properly managed, restricted suckling systems have several advantages including better calf growth and health, higher milk yields including more saleable milk and are associated with reduced mastitis in the cows.

Weaning

In many systems calves are naturally weaned when the milk supply from the cows ceases due to the poorer nutrition of the dry season. This leaves calves at varying liveweights and different degrees of readiness for survival during the dry period. Where cows continue to produce milk, the chances of reconnection are reduced, often to such an extent that a calving pattern of a calf every two years develops.

In some systems weaning is effected earlier by traditional methods. These may include thorns tied to the calf's head or sacks tied around the cows' udders. Dairy heifers in less extensive systems are best weaned at four to five months of age, depending on the availability of alternative feeds of adequate quality. Beef calves should have maximum benefit from the cows' milk and hence should be weaned as late as seven months. Heifer calves should be weaned early enough to prevent them conceiving to the bull running with the cows. Avoiding early conceptions is difficult in many extensive traditional systems, though in many zebu breeds maturity does not occur until a greater age (i.e. 18 months plus) when animals have reached approximately 66 per cent of their mature weight.

Post weaning management

Once weaned, calves usually encounter a period of sub-optimal nutrition. Reasonable gains can be made in the

rainy season, but weight loss frequently occurs in the dry season caused by combined energy and protein deficiencies. Of the two, protein is usually the more important. Levels of nitrogen in dry tropical grasses commonly fall to around 0.5 per cent, equivalent to 3–4 per cent digestible crude protein (DCP) in the dry matter. At this level of protein, grass digestibility is low and intake falls. The calf may enter a negative nitrogen balance as metabolic faecal nitrogen loss exceeds nitrogen intake. Young cattle allowed only poor quality roughages thus tend to develop a 'bloated' appearance.

Breeds differ in their ability to recover from weight loss. These differences include the ability to reduce metabolic rate during feed shortage and the efficiency of water conservation in periods of water shortage. The latter may lead to increases in feed digestibility due to slower rates of passage. The risk with major weight loss, in excess of 15–20 per cent, is permanent stunting and increased disease susceptibility.

During 'normal' dry seasons deaths are often rare, but once the rains begin, losses may occur due to the stresses of wetting, lower temperatures and highly succulent grasses causing digestive upsets.

Provided that the dry season weight loss is within the range of tolerance of the breed type, then rearing cattle usually show compensatory growth during the subsequent rainy season and make rapid gains (Hogg, 1991). Tropical cattle have been naturally selected to cope with recurring periods of undernutrition and then to compensate effectively. This is a characteristic of great importance which may be threatened by the increased introduction of exotic genes. The physiological mechanisms that allow compensation involve reduced metabolic rate, induced by a period of undernutrition, and increased voluntary food intake during realimentation. The period of realimentation and compensation is determined by the length of the rainy season. This is often short and animals again enter a period of under-nutrition resulting in further weight loss. A 'zig-zag' pattern of animal growth thus characterizes many tropical rearing systems. Whilst dry season losses can be avoided by supplementation this is rarely justified economically.

An understanding of compensatory growth is important for reasons of rearing economy and in the management of feeding trials involving measurement of liveweight gain. Animals that are in a compensation phase may give a misleading result if compared with animals not in a compensation phase.

The consequences of the weight gain/weight loss pattern of growing tropical cattle are several and include delayed oestrus, reduced lifetime performance, reduced selection opportunities and also increased susceptibility to disease.

When rearing stock are housed or confined they may still suffer extended periods of poor nutrition when they are fed adult diets, such as sugar-cane tops or other low-quality byproduct feeds. In pastoral systems greater care is normally given to female stock because of their importance in producing calves and milk. Sub-optimal management of rearing stock is common in all ruminant systems, tropical or temperate. It is unfortunate that the consequences cannot be better communicated to the livestock owners and herders so as to motivate them to improve the management of their rearing stock.

Onset of puberty

Oestrus

In heifers, the period between weaning and calving can be divided into two phases: weaning to first service and first service to calving. The aim is to achieve optimum growth with the earliest maturity at the lowest cost. To achieve this small quantities of concentrate or supplement can be a great benefit. A check in growth occurs at weaning, but can be compensated for by the addition of concentrates.

The onset of oestrus occurs at a particular weight according to breed. Under good conditions regular cycling may be achieved at 13–14 months. In the tropics low nutritive quality of grasses, disease and environmental stresses usually result in delayed oestrus compared with temperate conditions. Whereas *Bos taurus* reach puberty at 30–40 per cent of mature weight, *B. indicus* reach puberty at around 60 per cent of mature weight (Macfarlane and Worrall, 1970).

The weight of the young heifer at first service and its rate of growth up to calving have an important effect on milk yield in later lactations. If early calving is combined with underfeeding in the rearing stage, heifers may be permanently stunted and milk production reduced.

Once heifers are cycling normally and have achieved an adequate body weight, mating or service should be timed to ensure calving at the optimum time of the year. This is often assumed to be the beginning of the rains, but it may be better to aim for calving just before the rainy season. This will allow the calves to start grazing during the rainy season before the quality of the herbage falls and as the dry season approaches.

Sperm production

The onset of sperm production is not as critical as the onset of oestrus. Only where conditions are very poor and liveweights low is the onset of sperm production delayed.

Castration is carried out in many traditional cattle systems, but is usually left until the animal's potential has been assessed. Inferior animals are castrated in order to stop them mating. However, sometimes the 'biggest and best' are castrated to produce draught oxen.

Monitoring growth

In traditional systems, monitoring of liveweight is by eye, but in more controlled systems regular weighing is desirable. If weighing facilities are not available on the farm, heart-girth measurements can be taken using a weigh-band. Attention should be paid to the breed for which the weigh-bands were initially designed, and if possible the accuracy should be checked against actual weighings and the bands calibrated appropriately. Direct weighing and heart-girths do not always fully define the state of the animal and condition scoring may be appropriate. Systems of condition scoring for *B. taurus* cattle (pp. 10, 11) may not be appropriate for *B. indicus* breeds, and scoring systems designed for tropical cattle should be used (Pullen, 1978; Nicholson and Butterworth, 1985). Pullen suggested a score range of 0–5 from emaciated to fattest while Nicholson and Butterworth suggested a nine-point scoring range.

Adult production

The different tropical cattle production systems are the result of differing levels of dry matter production per unit area available for grazing. This varies from very low levels in the arid areas (<1000 kg/ha per annum) to high levels (>10000 kg/ha per annum) in the humid areas, reducing again to low levels where intensive crop production limits grazing to roadside verges and intercrop areas.

Grazing utilization is often complicated by land ownership, which includes 'ownership' by nation, tribe, group or individual. Most grazing is communal and herders have the right to graze as many animals as they wish. Individual ownership and/or leasing of grazing land are increasing and this may stimulate intensification and improvement. Much depends on the availability of employment opportunities for those who are unsuccessful when land rights are allocated. If such opportunities are not available enforcement of land ownership is difficult and social pressure tends to result in the continuation of communal grazing.

Since grazing is crucial in cattle nutrition, the following sections highlight important aspects of grassland production.

Grass production

Grass represents the major link between the sun as the ultimate source of energy and the grazing animal. For the grass, however, the grazing animal can be regarded as a parasite. It is thus important that this relationship is not a destructive one for the grass. Animal productivity depends on a vigorous grass sward and management must safeguard the viability of the herbage above all else.

The factors that determine grassland dry matter productions are amount of light, leaf area, efficiency of species, amount of carbon dioxide, temperature, water and nutrients.

In the short term the manager can determine leaf area and nutrient level and in the longer term the species and possibly water level, through run-off control. Many tropical grasses are physiologically different from temperate grasses. They fix carbon as C_4 rather than C_3 compounds and are regarded as biologically more efficient than temperate grasses. This is partly the result of the structure of tropical grasses, which are taller and more effective in sunlight interception.

Tropical grasses have evolved to survive short rainy seasons. They grow quickly, reproduce and senesce. Whilst grass breeders have extended the growing period of many species, the short life cycle of grasses is still a problem when grazing animals require dry matter throughout the year.

Figure 6.3 illustrates the changes in the nutrient composition of grasses with time.

The fall-off in crude protein (CP) percentages reduces the rate of degradation of dry matter and rate of passage and thereby dry matter intake. While growing conditions are good in the wet season, CP levels can be as high as 12–14 per cent, but can be as low as 2–3 per cent in the dry season. The aim of the manager is to counteract low dry matter intake by appropriate management measures as discussed below.

Range monitoring

The interaction between animals and range is constantly changing and the result may be a long-term improvement or deterioration. A knowledge of the direction of this trend is very important and regular observation (monitoring) should be carried out using the following methods.

Remote sensing: This involves the use of satellites or aircraft to determine land use, land potential and changes in herbage production over time.

Soil and botanical trend monitoring: This involves establishing specific points or transects on the range

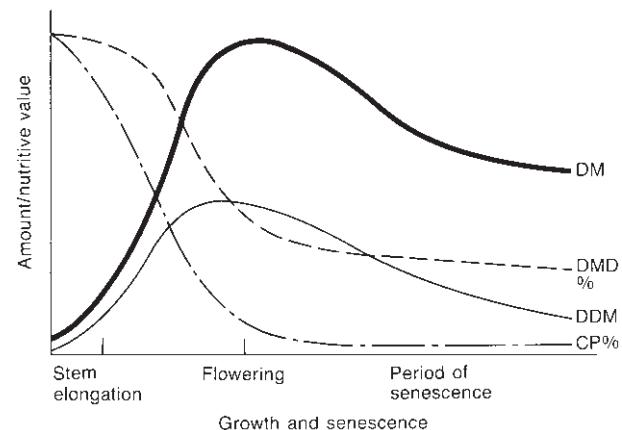

Fig. 6.3 Generalized changes in the amount and nutritive value of herbage during growth and senescence of the herbage. DM, dry matter available for grazing – determined by species and available nutrients; DMD, dry matter digestibility – falls from over 65% to around 40% largely as a result of changes in the crude protein level; DDM, available digestible dry matter – the resultant of DM and DMD; CP, crude protein – falls from over 12% to around 2%.

that can be visited annually to assess the degree of soil erosion and ground cover. The botanical species are identified and the increase or decrease in particular species is recorded. Botanical trend monitoring is appropriate for stable ecosystems where changes occur only slowly. In arid and semi-arid areas with variable rainfall changes can occur relatively quickly. When rains are adequate and grazing pressure reduced areas that appeared seriously overgrazed can recover dramatically through the germination of seeds of annual grasses (Behnke *et al.*, 1993).

Management to maximize voluntary food intake

Maximization of voluntary food intake is the underlying objective in ruminant feeding management. Tropical grasses are less digestible at the same stage of growth than temperate grasses, due to greater lignification. The lower digestibility reduces rate of passage and hence reduces food intake. Some breeds of tropical cattle may have evolved to cope with poor quality feeds through a greater dry matter intake capacity per unit body weight than temperate cattle.

Management strategies to maximize voluntary intake involve maximizing food production, avoiding food losses and stimulating intake as follows.

- (1) Provision of adequate water and water harvesting through the use of ponds and micro terraces.
- (2) Control of grazing time, intensity and frequency to maximize grass production, i.e. maintenance of

- a sustainable carrying capacity according to the manager's objectives.
- (3) Inclusion of legumes in the sward or as browse.
 - (4) Fire control to prevent destruction of accumulated standing hay in the dry season and in ranching systems to control bush encroachment.
 - (5) Exclusion of wildlife and non-authorized grazers.
 - (6) Provision of minerals and, in the long term, correction of soil mineral deficiencies.
 - (7) Simple rotation and grazing by appropriate herding, or use of fencing under intensive systems.
 - (8) Division of the herd into units of need, i.e. young stock, dry cows, lactating cows.
 - (9) Good herding practices, including choice of area to be grazed and duration of grazing.
 - (10) Routine health maintenance.

Systems of production

Management and production levels are determined by factors such as the herder's objectives, climate and land tenure. In communally owned dry areas that are marginal or exclude crops pastoral livestock systems are found with cattle (Fig. 6.4), sheep, goats and camels. In wetter areas small-scale mixed farming systems have developed where sheep and goats are important and where cattle and buffaloes may have a role for milk, meat, dung and draught power. In tropical highland areas where the climate is less severe milk production is often based on exotic cross cattle (Fig. 6.5). Where land is privately owned, particularly in South America, more intensive dairy farming methods occur in combination with large-scale dairy and beef ranching.

Fig. 6.4 Fulani cattle in Nigeria.

Fig. 6.5 Sahiwal x Friesian cattle in Malaysia.

Pastoralism and settled extensive systems of production

Low and unpredictable rainfall coupled with communal land-use rights have led to migratory and seasonal patterns of grazing. Such systems are found throughout the Sahel from Mauritania to Sudan and through Ethiopia, Somalia, Kenya, Uganda and Tanzania. Cattle owners include the Fulani (Fulbe), Tuareg, Dinka, Borana, Karamajong and Masai. Pastoralists keep cattle to meet subsistence needs in areas unsuitable for crops. Milk is a major product that provides a daily source of food or tradeable produce and allows herders to exploit remote areas. Due to recurring droughts and increased population pressure resulting in loss of traditional grazing areas, these patterns are changing in many areas. Pastoralists are being forced to settle and engage in agriculture or some other activity.

Settled production occurs where cattle are combined with crop production. In Nigeria the term 'mixed farming' has been used to denote the use of cattle as draught animals for cultivation. Draught animals are common throughout the tropics and because of their vital role in the production of subsistence crops such as maize, sorghum, millet or rice their management is often better than that of cattle which are not used for draught.

Most settled farming is subsistence in nature and except where used for draught, livestock have a secondary role to crop farming. Management inputs are often relatively low. Land is seldom individually owned and communal grazing is a major method of food supply. The management and improvement of communally owned land are limited by the difficulties associated with getting people to cooperate.

Food inputs are natural pasture, browse, crop residues and supplements. Crop residue grazing is seasonal, but important for extensively managed cattle. Millet and sorghum residues provide early dry-season food and may be stored in stacks for use in the dry season, although they are often grazed off quickly in a 'free for all'.

One technology that has been proposed for improving the system as a whole is that of fodder banks. Fodder banks are fenced areas of high-quality forage that are made available for grazing for only a few hours per day and for only the most needy stock. The establishment of fodder banks has been described by Otsyina *et al.* (1987) using *Stylosanthes* species such as *S. guianensis* cv. Cook and *S. hamata* cv. Verano. Fodder banks have had limited success as has the oversowing of rangeland with legumes. The latter depends for success on the control of grazing, which with extensive grazing is virtually impossible.

Milk production

Milk is produced under a variety of systems, ranging from one-cow zero-grazed units in Mauritius where cows are fed on sugar-cane tops and roadside grasses, to large-scale extensive dairy ranching in Central and South America, intensive large-scale milk cooperatives in India, and very large, zero-grazed, environmentally controlled exotic cow units in Saudi Arabia.

Consumers in the tropics accord a high value to milk as a human food. The rate of increase in milk production has been considerably greater in tropical countries than in traditional milk producing and exporting nations (FAO, 1998). World milk production actually declined between 1989–91 and 1998, but increased by 18 per cent in Africa and 42 per cent in South America over the same period (FAO, 1998). Milk production can be an important enterprise in rural development for several reasons:

- it provides a year-round source of income for the farmer;
- it contributes to family nutrition;
- it can utilize crop byproducts;
- it serves to transfer money from urban to rural areas; and
- it creates rural employment opportunities.

These advantages have led to many development initiatives involving local/exotic crossbreds and sometimes pure exotics. There have been many disasters and failures, but also some notable successes as in India with Operation Flood, and in Kenya and Uganda with smallholder milk production schemes.

The major challenges for milk producers in the tropics include:

- achieving a high intake of good quality food throughout the year;
- coping with disease challenges;
- storage and transporting a bulky and perishable commodity.

Extensive systems: dairy ranching: Dairy ranching is an extensive system of milk and calf production particularly associated with South America, and countries such as Bolivia and Columbia. It is a flexible, dual purpose, low input low output system that depends for its success on the plentiful availability of low cost land and labour. Dairy ranching occurs particularly in those areas where conditions are hot and humid. There is enough moisture to produce sufficient food throughout the year but the temperature is too high to permit specialized high output milk production.

A wide range of genotypes are used in dairy ranching. Crossbreds between *Bos indicus* and *Bos taurus* are

commonly encountered. In the more favourable environments high grade cattle are used whilst in the more difficult areas use is made of pure *Bos indicus* types. Similarly, there is a wide range of production systems. Some farmers milk their cattle twice a day whilst others milk their cattle only once a day. Some depend entirely on grazing whilst others use concentrates. In most cases the presence of the calf is used to stimulate milk let-down and one or more quarters are left for suckling by the calf after milking. The calves are allowed only limited access to the cows. However, much depends on the relative prices of meat and milk. If meat is in high demand then the calf may be allowed more milk in order to promote growth. If the price of fresh milk is high then the amount allowed for the calf may be severely restricted, which sometimes leads to increased calf mortality.

The total milk production from dairy ranching in South America is considerable and may represent half of the total milk consumed in a country such as Colombia. One of the great advantages of dairy ranching is its flexibility and the regular income from milk sales that it offers. It has been adopted as a system by many farmers throughout South America and clearly therefore must be meeting their needs.

Smallholder dairying: the Indian model: India is famous for its Anand pattern of dairy development. It is the fourth highest milk producer in the world after Europe, the Russian Federation and the USA and since 1950 it has more than doubled its output. This has involved the setting up of dairy cooperative societies which all milk producers are eligible to join. Farmers are usually paid for their milk within 12 hours of delivery to a collection point. Payment is based on quality and quantity.

The societies are formed into milk unions, which provide collection, processing and marketing services, and may market livestock feed and provide artificial insemination (AI), veterinary and other services.

Urban dairying in Africa: Recent years have seen a huge increase in urban dairying in and around cities and major towns throughout the tropics. Whilst such developments provide a regular income for producers and readily available fresh milk for the consumers they are also associated with a number of problems. These include urban pollution due to waste accumulation and undesirable smells and noises. Disposal of the carcasses of dead animals is a further problem as are the various threats to human health. The latter arise directly from the consumption of milk and meat containing organisms that cause diseases, such as tuberculosis and brucellosis, or indirectly from the increased activities of

flies and rats which multiply on the wastes associated with livestock farming in confined conditions (Waters-Bayer, 1995). Urban livestock farming, and dairying in particular, has largely developed without outside involvement in response to people's needs for income. They are undertakings that have usually been ignored by traditional ministries and organizations. However, if cities and towns in the tropics are to be developed in keeping with governments' aspirations and hopes then policies to limit and perhaps relocate urban dairying and livestock production are urgently needed.

Semi-intensive and intensive dairy production: In South America, exotic breeds are used intensively in highland areas. Highland areas are found throughout South America and also in Africa on the Jos Plateau in Nigeria, the Kenyan and Ethiopian Highlands and in parts of Tanzania such as Arusha.

Kenya Highlands: The smallholder dairy industry in Kenya has grown impressively over the last 25 years. There are now over 400 000 smallholder dairy farmers producing 70 per cent of milk sold. It is estimated that there are over 3 million dairy cattle in Kenya, concentrated for the most part in peri-urban areas. The majority include some amount of Friesian in their genetic make-up, but other breeds including Sahiwal, Brown Swiss, Ayrshire and Channel Islands have a significant role (Fig. 6.6). The pure exotics are found in the high potential areas in the highlands where lower temperatures and more dependable rains and food supplies make them a sustainable option. Dairy crosses with local Zebus are found in the harsher lower potential environments.

In the most fertile highland areas the production system is based on zero-grazing of Napier grass (*Pennisetum purpureum*) together with the use of roadside grasses and available byproducts such as maize stover, banana stems and sweet potato vines. The use of forage and tree legumes is being encouraged. So intensive is the system that 29 per cent of smallholders buy forage to feed their cows at some time during the year. Commercial concentrates are widely used. Grazing systems of varying intensity are encountered in less fertile areas. In these systems use is made of grasses such as Kikuyu grass (*Pennisetum clandestinum*) and Rhodes grass (*Chloris gayana*).

Yields of around 2500 kg per 10-month lactation period are commonly obtained. The median calving interval amongst the better smallholder herds has been estimated at 426 days. Fifty per cent of herds use artificial insemination with an approximate success rate of 50 per cent. Zero-grazed systems do not lend themselves to easy heat detection and this is an area for continuing extension inputs and training.

Fig. 6.6 Sahiwal and Sahiwal × Friesian cattle in Kenya.

East coast fever (pp. 750–53), transmitted by ticks, is the biggest threat to exotic breeds, although zero-grazing represents a significant tick avoidance strategy. Smallholders are increasingly adopting strategic hand-spraying methods of tick control rather than using government dips.

Many smallholder households in Kenya have benefited both nutritionally and financially from their dairy-enterprise. Perhaps regrettably, intensification and commercialization of milk production tend to be associated with the control of income from milk moving from the women to the men. Nevertheless, it is hoped that the accumulated expertise and improved technologies will allow the continuing expansion of smallholder dairying into the low potential areas of the country (Reynolds *et al.*, 1996).

Beef production

In Africa and Asia beef has traditionally been a byproduct of milk and draught power production. Governments have often been disappointed with the level of beef production from their traditional herds. This has led to the mounting of many projects aimed at increasing beef output. These have included group ranching schemes as in Kenya and parastatal ranching initiatives as in Uganda and several other countries. Most of these projects have ultimately proved uneconomic, although private commercial ranches have usually been more successful.

Increased beef production from medium- to large-scale intensive feedlots has also been attempted with the aim of drawing immature stock from the rural areas for finishing to produce improved quality beef. These initiatives have not usually been successful and small-scale finishing schemes are proving a more successful form of intensification.

Beef may remain a byproduct of milk and draught power in Africa and Asia for the foreseeable future. It is appropriate therefore to focus research on ways of feeding and managing culled cows and oxen so as to maximize their value as meat animals.

In South America the situation is different and specialized high quality ranch beef from extensive systems has found a ready market in America, Europe and the Far East for many years.

There are indications that the demand for meat is growing rapidly in urban areas of the tropics. This represents a tremendous opportunity for beef producers, large and small, in tropical areas (Delgado *et al.*, 1999).

Management of dairy cows

The general objectives of management can be assumed to be broadly the same for all types of dairy cattle.

Ideally, dairy cows should produce a calf every year, since milk production is usually maximized with a 305-day lactation and yearly calving. Since gestation lengths vary between 275 and 287 days, it is necessary for the cow to conceive again within 80–90 days of calving. First service should be at about 50 days after calving. This is seldom achieved in tropical systems, and calving intervals of up to 500 days occur. The main reason is a delayed return to oestrus due to poor nutrition, suckling and other stresses including those of climate and disease.

Artificial insemination is not widespread in the tropics, but in some countries, such as Kenya and Pakistan, insemination services have been operational for many years. The benefits of genetic improvement from AI are constrained by the problems of detecting oestrus, which are especially acute in smallholder one cow units. The achievement of optimum breeding patterns and milk production also depends on the

provision of suitable environmental conditions and proper feeding.

A major objective of the management of dairy cows in the tropics should be the reduction or the avoidance of environmental heat load. This can be achieved in a number of ways:

- Where possible animals should be grazed at night.
- Concentrates should be fed early in the morning and late in the afternoon.
- Adequate water should be provided.
- Natural and constructed shade should be provided.
- Buildings and shelters should be made of appropriate materials.
- Houses and yards should be sited so as to take full advantage of prevailing winds.
- Calving should occur in the coolest season, if nutrition allows.
- Animals should be managed indoors wherever possible, so as to reduce muscular work.
- Animals should be sprayed with water during the hottest periods to facilitate cooling.

The effect of adverse tropical environmental conditions can be overcome to a large extent if cost is not a constraint. In the Middle East, exotic breeds of dairy cattle are maintained in intensive systems and can achieve yields in excess of 8000l/cow per year (Chapters 8, 71).

Feeding (see also Chapter 9)

Dairy cows require higher levels of feeding than growing or working animals. Energy inputs for lactation may equal or even exceed maintenance requirements, though in the tropics requirements for lactation will not usually exceed maintenance. For a 300kg cow producing 1000l in a 300-day lactation, average daily metabolisable energy (ME) requirements will be approximately 30MJ for maintenance and 15–20MJ for lactation depending on the butterfat (BF) content of the milk. Such levels of milk production can be achieved by a number of rations and feeds can be combined according to their degradability, ME content and their CP content. Some typical dairy rations used in southern Africa are shown in Table 6.4.

Other rations can be devised for different tropical regions based on a knowledge of locally available foods such as groundnut cake, wheat bran, maize, oats/barley, green grain, tapioca, rice bran, urea, molasses and cottonseed.

Health and hygiene

The two prime considerations of dairy cow health are the need to maintain optimum milk production

Table 6.4 Typical rations for dairy cows using combinations of feedstuffs. BF = butterfat.

| Feedstuff | Diet (kg fresh weight) | |
|-------------------------------|------------------------|------------|
| | 360 kg cow | 540 kg cow |
| | Diet 1 | Diet 2 |
| Legume hay (average) | 1 | 1.6 |
| Maize silage (average) | 11 | 16 |
| Grass hay (mature) | 2 | 3.9 |
| | Diet 3 | Diet 4 |
| Legume hay (average) | 4 | 4 |
| Maize silage (average) | 18 | 27 |
| <i>Maintenance + 4 litres</i> | (4.5% BF) | (3.5% BF) |
| | Diet 5 | Diet 6 |
| Green lucerne (early flower) | 11 | 3 |
| Grass hay (average) | 3.5 | 18 |
| Maize silage (average) | 9 | 4.5 |
| <i>Maintenance + 4 litres</i> | (4.5% BF) | (3.5% BF) |

throughout lactation and optimum levels of fertility so that cows produce calves at regular intervals. In addition it is necessary to rear a healthy calf to weaning and to first calving. Attention must be given to a number of disease and general health problems.

Tick-borne infections, trypanosomiasis (Chapter 45), helminths and liver fluke (Chapter 19) are major problems in many areas, as is streptothricosis (see p. 886) in parts of Africa. Exotic animals are particularly susceptible to many of the endemic diseases.

Adequate attention to disease prevention is of primary importance in the tropics, where veterinary services are often unavailable (Chapter 69).

In hot climates it is better to milk at the cooler times of day. Milk cooling can present problems where constant electricity supplies are not present. Water supplies to local dairies are often poor and hygiene may be neglected.

Management of beef production

Ranching

In commercial ranching systems both land and animals are under the control of the same active management. This contrasts with pastoral systems where land is communally owned but rarely communally managed.

Table 6.5 Example of routine management programme for an East African cattle ranch.

| Month | Approximate monthly rainfall (mm) | Operation |
|---------------------------|-----------------------------------|--|
| December/January/February | 110 | Calving; ear tagging, weighing and recording |
| February | 100 | Check breeding bulls and cows; cull and replace |
| March | 160 | Improved nutrition for breeding bulls and cows (bulls throughout mating season) |
| March/April/May | 140 | Brand, castrate, dehorn last year's calves |
| April/May/June | 110 | Join breeding bulls to herd of breeding cows Sell marketable stock; steers, surplus heifers, culs |
| May/June | 60 | Supplementation of lactating cows Conserve forage |
| July | 10 | Remove bulls from breeding herd |
| July/August/September | 10 | Wean |
| August | 10 | Pregnancy diagnosis; remove non-pregnant stock |

Under some circumstances a system with two 70-day breeding seasons at four month intervals can be applied and may improve annual calving percentage and economic returns.

Animals are owned by individuals or groups of individuals who try to maximize rather than optimize their use of the communal land.

Ranching can operate throughout a range of intensity levels. Extensive systems may involve a one-herd system with little or no monetary investment other than in the cattle. Intensification may involve one or more of the following stages.

- Water development, e.g. boreholes or small dams.
- Routine health care.
- Mineral supplementation.
- Construction of handling and dipping facilities.
- Correct use of fire, e.g. creation of firebreaks.
- Multiple herd systems, e.g. young stock, steer herds, etc.
- Protein supplementation.
- Fencing, e.g. perimeter and paddock.
- Forage conservation.

An important aspect of ranch management is organizing routines. A routine approach means that the

important husbandry tasks are designated to be carried out at particular times during the year. All concerned then know what should be done and when it should be carried out. Table 6.5 shows an example of a routine programme for a cattle ranch in East Africa. The programme of activities is determined by seasonal feed availability, which is determined by rainfall.

Government and parastatal companies have often involved themselves in ranching to intensify cattle production away from subsistence systems. The attempts have rarely been successful. The reasons have usually been economic, arising from indifferent managements, low meat prices and the high costs of intensification, which have rarely been justified. Most successful ranching is in the purely commercial sector.

Supplementation

Tropical cattle commonly suffer a period of weight loss during the dry season. Compensatory growth

can overcome the worst effects, but feed supplementation may be feasible where it can be controlled. The practical approach should include the use of sustainable stocking rates, fire control, deferred grazing, seasonal control of breeding and tactical marketing. Once supplementation is accepted as a workable option two considerations arise: the nature of the supplement and the stock to be supplemented.

Nature of the supplementation: The supplement should improve the quality of the overall diet rather than act as a substitute for a part of that diet. The effective utilization of nitrogen supplementation in the form of urea mixed in a carrier such as molasses depends upon there being a deficiency of degradable protein in the rumen. This is not always the case and the response to urea supplementation has not always been as predictable as anticipated.

Other forms of background supplement such as minerals are important over the long term, but have no effect on reducing dry-season weight losses. The possible exception is salt, which may serve to stimulate the intake of poor-quality roughage. In Nigeria, a naturally occurring and renewable mineral supplement known as Kanwa is fed to both settled and transhumant cattle owned by Fulani and agropastoralists. Kanwa contains 1.5 per cent Na, 4.7 per cent K, 23.7 per cent Ca, 0.6 per cent P and trace amounts of Mg, Fe, Mn, Cu, Co and Zn.

Increased attention is being paid to the potential of small amounts of highly digestible cellulose as a supplement in the form of legume or browse material. Such material can stimulate cellulolytic bacteria and enable an improved utilization of a low quality diet. Browse usually contains over 10 per cent CP/unit DM and can often have as high as 25 per cent CP/unit DM. It thus forms a good supplement to poor-quality roughage.

Other forms of supplement in Nigeria include cottonseed cake, groundnut tops, cow pea stalks, groundnut cake and also salt, chaff, bran, cut branches and cut grass. In Sudan some livestock owners in the Gezira area provide daily supplement mixtures containing cottonseed cake, groundnut cake, bran and molasses. Where breweries are nearby, brewers' grains may also be available.

Animals to supplement: Not all animals have the same need for supplementation and optimum use of resources can be achieved by identifying an order of priority, e.g. weaned calves, late pregnancy/early lactation cows, breeding heifers. Lowest priority will normally be given to growing steers.

Drought: Drought conditions represent a special case for supplementation where survival is the objective. An early difficulty is establishing that drought, as opposed to a long dry season, exists. When the fact is established a number of options are available: (i) do nothing; (ii) sell some stock and buy feed; (iii) sell all stock and restock later; or (iv) move animals to an area with grazing.

Where supplementation is adopted it is important not to start supplementing too soon, but to allow animals to lose some weight to reduce their maintenance requirements. Bovines have adaptive mechanisms for dealing with drought, one of which involves a reduction in metabolic rate. Such mechanisms should be activated prior to survival supplementation.

Animals at greatest risk and females required to continue the herd after the drought should be given priority for drought feeding. Once a decision has been taken to provide survival feeding the feedstuff is usually determined by cost and availability. Infrequent feeding of large amounts is probably preferred so as to ensure every targeted animal gets some feed.

Feedlots

Feedlots have been set up in different forms and for a wide variety of reasons; as large- or small-scale units, as commercial or government sponsored ventures to produce export quality carcasses and as a means of trying to reduce overgrazing of communal areas. Initial developments tended to follow the large-scale pattern of North American feedlots, but it is now recognized that small-scale projects that demand more labour than capital are more sustainable.

Certain circumstances are required before intensification becomes an economic strategy, as follows.

- Beef is one of the most expensive meats within the country.
- Animals are economically available for feeding on a continuing basis.
- Above average quality feeds are economically available on a continuing basis.
- Adequate initial funding is available.
- Infrastructural factors such as transport, communications, husbandry and health services are available and adequate.
- There is an absence of restrictive factors, e.g. butcher cartels or legal restrictions on export.

A failure to satisfy these requirements has led to the limited success of many feedlots.

Fig. 6.7 Stall-fed fattening of Fulani cattle in Nigeria.

Smallholder fattening

In Malawi a smallholder fattening project was started as long ago as 1957 and has now expanded to other parts of the country. It has proved to have many benefits, as follows.

- Home-grown beef for the local market saving foreign exchange.
- A means of saving for farmers, which can be used to invest in crop production.
- The provision of manure for the maintenance of soil fertility.
- Stabilization of the farming system by providing an employment opportunity.

The participating farmer must build a suitable stall for one or two animals. Several farmers commonly build their stalls together. Farmers receive a credit steer of 260–280 kg with the assistance of the extension services. This is fed on maize stover, groundnut haulms and maize bran during the dry season and cut-and-carry Napier grass (*Pennisetum purpureum*) and/or Rhodes grass (*Chloris gayana*) during the rainy season. Average daily gain is about 0.5 kg and with approximately 200 days feeding total gains of 100 kg are achieved producing a final weight of 360–380 kg.

In Nigeria, stall feeding and fattening is also carried out and is a common method of cattle production in the subhumid zone and northern savannah areas (Fig. 6.7). Farmers often keep up to six animals, usually young bulls, for 18–24 months before selling them to urban traders. This method of production has been the subject of a major extension exercise by the National Livestock Projects Department in Nigeria, and has been of some

success in Kano State where work bulls after 2–3 years are stall-fattened for 6–8 months and sold to butchers.

Introduction

Over the last 30 to 40 years most ‘top-down’ rural development projects in the tropics have continued to have disappointing results. In response to this, and prompted largely by social scientists, there has been a growing awareness that an appreciation of rural people’s local knowledge should be the starting point for discussing development interventions of any kind. This participatory ‘bottom-up’ approach is now being applied across all areas of natural resource use in the tropics. As regards the maintenance of health amongst the livestock resource it is Constance McCorkle, an anthropologist, and Evelyn Mathius-Mundy, a veterinarian, who have done most in the last 15 years or so to bring attention to that local knowledge in the tropics which deals with animal disease treatment. This body of knowledge is now commonly referred to as ethnoveterinary medicine (EVM). The objective of this chapter is to highlight the key issues and developments in EVM in the tropics.

Definition and examples of nature of EVM

For the purposes of this chapter ethnoveterinary medicine is defined simply as the traditional treatments and practices that livestock keepers are using now, other than modern synthetic drugs. The majority of the treatments are of plant origin. Some EVM involves magico-religious practices. Although these latter practices can be very important to those who use them, they are not discussed here.

There is an increasing amount of literature listing and describing EVM practices (Mathius-Mundy &

McCorkle, 1989; Bizimana, 1994; IIRR, 1994), including various internet sites. Some examples of EVM from these and other sources are presented below.

The majority of ethnoveterinary practices are aimed at relatively chronic conditions such as internal and external parasites, digestive disorders such as inappetance, constipation, diarrhoea and bloat, wounds, lameness, non-specific ‘fevers’ and ‘coughs and colds’.

In Ethiopia goatkeepers boil the leaves of the castor-oil plant (*Ricinus communis*) to provide a viscous liquid which they use to control mange in their goats. The active agent, ricin, is very poisonous for humans and provides an example of an EVM agent that must be handled with care (Peacock, 1996).

In many Mediterranean countries honey is used on wounds to promote healing (personal observation). The mode of action is believed to be partly achieved through an osmotic effect which draws fluid into the wound. This fluid serves to ‘flush out’ dirt and other contaminants and thus promotes healing.

There are many plants which appear to have some anthelmintic effect: *Artemisia maritima*, *Caesalpinia crista*, *Melia azedarach*, *Mallotus philippensis*, *Chrysanthemum* spp., *Matteuccia orientalis*, *Carica papaya*, *Heracleum* spp., *Hedysarum coronarium*, *Aloe barteri*, *Terminalia avicennioides* and *Diospyros mollis* (Hammond *et al.*, 1997). Firing and bloodletting are widely used practices to treat problems such as lameness and inflammation. These practices are most commonly used by owners of horses and donkeys.

Why ethnoveterinary medicine?

In addition to the increasing appreciation of local knowledge as explained above there are several other reasons which have contributed to the recent growth in interest in EVM at farm, local, national and international levels.

Antibiotics, acaricides and anthelmintics can be dramatically effective when affordable and correctly used. However, the rising cost of these medicines and its consequences is now a major issue. If the cost of a treatment is a significant proportion of the value

of the animal that is being treated then one or more things may happen:

- The animal is left untreated or a low cost EVM method is used.
- The seller of the chemical dilutes it to make it cheaper and so that it will 'go further'. Monteiro *et al.* (1998) in Kenya found that of seven anthelmintics marketed as containing levamisole, an effective anthelmintic agent, two contained none, whilst two others had levels of levamisole of 11.8 per cent and 78.7 per cent of the amount stated on the label.
- Livestock owners who buy costly drugs may also try to make them 'go further' by diluting them, by underdosing or by not completing the full recommended course of treatment. All abuses of drugs are associated with incomplete cures and with the promotion of organism resistance.

Even when properly administered the long-term regular use of drugs and chemicals such as anthelmintics and acaricides leads to the loss of an animal's natural resistance. If for whatever reason the anthelmintics/acaricides are suddenly unavailable the animal is totally exposed to the worst effects of the parasites and organisms which these drugs are keeping under control. For this reason the routine use of acaricides, for example, has been questioned for some time (Norval, 1983).

Farmers in the tropics rarely have any awareness of the environmental damage and pollution that may be caused by the incorrect disposal of chemicals and/or the associated packaging.

Globally there is a growing interest in 'alternative' and 'sustainable' approaches to disease treatment. In human medicine what were once regarded as 'odd', such as herbalism, acupuncture and homeopathy, are now taken seriously. Veterinary medicine is currently evolving, in a similar way (see Chapter 65).

Advantages and disadvantages of EVM

The advantages of EVM are as follows:

- Livestock keepers are already familiar with it, it is what they use now.
- A significant part of it appears to 'work'. For example, Bennet-Jenkins and Bryant (1996) tested the anthelmintic effect of *Eucalyptus grandis* leaves with feral goats. On autopsy these authors found 91

per cent fewer *Haemonchus contortus* in the treated group as compared to the control ($p < 0.05$).

- It is freely available or at a cost in proportion to the value of the animal.
- It is easily administered, usually topically or orally.
- EVM relieves the worry and concern of owners of sick animals in that it makes it possible to do something, effective or not, for their animals.

However, EVM is not without disadvantages and limitations:

- Particular methods are often geographically localized and the scope for their further dissemination is limited.
- Cures are variable in their effectiveness according to season, method of preparation, etc., and few if any have been validated in the same way in which synthetic drugs must be validated.
- From a technical standpoint some are totally ineffective.
- EVM has little to offer against the acute viral diseases of animals, other than treatments for the signs.
- EVM is not always practical on a large scale. A particular EVM method may require considerable amounts of leaves, seeds or even roots. Identifying a plant as certainly medicinal may lead to its total destruction. In Nepal people have been excluded from some forests because of the excessive collection of medicinal plants, albeit they were for use in human medicine.

In the new millennium the major arguments for giving greater attention to EVM include the following:

- It is what livestock keepers use now and, by definition therefore, should be the starting point for any animal health intervention.
- It would be unwise to rely on only one strategy for disease control, i.e. modern drugs, when the strategy has limitations, some of which have been highlighted above.
- In the long term the 'official' recognition of EVM empowers those who practise it, with potential benefits for increased participation in other areas of social and economic development.

The way forward – validation?

Over the last 15 years or so there have been many publications listing EVM medicines and practices, as indicated above. However, there have been very few trials and validations of EVM that stand up to rigorous

scientific scrutiny. There may be a bias in favour of identifying treatment success with EVM, as has been observed in human ethnomedicine (Roscoe, 1991). Thus it is now timely to bring to EVM the rigour of objective assessment.

Hammond *et al.* (1997) have outlined one approach for the identification and validation of anthelmintic plants used in EVM. In brief this methodology involves the following stages:

- A wide-ranging survey to identify all relevant EVMs and the people involved.
- Selection of the 'best bet' anthelmintic plants being used against the most economically important diseases.
- Study of selected plants in terms of their use in human medicine, given that many plants are used in both human and animal medicine.
- Preparation of the test medicines in the ways used by the livestock owners/healers.
- Testing for activity against indicator helminths.
- Testing for toxic effects, probably on-station.
- Validation on-farm with livestock owners.

If the results of the above are positive it is logical to proceed to more detailed identification of the active principles and of how their effects might be extended, for example through improved storage.

It is relatively easy to list EVM practices and to review the literature in human and animal medicine. However, as soon as any attempt is made to test EVM in a quantitative way major problems arise. The ultimate one is cost, but this arises from the fact that so many EVM practices are locally specific and highly variable in their application and use.

One response to the above problem is a qualitative method of validation based on 'confidently used' EVM. IIRR (1994) produced a collection of EVM practices in Asia using a workshop brainstorming technique. The authors attempted to 'validate' practices on a scale of 1–6 as follows:

- (1) Workshop participants agreed that the treatment would be useful.
- (2) Treatment is widely used in a region or a country. (Some remedies were also validated against practices from outside Asia.)
- (3) Workshop participants had first-hand knowledge of the remedy's use on-farm.
- (4) Traditional healers are known to use the remedy.
- (5) The remedy is cited in the literature in one of two ways: either it is used to treat the same problem in humans or another animal species or this plant has proven pharmacological activity to treat the problem in question (laboratory validation).

- (6) The remedy has been scientifically validated as effective to treat the problem in the livestock species in question.

Of some 330 treatments listed by IIRR (1994) only five are designated as '6', i.e. as being scientifically validated. Of these five, one is for a pig sedative using the leaves of *Mimosa pudica*, the other four are for upper respiratory problems in poultry (leaves of *Heliotropium indicum*, *Spondias pinnata* and garlic, *Allium sativum*) and for internal parasites (garlic and the latex of papaya, *Carica papaya*).

Is validation of EVM important for the livestock owners who use it? Possibly 'no' if they are using practices that have been used 'successfully' for generations. But possibly 'yes' if they have seen the effectiveness of modern drugs as indicated above. Are users of EVM experimenting with/validating EVM medicines and methods now in any way at all? Until relatively recently the answer given by outsiders would have been 'no'. But following on from the work of van Veldhuizen *et al.* (1997) and others, it is now clear that much experimentation is done by ordinary farmers in the tropics although its extent remains to be fully documented. One example of an on-farm ethnoveterinary validation with farmers has been provided in Peru within the Project for the Validation of Technologies in Communities (McCorkle & Bazalar, 1996). In this instance the validation exercise proved to be very positive and beneficial for the community concerned.

If EVM is locally specific then validation probably has to be locally specific. In the past validation work has been something usually done on-station and in laboratories with the use of specialized equipment. The need for these has not gone away, but there are a number of tools such as weigh-bands and body condition scoring systems which serve to make validation on-farm more feasible. Van Wyk *et al.* (1997) have reported an eyelid colour system for measuring anaemia in sheep and relating this to worm burdens. This system could be used to help organize balanced groups of animals with similar worm burdens for the purposes of testing the efficacy of, for example, anthelmintic plants. The McMaster method for counting parasite eggs in animal faeces is one that can be learnt relatively easily and used at farmer group level. Although facilitated farmer validation may seem ambitious it seems unlikely that extensive validation of EVM in the tropics will be achieved in any other way.

Discussion

If it is assumed that validation trials can be organized and carried out, there are two possible outcomes. One

is that the plant has no statistically significant effect on the targeted organism. For example, on the basis of a literature review, Hammond *et al.* (1997) suggested that *Mallotus philippensis*, widely used in EVM in Asia, could be effective as a broad spectrum anthelmintic. Following an actual validation of the dried powdered fruit of this plant, termed kamala, Jost *et al.* (1996) concluded that a particular sample of the dried fruit was ineffective against particular gastrointestinal nematodes in certain goats indigenous to Balochistan, Pakistan. If a medicinal plant is found to be ineffective in a validation it will be difficult to communicate the result to many livestock owners. There is unlikely to be any campaign, or funding, to stop livestock owners using it. Furthermore, livestock owners may not believe the negative result, and in any case there may be some medicinal effect albeit in different circumstances and at a biological but statistically insignificant level.

If a validation proves positive, what are the options? One obvious option is to encourage greater use of the medicine in question through extension services and publications. Even so it will be difficult to make universal recommendations as is possible with a synthetic drug, because of the underlying variability in EVM as arising, for example, from species, seasonal and method of preparation effects.

Thus, whether or not validation is carried out and whether or not it is positive seems unlikely to have much effect on the short-term use of ethnoveterinary medicines by livestock owners outwith the specific locality in question, although this is not necessarily the case for the long term.

Conclusions

The key issues highlighted above are as follows:

- If poverty and/or drug costs continue to increase then so will the use of EVM.
- Some EVM ‘works’ and is worth investigating/validating objectively.
- The evolution of evidence-based EVM will be slow and may require a new participative approach to validation.

From the above points it can be further concluded that there is likely to be a continuing place for EVM in the tropics alongside modern methods of disease treatment and according to circumstances.

Introduction

Cattle, like all mammals and birds, are homeotherms. Despite wide fluctuations in environmental temperature they are capable of maintaining a relatively constant body temperature. This ability to regulate or stabilize body temperature is essential to preserve the multitude of biochemical reactions and physiological processes that occur with normal metabolism. As environmental temperatures rise a series of thermoregulatory responses designed to stabilize body temperature are initiated. These include physiological, anatomical and behavioural changes which exhibit themselves as reduced feed intake, decreased activity, shade or wind seeking, increased peripheral blood flow, sweating and panting.

During periods when ambient air temperature and humidity are particularly high, thermoregulatory activities may not be sufficient to maintain normal body temperature. The result is a rise in body temperature and the induction of a series of thermoregulatory events whose objective is survival from a potentially life-threatening crisis. Performance is naturally a sec-

ondary concern and almost always suffers. The specific thermoregulatory responses that impact performance are a reduction in feed intake and nutrient absorption, and a redirection of blood flow from internal organs to peripheral tissues. During the prepartum period, this results in lower calf birthweight and reduced milk yield in the subsequent lactation. Postpartum, hyperthermia depresses dry matter intake, reduces milk yield and decreases reproductive performance.

Methods to relieve heat stress include the provision of shade, forced air movement as with fans, and water in the form of a fog, mist or sprinkle droplet. In some areas of the world cooling of cows may be accomplished by permitting access to ponds which are managed for such purposes. Depending upon specific climatic conditions (i.e. hot dry or arid versus hot and humid) these can be used in combination to assist cows in the achievement of acceptable heat balance.

Thermoregulation and the thermal comfort zone

For lactating dairy cattle, the most comfortable environmental temperature range is between 5 and 25°C (41 and 77°F), otherwise known as the thermal comfort zone. Within this range of temperatures optimal animal performance can be expected. Temperatures that range outside this zone may require an alteration in the basal metabolic rate for the animal to maintain normal body temperature. The lower critical temperature is the point at which an animal will begin to feel cold and must increase body heat production. It varies with age, physiological status (lactating or non-lactating), degree of insulation, level of milk production and acclimatization. For example, the lower critical temperature for neonatal calves is reported to be 12.8°C (55°F). On the other hand, a mature cow in peak lactation may be comfortable at a temperature of -25°C (-13°F). The upper critical temperature is the point above which an animal begins to feel warm and must begin to compensate. Unlike the variability described for lower critical temperature, the upper

critical temperature limit remains constant at about 25°C (77°F) regardless of age or physiological status.

Body heat production

Total body heat load is a combination of heat derived from metabolism and that obtained from environmental sources. Internal body heat associated with basal body functions (digestion and cellular biochemical reactions) accounts for 35–70 per cent of total daily heat production. In ruminants there is greater heat gain associated with the digestion of roughages as compared with concentrate feedstuffs. Other sources of body heat include that associated with daily physical activity and increased metabolic activity associated with lactational performance. Finally, it is significant to note that the increased respiratory rates and panting associated with evaporative cooling, while necessary to cool the cow, also account for an increase in daily maintenance requirements by 7–25 per cent.

Heat gain from the environment

The primary sources of heat gain from the environment are solar radiation and high ambient air temperature. The amount of heat absorbed by an animal exposed to direct sunlight is related to coat colour. Black cows absorb over twice as much heat from the sun as white cows. This is complicated by virtue of the fact that the flow of heat away from the cow's body is restricted by high ambient air temperature which narrows the thermal gradient between the cow's body and the surrounding air. Thus, solar radiation together with high ambient air temperature are important sources of heat gain from the environment. Since little can be done to reduce air temperature, efforts to provide shade should be a high priority.

Body heat loss

The release of heat from any object to the environment is proportional to its exposed surface area. Further, the ratio of surface area to body mass decreases as overall size increases. This means that large animals such as cows are at a disadvantage in losing excess body heat. They are also at greater risk of becoming overheated. Calves, on the other hand, have a greater amount of surface area relative to body mass and, therefore, are much better at dissipating heat than a mature cow.

Avenues for the dissipation of heat in cows include both non-evaporative and evaporative cooling

mechanisms. Between the temperatures of -17.8 and 10°C (0–50°F), 75 per cent or more of heat loss from the body occurs by non-evaporative cooling (i.e. conduction, convection and radiation). However, at temperatures of 29.5°C (85°F) and above, nearly 80 per cent of heat is dissipated by evaporative cooling (i.e. the evaporation of water from the skin and respiratory tract). In general, whenever temperatures exceed 21°C (70°F), evaporative cooling becomes the predominant mechanism of heat loss in cattle.

Bos indicus (Zebu) cattle have larger and a greater number of sweat glands than *Bos taurus* cattle, but actual sweating rates are only slightly higher. The evaporation of water from the cow's skin is a very effective cooling mechanism. It is enhanced by conditions which provide air movement which moves water vapour away from the skin thereby increasing the vapour-pressure gradient in the immediate air space surrounding the animal.

The primary obstacle to evaporative cooling is high relative humidity. Humid air is more saturated with water vapour. Thus, the vapour-pressure gradient is reduced. In some environments this is exacerbated still further by limited air movement. This results in very low water evaporation rates and consequently minimal cooling. In hot and humid environments this condition may be overcome by a combination of sprinkling the skin with water and forced air movement with fans. Fanning cools wetted cows by accelerating the water vaporization rate.

Effects of heat stress on performance

Prepartum heat stress

Elevated environmental temperatures during the last trimester of gestation alter blood flow to the uterus and maternal-fetal hormone concentrations. The result is lower calf birthweight and reduced milk yield in the subsequent lactation. Approximately 60 per cent of fetal growth occurs during the last 90 days of gestation. Chronic heat stress during late gestation leads to reduced blood flow to the uterus which retards placental and fetal growth. As a consequence, placental mass is reduced and calf birthweights are lowered by as much as 6 to 8 per cent. Studies have also shown that milk yield is related to calf birthweight and lower calf birthweights are associated with reduced milk production. Although the precise reasons for reduced milk yield are unknown, most researchers believe that hyperthermia in late gestation interferes with normal hormonal regulation of mammary development, lactogenesis and milk yield.

Peripartum heat stress

Cows calving during daylight hours in hot climates with direct exposure to solar radiation are particularly subject to hyperthermia and heat stroke (p. 935). This is particularly true for cows experiencing hypocalcaemia at calving, when control of body temperature by natural mechanisms is greatly diminished. Therefore close monitoring of calving cows is essential in hot climates.

Heat stress at parturition also creates significant consequences for calves. Once delivered, calves born in stressful conditions are weaker and slower to suck colostrum. Indeed, passive transfer of immunoglobulins has a seasonal pattern in calves. Calves born during the hotter summer months have higher rates of failure of passive transfer whereas calves born during the more moderate times of the year tend to have better rates of passive transfer. At least one study suggests that an increase in serum corticosteroids in heat stressed neonates reduces permeability of the intestine to immunoglobulin absorption. Thus, it would appear that both physical and physiological mechanisms are responsible for high rates of failure of passive transfer in calves.

Postpartum heat stress

Reduced feed intake is a primary strategy for lowering body heat production. The consequence is a reduction in milk production of as much as 10 to 20 per cent or more. Similar effects on constituent (milk fat and protein) yield are observed. Milk quality parameters are also affected whereby somatic cell and bacterial counts tend to increase during periods of hot and humid weather. Although specific data are limited, the observed increase in somatic cell counts suggests a greater susceptibility to infection due to decreased host resistance or increased exposure to pathogens created by an environment more favourable for their propagation.

Improper ration formulation, intermittent feeding behaviour, a lack of cud chewing, elevated respiratory rates, excessive losses of saliva from drooling and an overall reduction in the buffering capacity may interfere with the normal buffering of rumen contents. This is believed to be a significant contributor to rumen acidosis (see p. 829), laminitis (see p. 420) and other lameness conditions (see Chapter 31) that seem to be particularly prevalent during periods of hot weather. Feeding the lactating cow is particularly challenging during periods of intense heat. The objective is to maintain some level of performance and homeostasis yet not add to the internal heat load or tendency toward rumen acidosis.

Heat stress has a major impact on reproductive performance. It lowers conception rates, reduces the length of the oestrous period and oestrous intensity, modifies endocrine function, alters the oviductal and uterine environment and increases early embryonic death by interrupting embryo development. The seasonal depression in reproductive performance that results is one of the most serious problems for the dairy and livestock industry of subtropical and tropical regions throughout the entire world.

Methods to reduce heat stress (p. 975)

Successful abatement of heat stress generally requires environmental modification. Critical components include shade, water in the form of a fog, mist or sprinkling and air flow – either natural or by forced air movement with fans. The primary objectives are to reduce direct solar radiation, lower air temperature, improve or assist air movement or in some cases increase the natural evaporative cooling from skin surfaces.

Natural shade

Trees are an excellent source of shade. They are not only effective blockers of solar radiation but the evaporation of moisture from leaf surfaces cools the surrounding air without appreciably interfering with air circulation. In addition, animals acquire very little radiant heat load from the shade of a tree compared with a metal roof. Therefore, trees are a highly desirable natural resource in the environment of the dairy cow. However, trees have a short life span in operations where they are not protected. In fact, most last only about one to two summers after the onset of cow exposure where stocking rates are high. As cows congregate to seek protection from the summer sun they quickly develop mud holes at the base of trees. This soon leads to death of the tree and loss of this natural shade source. In order to take advantage of natural shade, some effort must be made to ensure that trees are protected from damage by cows.

Artificial shade

Solar radiation is a major factor in heat stress and increases heat gain by direct as well as indirect means. Blocking its effects through the use of properly constructed shade structures alone increased milk production by 10–19 per cent in studies conducted in Florida. Options include permanent or portable shade structures. In the following sections consideration will be given to design and maintenance factors.

Permanent shade structures

Major design parameters for permanent shade structures include:

- Orientation
- Floor space
- Height
- Ventilation
- Roof construction
- Feeding and water facilities
- Waste management system.

The preferred orientation of a shade structure depends upon whether or not cows are confined to the structure. Alignment of the long axis in an east–west direction achieves the maximum amount of shade under the structure and is therefore the preferred orientation for confined animals. On the other hand, where cows are free to move with the shadow of the structure a north–south orientation is better because this orientation will allow sunlight to dry out as much as 35–50 per cent of the area beneath the shade structure during both the morning and afternoon hours. This is particularly important for shade structures with earthen floors.

Some prefer concrete slab floors. A reinforced concrete slab at least 10 cm (4 inches) thick, with a smooth finish and grooved for good footing, is recommended. If a flush system is to be used the floor should be sloped 1.5–2 per cent. Water availability, space and environmental concerns are currently of interest in floor scraping and removal of manure solids from the premises. Various other waste handling facilities incorporate settling basins, liquid/solid separators, pumping and gravity-flow systems.

Guidelines regarding the size of shade structures vary according to climatic conditions. Some recommend 1.75–2.5 m² (19–27 square feet) of floor space per cow. However, for hot and humid environments, some would recommend a floor space equivalent to 5.5–6.0 m² (60–65 square feet) per cow. Space requirements are doubled for hot and humid climates to provide an additional open area for improved air movement.

Natural air movement under a shade structure is affected by its height and width, the slope of the roof and the presence of, or size of, the ridge opening. Air movement may occur naturally as breezes through the open sides of structures or by thermal buoyancy, in which air warmed by the presence of animals and thermal radiation through the roof creates air flow toward the ridge opening. A steady flow of air through a shade structure requires the following design specifications:

- Shade structures of 12 m (40 feet) or less in width require a minimum eave height of 3.7 m (12 feet).

Structures wider than 12 m (40 feet) should have eave heights of at least 5 m (16 feet) or more.

- There should be at least 15 m (50 feet) of clearance between adjacent buildings or other obstructions.
- Gable roofs should have at least a 4:12 slope (6:12 is acceptable but difficult to work on) and a continuous open ridge. Ridge caps if desired should have a minimum of 0.3 m (1 foot) of clearance between the cap and the roof peak.
- Ridge openings should be a minimum of 0.3 m (1 foot) wide plus 5 cm (2 inches) for each 3 m (10 feet) of structure width over 6 m (20 feet).
- Painting metal roofs white and adding insulation directly beneath the roofing will reflect and insulate from effects of solar radiation and will reduce thermal radiation on cows.

Thermal radiation from the roof of shade structures can add significant heat load to cattle, particularly in low structures without a ridge opening. In these types of structures thermal radiation can be reduced by cooling the roof with water, adding insulation or painting the roof with a reflective type of paint. However, it should be remembered that these additions to the structure do not cool air, reduce humidity or augment the natural evaporative cooling mechanisms of cows beneath the shade structure. Furthermore, proper design of the shade structure (adequate eave height and an open ridge) will naturally limit thermal radiation effects. When faced with the need to retrofit cooling into an ill-designed existing structure, the priorities should be directed to cooling the cows rather than the roof. Roof cooling (beyond painting with a reflective paint), while beneficial, is a secondary consideration.

Portable shade structures

Portable shades offer some advantages over permanent structures in their ability to be moved as required to cleaner and drier locations. However, protection from solar radiation is less than that achieved in permanent structures. Shade cloth patterns come in various weaves providing 30–90 per cent shade. One of the more common types is a woven polypropylene fabric which provides 80 per cent shade. While longevity is considerably less than that expected of permanent structures, shade cloth if properly maintained (kept tight) can last 5 years or longer.

Cooling by reducing ambient air temperature

As temperatures rise above the upper critical temperature threshold of 25.5°C (78°F) the dairy cow begins

to increase heat loss via the respiratory tract and skin surface. However, despite the remarkable efficiency of these thermoregulatory responses to dissipate heat, as temperatures continue to rise these natural mechanisms are overwhelmed, leading to hyperthermia and reduced performance. In these circumstances efforts to minimize additional heat gain and supplement cooling become necessary. Water and air movement become the agents by which the micro-environment is cooled and evaporative cooling by the cow is augmented.

Evaporative cooling pads and fans

Air temperatures can be lowered by air conditioning or refrigeration, but the expense of such types of mechanical air cooling makes these impractical for cooling dairy cows. A more economically feasible method to cool the micro-environment is the evaporative cooling pad (corrugated cardboard or similar material) and fan system which uses the energy from air to evaporate water. This process cools the air and raises its relative humidity. Although these systems are most effective in arid climates, they have been observed to reduce air temperature in humid climates as well.

***High pressure foggers* (see also Chapter 71)**

In recent years interest in high pressure foggers has grown. These systems offer effective cooling but with lower water use. Foggers disperse very fine droplets of water which quickly evaporate, cooling the surrounding air and raising the relative humidity in the process. The typical design incorporates a ring of fogger nozzles attached to the exhaust side of a fan. As fog droplets are emitted (200psi) they are immediately dispersed into the fan's air stream where they soon evaporate. The temperature of the animals is reduced as they inspire the cooled air and it is blown over their bodies. Fogger systems are most effective in areas of low humidity. However, even where humidity is normally quite high, daytime humidity is still low enough to allow effective cooling with fogger systems. In areas where relative humidity increases to nearly 90 or 100 per cent in the overnight hours foggers must be turned off. Once the air is saturated with moisture evaporation is reduced and cooling stops. High pressure foggers should be designed to operate during the less humid hours of the day. Finally, they should be used only in open-sided, ridge-vented, tall (greater than 3.7m (12 feet)) barns. Low barns with side walls restrict air flow and fog droplet evaporation. This reduces cooling and makes for excessively wet conditions in the barn.

High pressure foggers are advantageous in the fact that they use far less water (13.5–23 litres (3–5 gallons)/cow per day) compared with sprinkler systems (135–230

litres (30–50 gallons)/cow per day). The primary disadvantage is that they require more maintenance. In-line water filters must be cleaned or checked daily to prevent clogging of fogger nozzles.

Misters

A mist droplet is larger than a fog droplet but cools air by the same principle. These systems do not work well in windy conditions or in combination with fans in humid environments. In warm humid environments mist droplets are too large to evaporate fully before settling to the ground. The consequence is wet bedding and wet feed. A further complication with misters is the formation of an insulating layer of air between the droplets of water on hair shafts and the cow's skin. When this occurs it impedes natural evaporative heat loss from the skin and can result in body heat build-up.

Enhancing the cow's natural mechanisms of heat loss

Protecting the cow from solar radiation with shades and reducing ambient air temperatures through the process of water vaporization and controlled ventilation are important considerations in cooling dairy cattle. Various combinations of these techniques have proven to be particularly useful in arid climates. Cooling in hot and humid climates, on the other hand, can be more challenging. Instead of trying to lower ambient air temperature, another technique is to provide shade, wet the skin and move air to enhance the cow's primary mechanism for the dissipation of heat – evaporative cooling from the skin.

Sprinklers and fans

Sprinkling systems utilize a larger size water droplet that is able to wet the hair coat to the skin. Cooling is accomplished as water evaporates from the hair and skin. In combination with forced air, sprinkling substantially increases the loss of body heat over that possible by sweating alone. Several studies have demonstrated upper body sprinkling followed by forced-air ventilation to be an effective means to reduce body temperature, increase feed intake and boost milk yield. This combination has been applied to holding areas outside milking areas, shade structures, feed barns and free-stall barns with a high degree of success.

Sprinkler and fan systems require a properly sloped concrete floor with facilities to handle water run-off at

rates of somewhere between 230 and 450 litres (50 and 100 gallons) of water per animal per day depending upon sprinkling rates. In early Florida studies water use amounted to 455 litres (120 gallons)/cow per day (sprinkling for 30 seconds every 5 minutes when ambient air temperatures exceeded 26.5°C (80°F)). Later work has shown that rates of 230 litres (50 gallons)/cow per day or less will provide effective cooling. Consequently, in addition to plans for water run-off and containment, some determination of the water supply is advised.

Sprinklers should be located above the cows, with nozzles directed such that they wet the cows but not the feed. The type of nozzle chosen depends upon the volume of water and sprinkling rate desired. Generally, low pressure (10 psi), 180° spray nozzles, capable of delivering the equivalent of 1.25 mm (0.05 inches) of rainfall per sprinkling cycle, are used. This sprinkling rate assures that the cows will be wetted to the skin. Nozzles are spaced approximately every 2.5 m (8 feet) or as far apart as necessary to provide overlapping coverage.

Fans (0.5–1.0 hp) capable of air flow rates of 11 000 cfm or greater are recommended. Ninety centimetre (36 inch) fans rated as such can be hung above the sprinklers every 9 m (30 feet) (every 1.2 m (40 feet) for 120 cm (48 inch) fans). They should be tilted downward at a 20–30° angle (from vertical) to direct the flow of air on to the cows. An air velocity of 120–185 m (400–600 feet) per minute over the cow is desired. The system combines fans and sprinkling, with cows being sprinkled for 1–2 minutes at 15-minute intervals. Fans should be run continuously. The entire system should be thermostatically controlled to operate automatically when ambient air temperatures reach or exceed 26.5°C (80°F).

Sprayers in parlour exit lanes

Exit lane sprayers are available commercially and designed to automatically spray water on to cows as they pass through. Fan nozzles and timing of the spray are designed to spray only on to the cow's back and sides. Fan spray nozzles must have a flow rate of at least 36 litres (8 gallons) per minute at 40 psi. These systems would seem to have greatest appeal in operations where cows travel some distance from the milking parlour to feed and in loafing areas. A less complex system can be made by simply locating an ordinary shower nozzle above cows in the parlour exit lane. Cows can be showered as they leave the parlour.

Cooling ponds

Tradition has held that it is better to limit or exclude access of cows to streams and farm ponds, and with

good reason. Experience has shown that free access to streams and ponds may predispose to a number of infectious diseases and some toxicities in dairy cattle. Most notable of these are leptospirosis (see pp. 734–7) and mastitis (see Chapter 23) caused by a variety of organisms, particularly *Protheaca* species (achlorophyllic algae). As a result, most advise that cows be fenced away from streams and ponds. Cooling ponds, therefore, represent a controversial method for the management of heat stress. However, studies in the USA have found that cooling ponds not only effectively reduce body temperature, but have no apparent adverse effect on udder health.

The primary mode of heat loss in cooling ponds is conduction, with a small amount lost by evaporative cooling during the 5–10 minutes after exiting the pond. Water temperature of the cooling ponds studied in the USA generally ranged from 24 to 30°C (75 to 86°F), or occasionally higher. At this temperature there was a favourable heat transfer gradient between the cow's body and the pond water.

Major questions remain as to how cooling ponds should be designed or maintained. Some operations that rely on ponds for cooling cows maintain them by providing a constant inflow of water, with an overflow at one end of the pond. They also drain, dredge and fill them with new sand every 1 to 2 years. Although total bacterial content does not appear to be appreciably affected there is less build-up of organic material. There is some evidence that allowing cows access to stagnant or natural ponds may negatively affect milk quality and the incidence of mastitis. Cows from herds with man-made ponds, which are maintained regularly, produce milk with lower bacteria and somatic cell counts compared with cows from herds which have no ponds or natural ponds. Thus, one would conclude that the use of ponds for heat stress management should be accompanied by plans for pond maintenance.

Introduction

The bovine animal, along with the other ruminants, depends very heavily on its symbiotic relationship with the microbial population of the rumen. Thus any consideration of the nutrition of the bovine must be focused on the rumen as the most important part of the bovine digestive system. The fermentation in the rumen is dominated by the degradation of plant cell walls, of which the most abundant constituent is cellulose. This adaptation to plant cell wall digestion, in addition to cell content degradation places the bovine in an important strategic position relative to other animals.

Van Soest (1994) classified cattle feeding habit as being one of grazing fresh grass, rather than browsing trees and shrubs. Cattle have a greater need for water than other ruminants, possibly because they retain fibre for relatively long periods in the rumen. A high free-water content, typically around 90 per cent, is essential for optimal bacterial activity. In addition, there is less absorption of water in the large intestine and a higher water content in the faeces than with sheep and goats.

The bovine is a relatively unselective eater compared with the other ruminants. This may be a disadvantage when tree and shrub leaves are abundant at a time when pasture supply is scarce because of drought. But the bovine can and does browse. In situations of excess food supply over consumption, selective eating occurs.

In temperate regions of the world, a constant supply of feed throughout the year is achieved by preserving excess herbage growth as hay or as silage. This activity, coupled with the production of root crops specifically for use when grass growth is slow or non-existent, has transformed the annual cycle of production from one totally dependent on grass growth to one which is not. Thus beef cattle, for example, no longer lose weight in the winter when grass is scarce, but are able to maintain or even increase in weight on a winter diet of hay,

silage or stored root crops. The development of the human food and drink industry has released a wide range of by-products, such as bran from the milling of grain for flour, and spent grains from the brewing of beer and the production of spirits. These by-products, which are not edible by the human population, play a vital role in the nutrition of the bovine when grazed pasture grass is in short supply.

A remaining challenge in bovine nutrition is to achieve a similar constancy of feed supply to that of the temperate regions of the world, to bovine populations in regions where drought is common, and where the technology of feed preservation and by-product utilization is less well developed.

In this chapter, the fermentation in the rumen is described, with particular emphasis on the kinetics of the process and its interaction with feed intake. Requirements for energy and protein are then considered. The composition of feeds is outlined, together with technologies for feed preservation and feed processing. Finally, the management of the feeding of the bovine is outlined in relation to maintaining stability in the rumen, maximizing intake and meeting requirements for high levels of productivity.

Fermentation in the rumen

The rumen accounts for more than half the total volume of the digestive tract of cattle. The animal relies very heavily on the reactions that occur in the rumen for its supply of major nutrients. Thus on a sole diet of grazed grass some 90 per cent of the animal's total energy and protein supply is derived directly from the rumen micro-organisms and the end-products of their metabolism. Therefore, the importance of maintaining optimal conditions for fermentation cannot be overstressed.

The symbiotic relationship between the micro-organisms of the rumen and the host animal has been crucial to the survival of the bovine, since the animal itself does not produce the enzymes to degrade the cellulose and hemicellulose in plant cell wall material. This task is undertaken by the microbial population of the rumen.

In the wild, surrounded by foliage and limited supplies of feeds containing starch or sugar, the bovine's fermentation of plant cell wall material secured not only the supply of energy, but also a vital supply of microbial protein. The ruminant has evolved a nutritional niche whereby it is independent of external sources of amino acids and B vitamins – a considerable advantage when grass is the only feed available.

Fermentation in the rumen is the anaerobic process of microbial activity, which also occurs in the lower digestive tract of animals and in the preservation of

crops by ensilage. Essentially, dietary carbohydrates, proteins and some fats are reduced to short-chain fatty acids with the production of carbon dioxide, methane and ATP.

The short-chain fatty acids produced in the digestive tract are principally acetic, propionic and butyric acids, although occasionally lactic acid is also produced.

The most important bacteria involved in fermentation in the rumen are the cell-wall digesting or cellulolytic micro-organisms. The concentration of bacteria in rumen fluid is about 10^{10} to 10^{11} bacteria/ml, with most being attached to particles of food. The predominant species of bacteria varies with the type of fermentation, which depends on the principal substrates in the diet. Thus the major species of bacteria in the rumen of animals given a diet of grass are those which digest cellulose and hemicellulose, such as *Ruminococcus albus*, *Ruminococcus flavefasciens* and *Bacteroides succinogenes* (see Table 9.1).

Other species, such as *Streptococcus bovis*, ferment starch to acetic acid and ethanol. This species, along with other streptococci, can produce lactic acid and are more tolerant of acid conditions than other species of rumen bacteria. Acidosis can occur if the diet of the animal is changed abruptly from cellulose to starch or sucrose. The population of bacteria in the rumen changes from cellulolytic to amylolytic as the pH falls. Lactic acid accumulates and accelerates the fall in pH. Even a small fall in the pH of the rumen from pH 7 to pH 6 is reflected in a reduction in cellulose digestion and a change in the population of the bacteria towards the more acid tolerant species.

Proteins are degraded to a varying extent during the fermentation to their constituent amino acids. Some amino acids are used directly by bacteria and protozoa, but most are used as a source of energy and are broken down further to ammonia and volatile fatty acids. Ammonia is used as a substrate for the production of microbial protein, with the excess being absorbed into the animal's portal blood and converted to urea in the liver. The extent to which proteins are degraded during the fermentation in the rumen depends on their solubility, which is generally relatively high. However, solubility is lower in feeds which have been subjected to heat treatment during processing. Thus the degradation of protein in brewer's grains is only about 0.6, compared to 0.9 for fresh herbage. Protein degradation also depends on the time the material spends in the rumen, and is lower for diets which pass rapidly through the rumen (concentrates and feeds of small particle size) than for long forages which are digested slowly.

Protozoa and fungi are also involved in the fermentation process. These organisms can digest cellulose, starch, sugars and fats to produce acetic acid, butyric acid, lactic acid, hydrogen and carbon dioxide.

Table 9.1 Common types of rumen micro-organisms and their action.

| Species | Energy source | Fermentation products | Requirements |
|-------------------------------------|-------------------------|--|---|
| Bacteria | | | |
| <i>Bacteroides amylophilus</i> | Starch | F, A, S | CO ₂ , NH ₃ , BrVFA |
| <i>succinogenes</i> | Cellulose | F, A, S | CO ₂ , NH ₃ , BrVFA, SVFA, Vit. |
| <i>Ruminococcus albus</i> | Cellulose, xylan | F, A, E, H ₂ , CO ₂ | BrVFA, CO ₂ , NH ₃ , Vit.(A) |
| <i>flavefaciens</i> | Cellulose, xylan | F, A, S, H ₂ | |
| <i>Butyrivibrio fibrosolvens</i> | Xylan, starch | F, A, B, L, H ₂ , CO ₂ | BrVFA, A, CO ₂ , NH ₃ , Vit.(A) |
| <i>Lachnospira multiparius</i> | Pectin | F, A, L, E, H ₂ , CO ₂ , A, Vit. | |
| <i>Selenomonas ruminantium</i> | Lactate, starch | A, P, L, CO ₂ , H ₂ | A(CO ₂) |
| <i>Methanobacterium ruminantium</i> | Formate, H ₂ | Methane | A, BrVFA, Haem, CO ₂ , NH ₃ |
| Protozoa | | | |
| <i>Holotrichs</i> | | | |
| <i>Isotricha</i> | Starch and sugars | A, B, L, H ₂ | |
| <i>Dasytricha</i> | Starch and sugars | A, B, L, H ₂ | |
| <i>Entodiniomorphs</i> | | | |
| <i>Entodinia</i> | Starch | F, A, P, B, (L) | |
| <i>Epidinium</i> | Starch, hemicell. | A, B, H ₂ , (F, P, L) | |
| <i>Ophryoscolex</i> | Starch | A, B, H ₂ , (P) | |
| <i>Diplodinium</i> | | | |
| <i>Eudiplodinium</i> | | H ₂ , fatty acids | |
| <i>Polyplastron</i> | | | |

Symbols: F, formate; A, acetate; P, propionate; B, butyrate; BrVFA, branched-chain VFA; E, ethanol; L, lactate; S, succinate; SVFA, straight-chain VFA; Vit., B vitamins.

The predominance of the weak acids acetic, propionic and butyric in the end-products of fermentations in the digestive tract highlights the importance of buffering agents to maintain the pH of the environment close to neutrality. Saliva, containing sodium and potassium bicarbonate and urea, is the most important buffering agent in the rumen, and the amount of saliva produced during eating and rumination is therefore crucial to the neutralization of the fermentation acids (see below). Long fibre is often included as a supplement to diets high in concentrates to stimulate chewing and rumination.

The constant flow of saliva (p. 98) into and outflow of digesta from the rumen, and the absorption of digested nutrients into the portal blood, ensure that in most nutri-

tional circumstances the environment for fermentation remains relatively constant. However, digestive disorders can arise to disrupt the equilibrium. Toxins, produced by undesirable bacteria and from moulds present in foods, can damage the sensitive lining of the wall of the rumen and reduce the absorption of nutrients. Sudden changes in diet can change the microbial population and result in the production of lactic acid in the rumen, as in the fermentation of crop material in the silo, with a consequent reduction in rumen pH. If the pH of the rumen falls below pH 5 and remains at a low level, there is a risk of rumen stasis which can result in bloat because the animal can no longer eructate the gases produced by the fermentation.

Methane loss from the rumen is estimated to account for about 8 per cent of the total gross energy eaten by the animal. Apart from the rumen fermentation, methane is also lost to the environment from hind gut fermentations and together these fermentations constitute a significant contribution of methane to the global environment. Ways of reducing methanogenesis include chemical food additives (ionophores), and changing the pattern of fermentation to increase the proportion of propionate and to reduce the proportion of acetate.

Saliva

Feeds are chewed during eating and also regurgitated during rumination to allow very thorough mastication. Throughout these activities large quantities of saliva are mixed with food. The effect of saliva is to buffer the acids that are produced in the rumen as a result of the fermentation. This buffering is vital to the maintenance of the correct type of fermentation, and can even prevent the collapse of normal rumen function in extreme situations.

The principal buffering constituent of saliva is bicarbonate. It has been estimated that a dairy cow may produce up to 3.5 kg of bicarbonate per day. Clearly, the need for adequate buffering is more important if the diet is rapidly fermented than if it is only slowly fermented. Further, if the diet is acidic, as in the case of silage, it is essential that salivary secretion is sufficient to prevent a build-up of excessive acidity in the rumen or in blood.

It follows that feeds which stimulate rumination are more useful to the maintenance of optimal conditions for fermentation in the rumen than those which do not. Unfortunately many constituents of high-energy concentrates, such as molasses and ground cereal grains, are fermented rapidly in the rumen and do not stimulate rumination. At the other extreme, hay and straw are chewed extensively to break down the fibre and their rate of digestion is also relatively slow. Hence a compromise with respect to saliva production is required; fibre is required together with concentrated feed sources in order that saliva output is maintained.

The actions of micro-organisms

The major organisms responsible for digestion in the rumen are anaerobic bacteria and protozoa, although anaerobic fungi are thought to be responsible for much of the initial colonization of feed particles in the rumen. The cellulolytic bacteria adhere to particles of fibrous feeds and secrete enzymes that gradually erode out the digestible material. Their enzymes break down hemi-

cellulose and cellulose to glucose and fructose. Starch and pectins are also similarly degraded (Fig. 9.1). In the case of plant cell wall material, this erosion continues until lignified tissue is encountered. Lignin, which is cross-linked to hemicellulose and cellulose, provides structural strength to the plant and is also very resistant to bacterial enzymic attack.

The protozoa in the rumen mainly ferment starch and sugar, but they also consume bacteria. The protozoa are thought to be active in assisting the bacterial population in adapting to new feeds.

The end-products of bacterial digestion are short-chain acids acetic, propionic and butyric (the volatile fatty acids, VFA), microbial cells (and their constituent protein), and the gases methane and carbon dioxide. Methane comprises the major gaseous energy loss as a result of fermentation. Gas is lost by eructation whilst the VFA are mainly absorbed through the rumen wall.

Some common types of rumen micro-organisms and their actions are summarized in Table 9.1.

Fermentation of different types of feed

The fermentation of plant cell walls is optimal at relatively high rumen pH (around pH 7.0) because the bacteria responsible are sensitive to excess acidity. Their growth is depressed if rumen pH falls below about pH 6.2. The principal end-product of cellulose fermentation is acetate, an important precursor of milk fat.

Starch and sugar are fermented to give propionic and butyric acids as the main end-products. The micro-organisms responsible for their fermentation are more tolerant of acidity than those which ferment cell wall. Some species of starch-digesting bacteria (e.g. *Streptococcus bovis*, *Selenomonas ruminantium*) produce lactic acid, a stronger acid than the VFA. Large amounts of lactic acid can predispose the animal to rumen stasis and to acidosis (see p. 829).

Protein is fermented to yield ammonia and VFA from the carbon skeletons of amino acids. The ammonia may be used by bacteria to synthesize new protein in their cells, but since bacterial growth is generally limited by the energy available from carbohydrate digestion, rather than from protein digestion, ammonia in excess of microbial requirements can easily be produced, especially on high-protein diets. Excess ammonia is converted, at an energy cost, to urea in the liver and excreted in urine. A deficit of ammonia in the rumen slows down bacterial growth, reduces rate of digestion and depresses feed intake. Thus the rate of release of ammonia should match as closely as possible the release of energy (see Fig. 9.2).

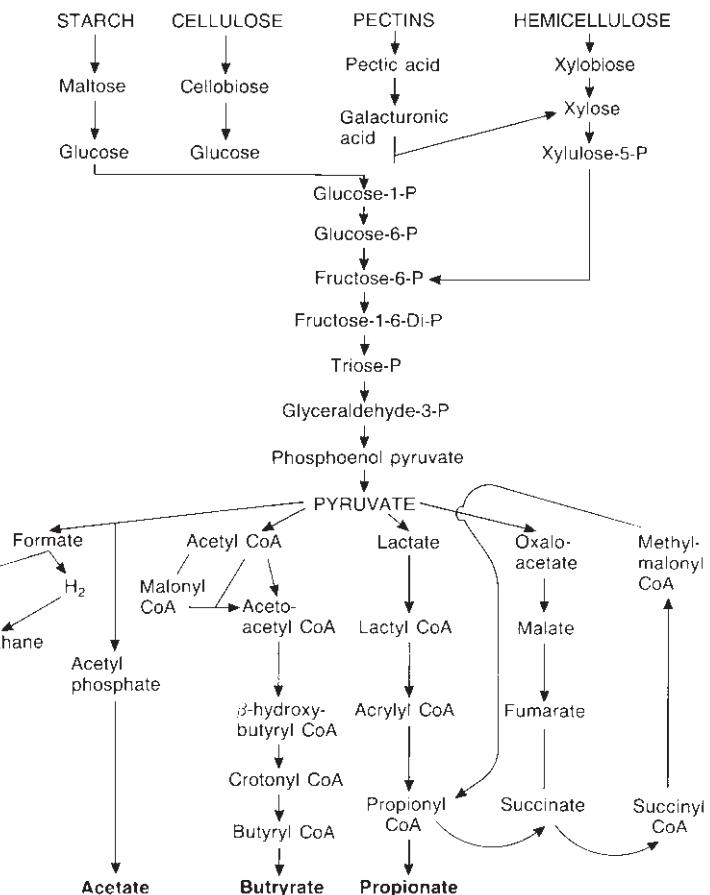

Fig. 9.1 Chemistry of rumen fermentation.

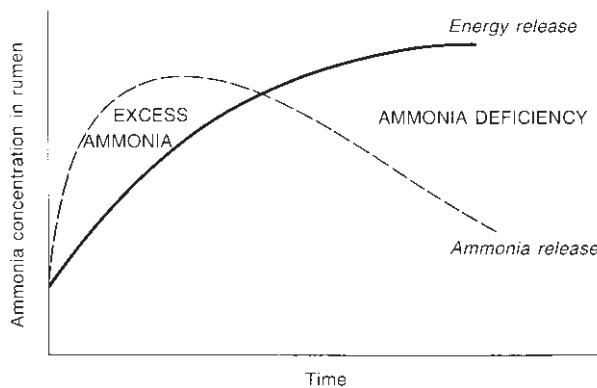

Fig. 9.2 Typical patterns for the rates of release in the rumen of ammonia from the breakdown of protein, and of energy, following a meal. The rate of ammonia release should match as closely as possible that of energy, either by reducing the amount of quickly degraded protein in the diet, or by increasing the quantity of readily-fermentable energy (e.g. starch or sugar) in the diet.

Actual and potential digestion

Fibre that has been reduced to a small enough particle size at which it can pass out of the rumen, and which has also resisted being digested by microbial activity, is

liable to pass on down the tract and out in the faeces. The rate of passage out of the rumen can influence the extent to which fibrous particles are actually digested. The faster the rate of passage, the lower the actual, relative to the potential, digestibility.

The same concept applies to protein, especially that fraction which is available for microbial fermentation in the rumen. A high-yielding dairy cow, given a high-quality diet with a fast rate of passage of feed through the rumen, will have a relatively lower fibre digestibility than a dry cow given less of the same diet, or a diet of lower energy content. However, the protein in the diet of the high-yielding cow will have a lower digestibility in the rumen, yield less ammonia and provide more undegraded protein to the abomasum than that in the dry cow's diet (see Table 9.13). Paradoxically, the lower the actual, relative to potential, digestibility in the rumen, the worse off the animal is with respect to energy, but the better off it is likely to be with respect to protein.

Optimizing digestion in the rumen

It follows from the above discussion that the following principles need to be adopted in order to optimize the fermentation in the rumen:

- Cell wall is the principal source of digestible energy in the diet of the bovine, and conditions in the rumen should be optimal for its digestion.
- Sufficient saliva must be produced to maintain rumen pH above pH 6.5, otherwise cell wall digestion will be reduced.
- Adequate degradable protein must be supplied to meet the requirements for microbial protein synthesis (see section on protein requirements, p. 106).
- Supplementary energy in the form of starch or sugar must not interfere with the maintenance of the above conditions in the rumen (see section on feeding management, p. 118).

When cell wall digestion is optimized, then feed intake is likely to be maximal, at least with respect to fibrous feeds (see below).

Feed intake

Most diets for cattle are offered in excess of the amount the animal actually consumes, although there are situations where the amount of feed offered each day is restricted intentionally. Two such situations are readily apparent: the dry cow and the suckler cow in late lactation. Both situations require that the animal does not overeat and become excessively fat.

The concept of voluntary feed intake is discussed in this section, that is, the amount of feed the animal will eat when offered an excess supply so that about 10 to 15 per cent of the daily amount offered is refused.

Is feed intake under control?

The fact that cattle can become overfat suggests that feed intake is under relatively imprecise control. Equally, sparse availability of range pastures or the provision of very low quality roughages as the sole feeds can lead to inadequate levels of feed intake and chronic undernutrition. The animal can suffer from deprivation because it is unable to ingest, or digest, enough nutrients daily to meet its requirements for maintenance of body weight. Nevertheless, there is evidence that cattle eat to satisfy their demand for energy to maintain weight and produce tissue growth or milk. The generalized relationships between the energy content of the diet and dry matter intake (Figs 9.3 and 9.4) suggest that signals received by the brain when the animal's energy needs are met in turn elicit the response to cease eating. Perhaps cattle eat as much as possible whilst at the same time attempting to minimize the total discomfort which may be caused physically or metabolically. Signals to commence eating may be metabolic (for example, the concentration of a metabo-

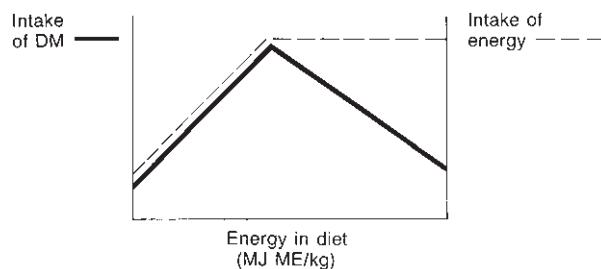

Fig. 9.3 Simplified relationship between the energy content of the diet and feed intake. As the energy content of the diet increases, dry matter intake will increase until it reaches a maximum. If energy content increases further, dry matter intake is reduced because metabolic factors, rather than the bulk, or 'fill', of the diet now control intake.

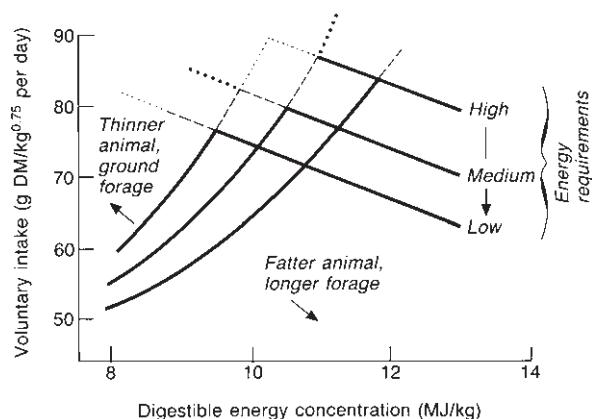

Fig. 9.4 Composite diagram of the relationships between intake and animal and feed factors in ruminants. At any given energy content, intake is higher for cows that have a greater requirement for energy (or potential milk production). Also, intake of dry matter is greater the thinner the cow, and the smaller the particle size of the feed. Source: Forbes (1983), reproduced with permission of CABI International.

lite such as acetate in blood), but the signals to cease eating may be physical (bulkiness of the food or restriction of rumen capacity by the fatness of the animal) or metabolic (concentrations of absorbed nutrients in blood), depending on the type of food. These concepts are discussed in more detail below.

Concentrates

With concentrates, satiety occurs long before the capacity of the rumen is reached. Intake is determined by the animal's capacity to metabolize the nutrients absorbed following digestion. Enhanced rate of metabolism, for example following the administration of somatotrophin, is reflected in increased feed consumption of

high-energy diets where physical limitations do not apply (see below).

Roughages

With roughage feeds the volume of the rumen usually restricts intake. Thus intake is proportional to the volume of the rumen – the larger the rumen, the more feed is consumed. Larger animals eat more than smaller animals because their rumen volumes are greater.

Rumen capacity

Animals with large rumen capacities relative to their total body weight eat more roughage than those with relatively smaller rumen volumes. The implications are that calves should be reared on diets that encourage rumen development, and cattle should be selected for large rumen capacities. Channel Island cattle (Jersey, Guernsey) typically eat more food relative to their body weight than Holstein cattle because, although they weigh much less, their rumen capacities are relatively greater. Thinner cattle tend to eat relatively more than fatter cattle (Fig. 9.4).

Digestibility of forages

Digestibility or energy concentration of forage feeds exerts a large influence on feed intake (Fig. 9.5). However, the relationship between intake and digestibility is much less evident for silages than for dried forages, where the pattern of fermentation in the silo, particularly the presence or absence of residual sugar and the pH value of the silage, can have an overriding influence on intake. Thus at the same digestibility drier silages of higher pH value and higher residual sugar concentrations tend to be eaten in greater amounts than more extensively fermented silages, possibly because they provide more readily available nutrients to the rumen microbial population.

Speed of digestion

Speed of digestion also has an important influence on intake, since it determines the length of time the feed remains in the rumen. Legumes are digested at a faster rate than grasses of the same overall digestibility, partly because they contain less cell wall than grasses (Fig. 9.5). Also, the structure of the cell walls of legumes enables bacteria to gain access more rapidly than with grasses.

The cell contents of forages are fermented very quickly in the rumen, provided they are released by eating and by rumination. For example, young grass may contain up to 40 per cent of its dry matter in the

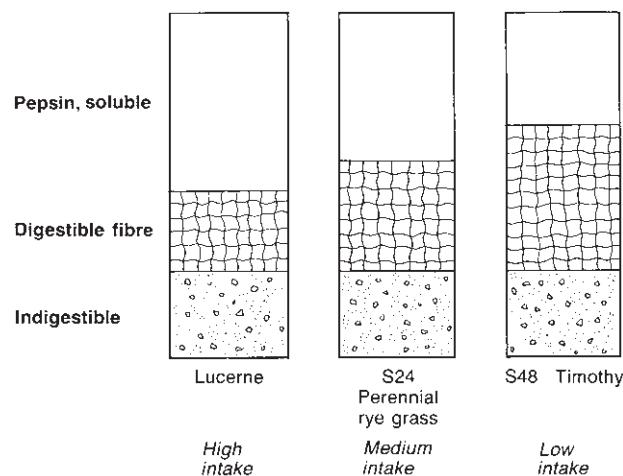

Fig. 9.5 Variations in the ratio of material soluble in acid pepsin (cell contents) to digestible fibre (cell wall) in three forages of the same digestibility, but differing in intake. Source: Osbourn (1967), reproduced with permission of the British Grassland Society.

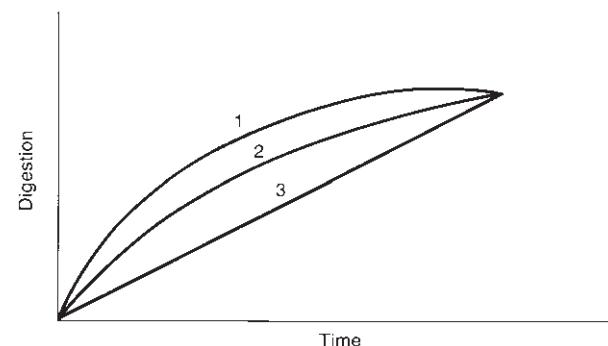

Fig. 9.6 Three feeds with the same potential digestibility but different speeds of digestion. The animal will eat most of feed 1 and least of feed 3. Reproduced from Orskov (1998) with permission of Chalcombe Publications.

form of cell contents, principally sugars and proteins, and in this regard it is nearer to a concentrate in terms of its speed of digestion in the rumen.

Cell walls are generally fermented at a slower rate than cell contents. The actual rate of cell wall digestion depends on initial particle size, the extent to which it is broken down by rumination, and the extent to which it may be lignified. Three feeds with the same potential digestibility but different speeds of digestion are represented in Fig. 9.6. The feed with the fastest speed of digestion will be eaten in the greatest amount by the animal.

Grazed pasture

Unlike indoor feeding, grazing animals select what they eat to a considerable extent, particularly when the

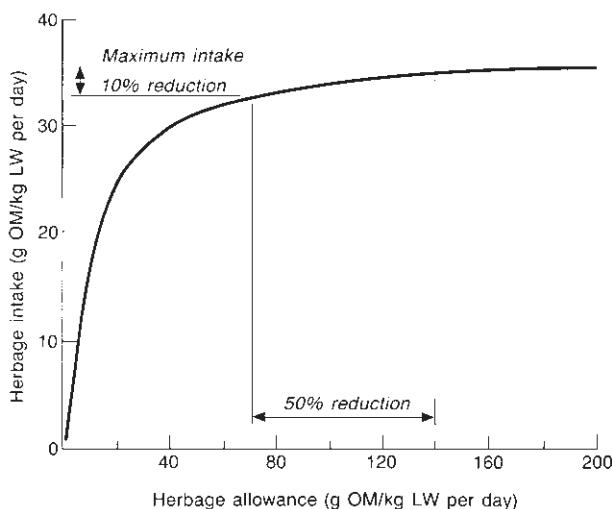

Fig. 9.7 Relationship between daily herbage allowance and herbage intake in grazing lambs. Source: Hodgson (1975), reproduced with permission of the British Grassland Society.

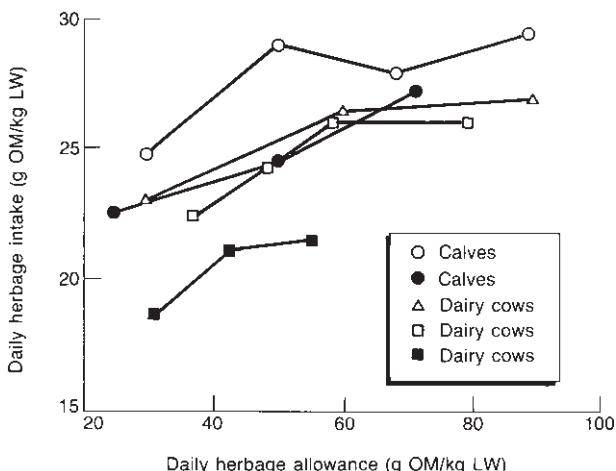

Fig. 9.8 Relationship between daily herbage allowance and herbage intake in cattle. (Data from different studies.) Source: Hodgson (1975), reproduced with permission of the British Grassland Society.

herbage on offer is heterogeneous and is offered in excess of consumption. Thus a measure of the digestibility of the herbage on offer is of little use as an indicator of intake, since the animals are usually able to select material of higher digestibility than the average of that on offer.

Herbage intake under grazing is predominantly influenced by the amount on offer. To achieve maximum intake, the amount on offer should exceed that actually consumed by three to four times (Figs 9.7 and 9.8).

Intake is usually expressed relative to liveweight, and it follows that the amount of herbage on offer should

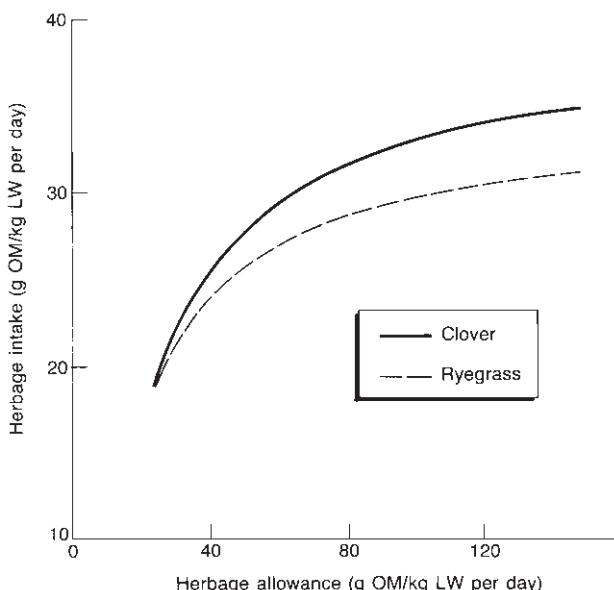

Fig. 9.9 Herbage intake of lambs grazing perennial ryegrass and red clover. Source: Gibb & Treacher (1978), reproduced with permission of Cambridge University Press.

be expressed per kilogramme liveweight rather than per hectare. It follows that stocking rate, a commonly used but empirical and inflexible way of describing herbage allowance, should not be expressed as number of animals per hectare, but as kilograms of liveweight per hectare (see section on feeding management, p. 118).

The relationship between herbage allowance and intake holds for animals in different physiological states, and for legumes as well as grasses (Fig. 9.9).

Studies of grazing behaviour and herbage intake by animals grazed on adjacent monocultures of grass and clover demonstrated that the grazing bovine has a strong preference for clover. Clover comprised 70% of total dry matter intake, and this preference was greater earlier in the day than during evening grazing, suggesting that some discomfort may have been induced following large meals of clover which the animal attempted to attenuate by preferentially eating grass in subsequent grazing meals.

Probable levels of intake

Estimated levels of voluntary dry matter intake for growing and lactating cattle are shown in Tables 9.2 and 9.3. The relative intake of cows given the same diet throughout lactation, expressed as a percentage of the mean for the whole lactation, is shown in Table 9.4. The important feature in Table 9.4 is the relatively low intake in the first month of lactation, when the demand for nutrients for milk production is at its highest, and

| 4 | 108 | 9 | 97 |
| 5 | 109 | 10 | 93 |

the consequent deficiency in intake of nutrients which results in the mobilization of nutrients from body tissues.

Energy requirements

Requirements and allowances

The notion of requirements takes no account of the variation between animals when kept in groups. Hence, if a group is given enough feed to meet the mean requirement for a given performance, a proportion of the group will be underfed and a proportion will be

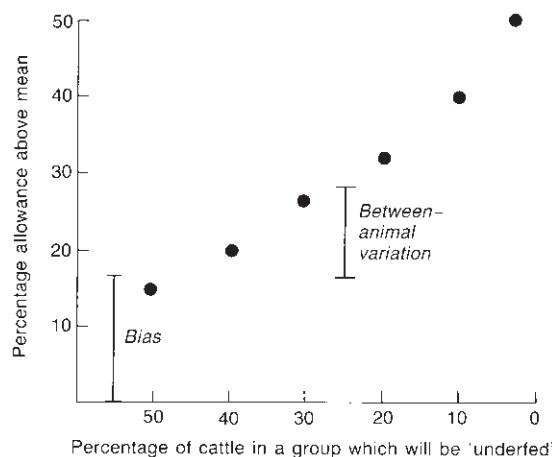

Fig. 9.10 Estimated allowances above mean requirements (ARC, 1980) required to meet the ME needs of a defined proportion of beef cattle in a group. Additional allowance due to bias in the estimate of requirements is shown separately from that due to estimated between-animal variation. Source: *Energy Group Report (1988)* Inter-Departmental Working Party.

overfed. Since underfeeding is considered to be the more serious failure of the system, allowances are made so that only a small proportion of the group remains underfed. If, as is the case with beef cattle, the metabolizable energy system of assessing requirement over-predicts performance, an additional increment (15 per cent) is added on to account for this inaccuracy. The result (Fig. 9.10) is that allowances may exceed requirements by some 30 per cent. 'Requirements' in practical feeding systems include a safety margin, although in most cases this margin is only 5 per cent and is arbitrary.

Partition of feed energy

The proportion of the gross energy (GE) of a feed that is absorbed by the animal depends on its digestibility. The amount remaining for metabolism (metabolizable energy, ME) is the digested energy less energy lost as methane or in urine. Further heat losses occur as a result of metabolism and the remaining energy (the net energy) is that which is available to the animal for maintenance of body weight, for weight gain or for milk production. The partitioning is shown diagrammatically in Fig. 9.11.

In calculating energy requirements, the term 'metabolizability' (q) is used. This is an expression of ME/GE , where GE is usually about 18.4 MJ/kg dry matter (DM) for conventional feeds. The greater the work of digestion, the higher the heat lost as a result of this work and the lower the q value of a feed. Thus q is generally

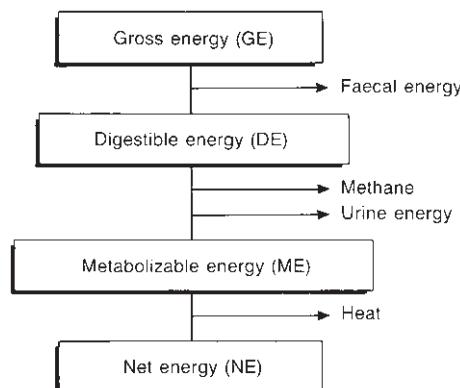

Fig. 9.11 Partition of energy.

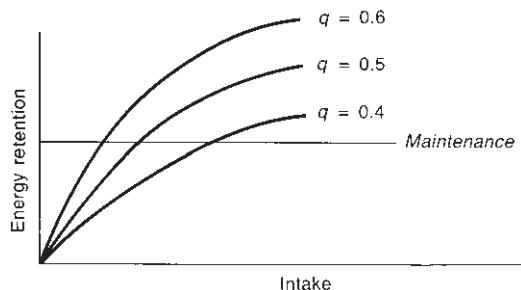

Fig. 9.12 Efficiency of use of ME for maintenance (k_m) is relatively high at 0.7. At twice the maintenance energy intake (common level for growing animals) efficiency of use of ME for growth (k_g) = 0.3 to 0.5 for diets ranging from $q = 0.4$ to $q = 0.6$; k_g declines further at higher levels of energy intake and correction must be made for the curvilinear decline.

lowest for feeds of low digestibility, such as straws, and highest for concentrates.

Efficiency of use of metabolizable energy

The proportion of ME used for maintenance and productive functions, such as growth or lactation, depends on the efficiency with which it is utilized by the animal (k). This depends on q , the level of feeding above maintenance and on the productive purpose for which the energy is to be used. Thus for growing cattle, k for maintenance (k_m) varies as shown in Fig. 9.12.

Energy requirements of growing cattle

For growing cattle, a variable net energy system has been adopted to take account of the fact that k_m varies with q . The system involves assessing the animal production level (APL), which depends on the weight of the animal and the desired level of weight gain, the net energy allowance for the particular animal and level of

Table 9.5 Net energy allowances for maintenance and production NE_{mp} in growing beef cattle (MJ/day). From MAFF (1975).

| Liveweight (kg) | Liveweight gain (kg/day) | | | | | |

gain, and the net energy value of a feed, which depends on its ME content and the particular APL. The relevant information is shown in Tables 9.5, 9.6 and 9.7. For two ingredient rations, a Pearson square is used to solve the simultaneous equations to derive the amount of each feed required in the diet (see example in Table 9.8).

Energy requirements of lactating cattle

As with growing cattle, the main determinant of the ME requirement for maintenance is liveweight, but the ME system for lactating cattle also recognizes that k_m varies with q (Fig. 9.13). A further important consideration is the composition of the milk produced by the cow. The higher the fat and protein concentration, the higher the milk energy concentration and the greater the requirement for ME for milk production at any given dietary q value. However, in most practical feeding situations the q of diets for lactating dairy cows is unlikely to vary significantly from about 0.7, because of the need to include high-energy forages and concentrates to meet the total energy requirement. The values for ME required for milk production in Table 9.9 relate to a q value of 0.7 for simplicity. If the diet has a q value lower than 0.7, then the requirement should be increased accordingly (Table 9.9).

Table 9.7 Net energy values of feeds for maintenance and production in growing beef cattle. From MAFF (1975).

Table 9.8 Example of feed requirements for a 300kg steer growing at 0.75 kg/day on silage (ME 10) and barley (ME 13).

- 1 Dry matter intake (DMI) (simplified), $0.02 W = 6 \text{ kg/day}$
- 2 Net energy for M + LWG (NE_{mp}) (from Table 9.5), 37.3 MJ/day
- 3 Animal production level (from Tables 9.6), 1.46
- 4 Net energy values of feeds (from Table 9.7)

$$\frac{NE_m + NE_p}{ME_{mp}}$$

Table 9.7
Silage ME 10 = 5.9 MJ/kg
Barley ME 13 = 8.6 MJ/kg
- 5 Energy concentration in ration,

$$NE_{mp}/DMI = \frac{37.3}{6} = 6.2 \text{ MJ/kg}$$
- 6 Pearson Square to calculate ration:

| | | |
|------------|-----|--|
| Barley 8.6 | 0.3 | $0.3/2.7 \times 6 = 0.67 \text{ kg barley DM}$ |
| 6.2 | | |
| Silage 5.9 | 2.4 | $2.4/2.7 \times 6 = 5.33 \text{ kg silage DM}$ |
| | 2.7 | |
- 7 Divide by DM, $0.67/0.85 = 0.8 \text{ kg fresh barley}$
 $5.33/0.25 = 21.3 \text{ kg fresh silage}$

The requirement for ME to support the growth of the fetus during pregnancy increases progressively with the duration of gestation. For the first half of gestation the requirement is negligible, and in practice the energy requirement of the fetus only assumes significance in the last two months of pregnancy, i.e. in the dry period. The requirement for ME for pregnancy (Fig. 9.14) assumes a 40kg calf at term. The requirement for heavier calves, such as Charolais × Holstein, is increased by direct linear scaling.

q = gross energy/metabolizable energy.

The net energy value of weight change is assumed to be relatively constant in the case of adult cattle, but the impact of weight loss on the ME requirement varies according to the presumed utilization of the body tissue catabolized – milk production in early lactation and growth of the fetus in the dry period. The ME value of weight change also varies with the *q* value of the diet (Table 9.10).

The energy requirement of the cow is also influenced by the amount of activity, especially walking, that the animal undertakes daily. In most temperate areas of the

world the energy expended in activity is considered to be moderate and the above requirements relate to that situation. However, cattle are sometimes subjected to extensive foraging under range and semi-arid conditions, and account should be taken of the increased energy required for activity when assessing requirements.

The total ME required is calculated as the sum of the above factors, but the overall efficiency of energy utilization of the lactating animal declines with increasing level of production, partly because of the faster rate of passage of food through the digestive tract at higher levels of voluntary intake and partly because the processes of absorption and metabolism are less efficient at higher levels of output. The correction for ME required depends on the animal production level (APL), defined here as the total ME required divided by the ME required for maintenance. Correction factors for level of production are in Table 9.11.

Protein requirements

Traditionally, protein requirements were expressed as digestible crude protein (DCP), that is, the proportion of the crude protein (CP or total nitrogen multiplied by 6.25) that is apparently digestible and therefore available to the animal. It is now recognized that DCP is totally inadequate as a system for assessing the protein requirements of ruminants.

The concept of digestible crude protein ignored the fact that a proportion of the digestible protein is degraded to ammonia by the action of the rumen micro-organisms. Some of this ammonia is synthesized into

q = gross energy/metabolizable energy.

microbial protein in the rumen; the rest is absorbed into the bloodstream, converted to urea in the liver and excreted in the urine.

There are many situations where the animal's requirements can be met entirely by microbial protein. However, in some situations, particularly with high-yielding dairy cows, the animal requires more protein than that supplied by the microbial cells and it is necessary to supply additional dietary protein to the abomasum that has not been broken down *en route* through the rumen.

Microbial protein synthesis

Microbial protein is of high value to the ruminant in that its balance of essential amino acids is very close to

Table 9.11 Correction factors for metabolizable energy requirement according to the animal production level (APL). Reproduced from Chamberlain & Wilkinson, 1996 with permission of Chalcombe Publications.

| APL | Correction factor |
|-----|-------------------|
| 0.7 | 0.99 |
| 1.0 | 1.00 |
| 2.0 | 1.02 |

| 4.0 | 1.05 |
| 5.0 | 1.07 |

APL = total ME/ME_{maint}

the animal's requirement (Table 9.12). Most classes of ruminant livestock can fulfil their total requirement for metabolizable protein (MP) from the supply of microbial true protein (MTP) alone. The exception is the high-yielding dairy cow, where supplementary digestible undegraded feed protein is required to meet the animal's total requirement for metabolizable protein (see below). In this situation, there may also be a requirement for supplementary essential amino acids such as methionine and lysine.

Much of the dietary protein eaten by the animal is degraded in the rumen to ammonia by the microbial population and it is possible to include non-protein nitrogen, such as urea, in diets which are deficient in degradable protein. Such deficiencies might arise in situations where the dietary ingredients, such as straw or maize silage, are low in total protein, or where the degradability of the feed protein is relatively low, as a result of heat-treatment during processing.

The production of microbial protein in the rumen depends on the supply of degradable protein and the supply of fermentable metabolizable energy (FME). The supply of degradable protein depends on the feed source and also on the time the feed spends in the rumen. Rumen outflow rate depends on the APL. The APL is therefore higher for high-producing animals than for low-producing animals. Degraded protein is not used with complete efficiency for microbial protein synthesis because some of the quickly degraded fraction is lost as ammonia through the rumen wall and is converted to urea in the liver. The proportion of quickly degraded protein (QDP) which is lost from the rumen is presumed to be 0.2, so that only 0.8 of the QDP is available to the rumen microbial population. All the slowly degraded protein (SDP) is potentially available to the micro-organisms and, together with 0.8 of the QDP, is the *effective* rumen degradable protein (ERDP) and is the amount of protein (or nitrogen) available for microbial growth and metabolism. However, the amount of ERDP which the microbial population can utilize depends on the amount of energy available, known as the fermentable metabolizable energy or FME. Some sources of energy in foods are considered to be of low value to the microbes, particularly those which yield low levels of ATP during their digestion in the rumen. Thus the energy in lipids and in silage acids is discounted, and the energy in undegraded protein should also be discounted (but is not) in the calculation of FME.

FME is therefore the total metabolizable energy minus the gross energy content of the lipids and (in the case of fermented feeds like silages) the content of fermentation acids. The yield of microbial crude protein (MCP) per MJ of FME, known as Y, depends on the APL because at lower APL the outflow rate from the rumen is reduced and at the lower outflow rate bacteria and protozoa die before passing out of the rumen and are digested by other rumen microbes. Their protein is recycled to produce new microbial protein. However, this process requires energy so additional FME is utilized with no net increase in yield of microbial protein.

The limit to the total yield of MCP is either the supply of ERDP (g per day) from the diet itself, in which case MCP production equals the supply of ERDP. Or, when the limit to the total yield of MCP is FME, the total amount of MCP produced is equal to the yield of MCP per MJ of FME (Y, which ranges from 8g MCP/MJ FME at an APL of 1.0 to 11.5 at an APL of 4.0) multiplied by the total supply of FME in MJ per day. The *lesser* of the two values is taken as the production of MCP in the rumen.

It is unusual to find a situation where the two limiting factors to the production of MCP – ERDP and FME – are equal and where the calculation of MCP production by the two methods gives the same result. For example, most grass silages contain an excess of ERDP and a deficit of FME, whilst maize silage has a deficit of ERDP relative to FME. The skill in formulating diets is to achieve the correct overall balance between the total supply of ERDP, the total supply of FME (see Figs 9.16 and 9.17 for examples of the ERDP and FME contents of different feeds) and their respective rates of digestion in the rumen.

Having calculated the production of MCP, this value is then reduced to take account of the fact that about 0.75 of MCP is true protein and that it is absorbed into the blood with an efficiency of about 0.85 (Fig. 9.15). Thus microbial true protein supply is only about 0.64 of the MCP produced.

Metabolizable protein

The digestion and metabolism of dietary protein are shown in simplified form in Fig. 9.15. Dietary crude protein (CP) ($\text{Total N} \times 6.25$) contains true protein, polypeptides, peptides and non-protein nitrogenous compounds (NPN) such as amino acids, amines, amides and ammonia. Urea, recycled to the rumen in saliva, is produced in the liver from ammonia which is in excess to that used by the microbial population of the rumen to synthesize microbial protein (see above). The amino acid content of microbial true protein is very constant,

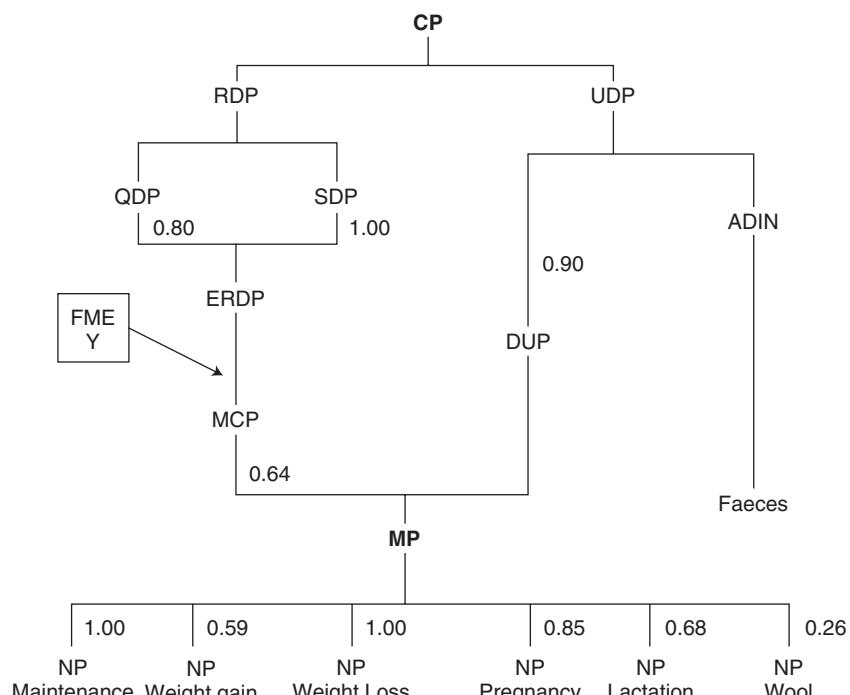

Fig. 9.15 The metabolizable protein system. Reproduced from Chamberlain & Wilkinson (1996) with permission of Chalcombe Publications.

and similar to the amino acid composition of tissue protein (beef) and also of milk (Table 9.12).

The degradable fraction, or ERDP, which yields microbial protein, is only part of the total supply of protein to the animal (Fig. 9.15). The protein which is not degraded in the rumen is termed undegraded dietary protein, of which a proportion, insoluble in acid detergent (ADIP or ADIN \times 6.25), is indigestible. The remainder is known as the digestible undegraded protein or DUP.

The extent of degradation depends not only on the inherent characteristics of the protein source, but also on the time the material is exposed to degradation in the rumen, i.e. on outflow rate from the rumen. Thus the same protein may have quite different values when given to different types of cattle (Table 9.13).

The supply of MP to the animal has two components (Fig. 9.15): MTP derived from the growth of bacteria and protozoa in the rumen (see the section on microbial protein above) and digested undegraded feed protein (DUP), which has passed intact through the rumen and has been digested in the abomasum together with the microbial protein. The rate of production of microbial protein in the rumen depends on the supply of ERDP, the supply of FME to the rumen microbes and the speed of flow of digesta out of the rumen. The supply of undegraded feed protein is also affected by the speed of flow of digesta through the rumen (Table 9.13). The speed with which feed particles pass through the rumen depends mainly on the APL of the animal.

Table 9.13 Example of differences in the proportion of degraded and undegraded soyabean meal protein according to class of livestock. Reproduced from Orskov, 1998 with permission of Chalcombe Publications.

| Dairy cows | | Growing cattle | | Suckler cows | |
|------------|------|----------------|------|--------------|------|
| ERDP | DUP | ERDP | DUP | ERDP | DUP |
| 0.50 | 0.50 | 0.65 | 0.35 | 0.85 | 0.15 |

ERDP = effective rumen degradable protein.

DUP = digestible undegraded protein.

The higher the APL, the faster the rate of passage of feed through the rumen. Thus MP supply depends not only on the feed itself but also on the type of animal to which the feed is being given. The requirement of the animal for MP depends on its level of productivity. The major requirement for MP in adult female ruminants is for the production of milk during lactation (see below), but the animal also requires MP for maintenance and growth, including the growth of the fetus during pregnancy, and for the production of wool. MP is released from the breakdown of muscle tissue during periods of body weight loss. MP is presumed to be utilized with variable efficiencies (net protein, NP) depending on its use (Fig. 9.15), with an efficiency of 1.0 for maintenance and with variable efficiencies for pregnancy (0.85), lactation (0.68), growth (0.6) and wool (0.26).

Requirements for metabolizable protein

The requirement of the animal for MP depends on the amount of protein produced in tissue growth or in milk. The young calf has a high rate of lean tissue growth relative to its feed intake. Hence the concentration of protein in its diet needs to be relatively high. The cow yields more milk and eats less feed in early lactation than in mid-lactation. At this time the energy output in the milk is higher than that consumed in the feed because the cow is using stored reserves, mostly body fat. However, fat from body reserves yields no metabolizable protein and as a result she requires more protein per unit of feed in early lactation than later on.

If sufficient energy is provided to maintain the animal, then microbial protein produced from ERDP is likely to be sufficient to meet the maintenance requirement for MP. On the other hand, if the animal is restricted to a submaintenance level of feeding, then it will lose not only body fat but also protein from muscle tissue.

|-----------------------------|------------------------|
| -1.0 | -131 |
| -0.5 | -66 |
| 0 | 0 |
| 0.5 | 122 |
| 1.0 | 245 |

The protein requirement of the bovine animal is generally considered in terms of the main activities of the body – the maintenance of essential functions, lactation, pregnancy and weight change. The requirements of cattle of different liveweights for metabolizable protein for maintenance are shown in Table 9.14.

The requirement for MP for lactation is quantitatively the most important and varies with milk yield and also, though to a much lesser degree, with the protein concentration in the milk. Values for the requirement for MP for milk production are shown in Table 9.15.

The requirement for MP to support fetal growth in pregnancy is very low in the early stages and only becomes of significance in the final two months of gestation (Table 9.16). Allowances for MP for weight loss and the requirement for weight gain are shown in Table 9.17.

The total requirement for MP is calculated as the sum of the requirements for the appropriate bodily functions. Thus, for a dairy cow weighing 600 kg liveweight, yielding 20 litres of milk of 3.2% protein, in her fifteenth week of pregnancy and gaining 0.5 kg liveweight/day the total requirement is 293 g for maintenance (Table 9.14) + 912 g for milk production (Table 9.15) + 8 g for pregnancy (Table 9.16) + 122 g for weight gain (Table 9.17) = 1335 g MP/day.

In some situations the total protein requirement is expressed as a recommended concentration of crude

Table 9.18 Recommended concentrations of crude protein in diets for cattle.

| Dairy cows | | Beef suckler cows | | Growing beef cattle | |
|----------------------------|--|----------------------------|--|---------------------|--|
| Milk yield (litres/day) | Dietary crude protein (g/kg dry matter) | Milk yield (litres/day) | Dietary crude protein (g/kg dry matter) | Liveweight (kg) | Dietary crude protein (g/kg dry matter) |
| | | | | | ME of total diet (MJ/kg DM) 11.0 12.0 |
| 0 | 135–145 | 0 | 120 | 100 | 180 210 |
| 10 | 145–155 | 5 | 150 | 200 | 140 150 |
| 20 | 155–165 | 10 | 150 | >200 | 130 140 |
| 30 | 165–175 | | | | |
| 40 | 175–180 | | | | |
| 50 | 180–190 | | | | |

protein in the total diet dry matter. This may appear to be an oversimplification, but where the degradability characteristics of the protein in some dietary ingredients are not known, or where there is uncertainty about the actual animal production level, then diets should be formulated according to the recommended concentrations of crude protein in Table 9.18.

Tests of the MP system with dairy cows have revealed that the system works reasonably well at low to medium levels of milk yield (20 to 30 litres/day), but that at higher levels of production the MP required is underestimated. This implies that the efficiency of utilization of MP for milk production is not constant at 0.68 (see section on metabolizable protein), but that it decreases at increased levels of output. The values for MP requirement for lactation in Table 9.15 have been adjusted upwards to take account of the decrease in efficiency of utilization of MP for milk production above a milk yield of 25 litres/day. Other systems of assessing protein supply and requirements, for example the French PDI system, also take account of the relatively greater requirement for MP of the high-yielding cow.

Composition of feeds

Cellulosic and non-cellulosic feeds

Feeds for cattle are best described in terms of the major components that undergo fermentation in the rumen. In other words, the conventional division into concentrates and roughages is only a crude way of distinguishing between feeds that contain mainly non-cellulosic (starch, sugar and protein) or cellulosic (plant cell wall) material.

The division into cellulosic and non-cellulosic feeds is relevant because the two fractions are fermented by

Table 9.19 Classification of feeds. From MAFF (1986b) and Lonsdale (1989).

| Mainly cellulosic (NDF >500 g/kg DM) | Mainly non-cellulosic (NDF <500 g/kg DM) |
|---|---|
| Straw | Kale |
| Hay | Very young grass |
| Grass (except very young grass) | Maize silage |
| Silage (except maize) | Fodder beet, root crops |
| Brewers' grains | Cereal grains |
| Malt distillers' draff | Molasses |
| Pectin-extracted fruit | Molassed sugar beet pulp |
| Coffee grounds | Maize gluten feed |
| Unmolassed sugar beet pulp | Soyabean meal |
| Bran | Fat |
| Wheat feed | Cottonseed cake |
| | Distillers' dark grains |
| | Citrus pulp |
| | Legume seeds |

different types of bacteria and at different rates (see section on fermentation in the rumen, p. 96). Cellulosic feeds are fermented at a slower rate, occupy more space in the rumen and are usually eaten in smaller quantities (i.e. at a slower rate) than non-cellulosic feeds.

When formulating diets it is useful to recognize the different fermentation patterns of the two types of feed and their different rates of intake by the animal. With productive cattle it is important to avoid too much of one type, or intake may be depressed – by acidosis if too much non-cellulosic material is eaten, or by a slow fermentation in the rumen and slow outflow rate if too much cellulosic material is eaten.

Feeds are classified into those which are mainly cellulosic and those which are mainly non-cellulosic, as

Table 9.20 Classification of raw materials according to their energy and protein contents. The degradability of the protein is also indicated*. Reproduced from Lonsdale (1989) with permission of Chalcombe Publications.

| Protein content (g/kg DM) | Metabolizable energy content (MJ/kg DM) | | |
|---------------------------|--|--|---|
| | High >12.0 | Medium 9.0–12.0 | Low <9.0 |
| High >200 | Maize gluten meal (prairie meal) (B) Groundnut cake (A) Soyabean meal (B) Sesame meal (B) Soya beans (whole processed) (C) Condensed corn steep liquor Lupins (sweet) (B) Pot ale syrup (A) Linseed meal (B) Spent wash syrups (A) US corn distillers' dark grains (C) Beans (field) (C) Wheat distillers' dark grains (C) Malt distillers' dark grains (C) Peas (B) Delactosed whey syrup (A) Copra expeller (B) Maize gluten feed (B) | Rapeseed meal (B) Sunflower seed meal (B) Cottonseed cake (B) Safflower meal (A) Malt culms (B) Brussels sprout packhouse waste (A) Malt residual pellets (B) Brewers' grains (B) Palm kernel meal (extr.) (B) | Cotton cake (undec.) (B) Sunflower seed meal (undec.) (B) Safflower meal expeller (A) |
| Medium 120–200 | Maize germ meal (B) Whey (A) Triticale (A) Wheat (A) | Wheat bran (B) Dried forages (grass, lucerne) (B) Wheatfeed (A) | Rice bran (C) Shea nut meal (D) Rape meal (D) |
| Low <120 | Barley (A) Oats (A) Sugar beet pulp (molassed, dried, pressed, ensiled) (B) Potatoes (A) Maize grain (B) Carrots (A) Citrus pulp (B) Molasses (A) Manioc (B) | Pectin extracted fruit (B) Apple pomace (B) | Oatfeed (C) |

* Degradability: category A = 0.71–0.90, B = 0.51–0.70, C = 0.31–0.50, D = <0.31.

shown in Table 9.19. Some forage feeds, which would at first sight be considered cellulosic, are not. High-quality grass, for example, typically contains less than half of the DM as cell wall or neutral detergent fibre (NDF) (MAFF, 1992); maize silage also contains less cell wall than cell contents, because of its high grain content; typically 250 to 300 g of the DM of maize silage is starch. Fodder beet contains 650 g sugar per kg DM, but it is contained within cell walls and is released in the rumen for fermentation at a slower rate than, say, the sugar from molasses.

Energy and protein in feeds

The two most important nutrients are energy and protein. Other nutrients, particularly minerals, can limit efficiency of feed use, but in practice if a wide range of feeds is included in the diet the risk of mineral imbalance is low. Most farmers add proprietary mineral supplements to the diets of their cattle. However, particular deficiency situations do arise due to inadequate management, for example hypomagnesaemia (see Chapter 46).

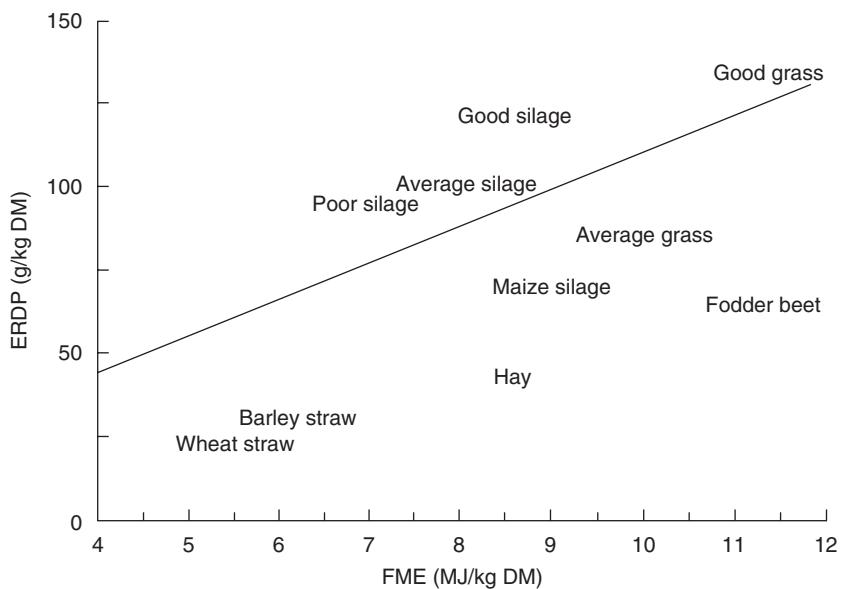

Fig. 9.16 Typical concentrations of ERDP and FME in selected forage crops. Reproduced from Chamberlain & Wilkinson (1996) with permission of Chalcombe Publications.

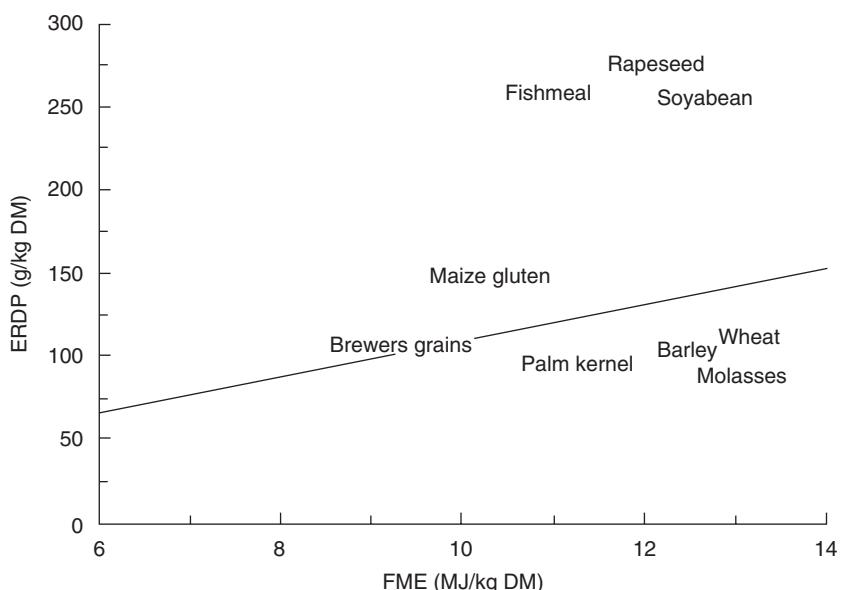

Fig. 9.17 Typical concentrations of ERDP and FME in selected concentrates. Reproduced from Chamberlain & Wilkinson (1996) with permission of Chalcombe Publications.

A simple classification of feeds is one which takes into account the concentrations of ME, FME, ERDP and DUP (see sections above for definitions of terms), as in Table 9.20. A fuller description of the composition of feeds is given in the UK Ministry of Agriculture, Fisheries and Food's book *Feed Composition* (MAFF, 1992).

An alternative way of considering feed sources is in terms of the balance between ERDP and FME, shown in Figs 9.16 and 9.17 for selected forages and concentrates, respectively. Maize silage, fodder beet, hay, straw, molasses and cereal grains are typically deficient in

ERDP relative to FME, whilst fishmeal, rapeseed meal, soyabean meal and maize gluten feed typically contain an excess of ERDP relative to their concentrations of FME.

Physical form

There are three easily recognizable categories for the physical form of feeds: (i) liquids, (ii) moist solids and (iii) dry solids. Examples of each category are shown in Table 9.21.

Table 9.21 Examples of the physical forms of raw material feeds. Reproduced from Stark & Lonsdale (1989) with permission of Chalcombe Publications.

| Liquid | Moist solid | Dry solid |
|-----------------------------|------------------------|-------------------------|
| Condensed corn steep liquor | Apple pomace | Bran (wheat and rice) |
| Delactosed whey syrup | Brewers' grains | Cereal grains |
| Fresh whey | Brussels sprout | Citrus pulp |
| Molasses | packhouse waste | Distillers' dark grains |
| Pot ale syrup | Carrot rejects | Dried grass and lucerne |
| | Maize gluten feed* | Legume seeds |
| | Pectin-extracted fruit | Maize germ meal |
| | Potatoes | Maize gluten feed* |
| | Sugar beet pulp* | Maize gluten meal |
| | | Malt culms |
| | | Malt residual pellets |
| | | Oatfeed |
| | | Oilseed residues |
| | | Sugar beet pulp* |
| | | Wheatfeed |
| | | Whole oilseeds |

* Available as either a moist or dry solid.

Liquids range from very low DM materials such as whey, which has handling characteristics similar to water, to viscous liquids such as molasses, which has a typical DM content of 750g/kg fresh weight. With the exception of whey, most liquid feeds have been condensed prior to shipment, in an attempt to reduce haulage costs.

Moist solids comprise those which contain fermentable sugars (e.g. fresh grass, molassed sugar beet pulp) and are usually stored as silage (see section on feed preservation, see below), and those which are low in fermentable components (e.g. apple pomace), and which benefit from the addition of a preservative.

Dry solids are a common form of feed and include cereal grains and by-products from the flour milling industry, hay, straw and residues from oil seed extraction. The DM content of dry solids is usually in the range 830 to 930g/kg fresh weight. Higher moisture contents increase the risk of spoilage during storage and for this reason most manufacturers of dry feeds aim to approach 900g DM/kg fresh weight if possible. Hay is usually stored at an initial DM content of around 800g/kg, but final DM content is typically 850g/kg fresh weight.

Feed preservation

The principle of preservation is to prevent the development of spoilage organisms such as the putrefying bacteria and moulds. These organisms prefer warm

temperatures, low levels of acidity (pH 6 to 8), oxygen and water. Hence preservation may be achieved by cooling (preferably freezing), by acidification, by exclusion or removal of oxygen, or by drying.

Drying

Drying is the most effective form of feed preservation. It is also the most costly and therefore tends to be used with the more valuable feeds (e.g. cereals) and with feeds that are prone to deterioration (e.g. citrus pulp).

The DM content of cereals is normally increased by drying to 850 to 870g/kg prior to storage. Hay is dried in the field to about 800g DM/kg fresh weight, unless it is to be dried artificially in the barn, when it may be harvested in a moist state at between 650 and 750g DM/kg. Drying in the barn proceeds until the safe DM content, more than 800g/kg, has been reached and the crop shows little sign of heating and moulding.

Ensiling

The process of ensilage involves the fermentation of plant water-soluble carbohydrate (WSC) monomers (simple sugars, mainly fructose and glucose) to organic acids, principally lactic acid. The acidity thus produced effectively 'pickles' the crop or feed in a stable state in the absence of air.

Fermentation is an anaerobic process. The crop must be completely sealed from the air to facilitate the growth

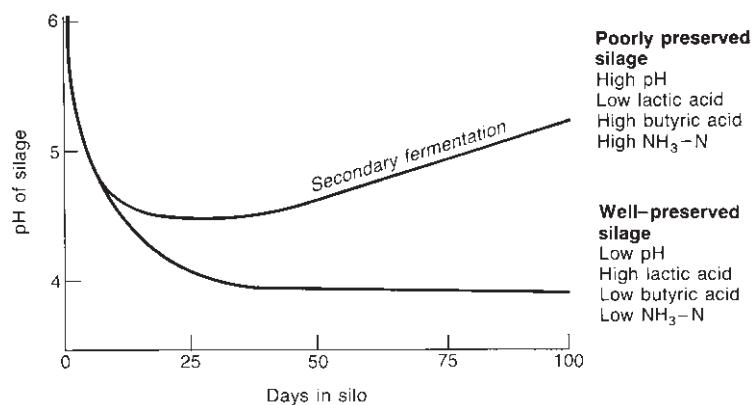

Fig. 9.18 Patterns of fermentation and changes in the pH value of silage as a result of secondary fermentation.

of the desirable anaerobic bacteria that are present on the crop in the field in relatively small numbers. As much air as possible should be removed from the crop at the time of ensiling, so that residual oxygen is exhausted as rapidly as possible. This is achieved by first chopping the crop as it is harvested from the field, by consolidating it once the crop is in the silo and finally by sealing it completely using a plastic sheet.

Primary and secondary fermentations

It is important to distinguish between primary and secondary fermentations, and to recognize that both are quite distinct from the process of aerobic spoilage that occurs on exposure of silage to the air at the time of feed-out.

Primary fermentation essentially comprises the conversion of sugars or WSC, mainly fructose and glucose, to lactic and other acids as the result of the metabolism of bacteria. This process can be rapid and completed in a few days.

Secondary fermentation, which sometimes follows the primary fermentation, involves the degradation of lactic and other acids, with the formation of恶臭 smelling acids like butyric acid. The process can also be accompanied by the complete degradation of nitrogenous compounds to ammonia. The main organisms involved in secondary fermentation are the obligate anaerobic clostridial bacteria.

At the point of entry to the silo the pH of the fresh crop is usually about 6.0. The crop is still alive, but it is consuming the products of photosynthesis (sugars) by respiration and producing carbon dioxide, water and heat. In addition, aerobic bacteria such as the Enterobacteriaceae (coliforms) consume sugars to produce acetic acid and degrade protein to ammonia.

As the supply of oxygen is exhausted, the primary fermentation dominates, with lactic acid the predomi-

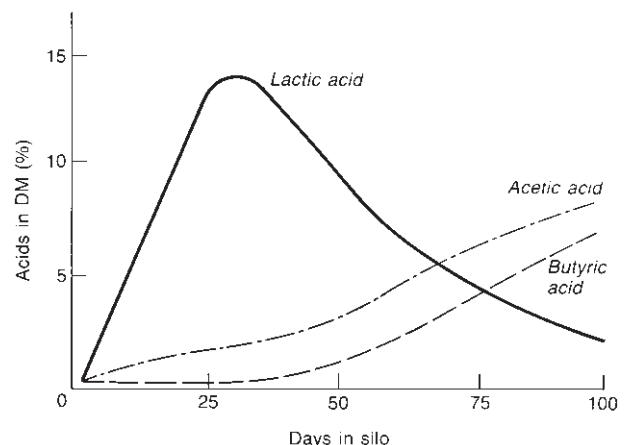

Fig. 9.19 Typical changes in the content of fermentation acids in silage as a result of secondary fermentation.

nant product. Acidity increases as the conversion of sugars to acids continues.

Primary fermentation proceeds until either the supply of fermentable substrate is exhausted or the amount of free water (i.e. that not associated with products of fermentation) is reduced to a sufficiently low level to restrict bacterial activity. A stable low pH is reached. The silage contains lactic acid as the main fermentation acid and the amount of protein completely degraded to ammonia is small (see Fig. 9.18). However, if the supply of sugar in the crop is low, or its resistance to acidification or buffering capacity is relatively high, secondary fermentation may occur during the storage period. In this situation the silage is unstable. Wet crops of low sugar content are particularly prone to secondary fermentation. Typical changes in the content of fermentation acids in silage as a result of secondary fermentation are shown in Fig. 9.19.

|---|---|
| Good | Maize Whole crop cereals Italian and hybrid ryegrass Perennial ryegrass Brome grass Timothy/meadow fescue Permanent pasture Cocksfoot Arable silage containing legumes Grass/clover Red clover Lucerne |
|  Poor | |

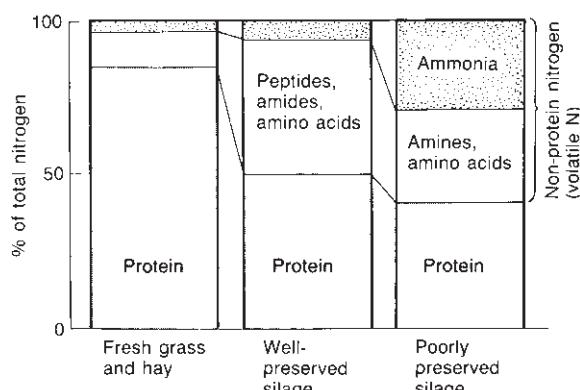

Fig. 9.20 The nitrogenous components of fresh grass, well-preserved silage and poorly preserved silage. Source: Wilkinson (1985).

Some crops, because they have a relatively low content of WSC or have relatively high buffering capacities, are more prone than others to secondary fermentations – their 'ensilability' is relatively low. Crops are ranked in order of their ensilability in Table 9.22. Maize combines adequate WSC with low buffering capacity, whilst the converse is true for the legumes, lucerne in particular.

Wilting in good weather prior to harvest has the effect of concentrating the sugars in the crop, and this is beneficial in terms of reducing the risk of secondary fermentation.

Silages that have undergone secondary fermentation are poorly preserved, but paradoxically they tend to be relatively stable on exposure to air. A major consequence of clostridial activity is an increase in the proportion of nitrogen present as ammonia in the silage (Fig. 9.20). Digestibility and energy value are also reduced due to secondary fermentation; hence losses of nutrients are elevated in poorly preserved silages.

Typical analytical composition of silage

Typical values for the composition of grass and maize silages made in bunker silos under European conditions are shown in Table 9.23. The most notable differences between grass and maize silage are in crude protein and NDF, which are higher for grass than maize, and in starch which is very low in grass silage. Poorly-preserved grass silages normally contain elevated levels of ash, fibre, acetic acid, butyric acid and ammonia-N, whilst energy values are depressed compared to well-preserved material. Amino acid-N is reduced as a proportion of the total non-protein nitrogen, indicating greater degradation to amines, amides and ammonia. Wilting grass silages generally undergo less extensive fermentations and consequently have higher pH values than wetter silages, residual (i.e. unfermented) WSC, lower concentrations of fermentation acids and less ammonia-N (Table 9.23).

Additives for silage

The main objective in applying an additive at the time of harvest is to prevent the multiplication of clostridia. The lactic acid bacteria are more tolerant of acid conditions than are the clostridia, so traditionally their growth has been inhibited by direct acidification of the crop with an organic acid such as formic, or an inorganic acid such as sulphuric. The former is relatively more expensive, but it does have a specific antimicrobial action against clostridia, whilst sulphuric acid acts solely through its effect in reducing pH. Some products comprise mixtures of acids and synergistic properties are claimed for them.

If the pH of the crop can be reduced from 6.0 to about 4.5 by acidification at the time of harvest then the risk of clostridial growth is greatly reduced.

An alternative approach is to accelerate the production of lactic acid by the direct inoculation of the crop at harvest. Provided sufficient live bacteria are added (ideally 1 million colony forming units/g fresh crop) and provided the content of fermentable sugar in the crop is sufficient for their growth then good preservation quality should be assured. Problems can arise with inoculants if there is insufficient sugar, either because the crop itself is deficient or because the crop is too wet at the time of ensiling. The most common species of bacteria in inoculants is *Lactobacillus plantarum*.

Enzyme additives, containing hemicellulase and cellulase, are another type of additive; the object in this case is to generate extra sugar from cell wall components to ensure sufficient acidification during primary fermentation so that clostridia are inhibited.

Products are now available which contain both lactic acid bacteria and enzymes. It is essential, however, to

Table 9.23 Typical composition of grass and maize silage stored in bunker silos.

| | Grass silage | | | Maize silage | |
|-------------------------------------|------------------|----------------|---------|--------------|--|
| | Direct-cut | | Wilting | | |
| | Poorly preserved | Well preserved | | | |
| pH | 5.5 | 3.8 | 4.5 | 4.0 | |
| DM (g/kg fresh weight) | 160 | 180 | 360 | 300 | |
| Ash (g/kg DM) | 110 | 80 | 90 | 55 | |
| Crude protein (g/kg DM) | 160 | 160 | 150 | 90 | |
| NDF (g/kg DM) | 650 | 550 | 550 | 450 | |
| WSC (g/kg DM) | 0 | 0 | 50 | 85 | |
| Starch (g/kg DM) | 0 | 0 | 0 | 250 | |
| Lactic acid (g/kg DM) | 50 | 150 | 65 | 100 | |
| Acetic acid (g/kg DM) | 25 | 20 | 35 | 45 | |
| Butyric acid (g/kg DM) | 35 | 0 | 0 | 0 | |
| DOMD (g/kg DM) | 675 | 700 | 700 | 720 | |

| NH ₃ -N (g/kg total N) | 300 | 75 | 40 | 30 | |
| Amino acid-N (g/kg total soluble N) | 405 | 700 | 750 | 650 | |

establish that the active ingredients in these biological additives really are active, and have not been destroyed by processing, packaging or storage.

Additives for hay and moist grain

The risk of development of moulds and mycotoxins in moist hay and moist grain may be reduced by adding an effective preservative at the time of storage. Propionic acid and salts of propionic acid such as ammonium bis-propanoate, added at 15kg active ingredient per tonne of fresh crop at the time of harvest, are effective in reducing mould development in both hay and grain and also in big bale silage, where moulding due to incomplete sealing is a common problem.

Feed processing

Physical processing of roughages

Traditionally, feeds like hays and straws were chopped or ground prior to feeding. There is now increasing evidence to indicate that although these procedures may be convenient for the processor, they are less than ideal from the point of view of the nutrition of the animal.

With fibrous feeds such as straw, intake is often limited by the speed with which long particles are reduced in size by chewing so that they can pass out of the rumen. Grinding removes this restriction to intake, but a consequence is that particles pass out of the rumen before they are fully digested. The net result is that although dry matter intake is increased, digestibility is reduced and nutrient intake is little changed.

Chopping long forages also reduces the opportunity for the animal to select the best quality material on offer. However, if straw is to be used in a complete diet, coarse chopping is a useful way of incorporating the feed uniformly into the total mixture.

Long fibre with an average particle length of at least 150mm is essential for milk fat synthesis and for the maintenance of rumen function on high-concentrate diets. It is therefore important to bear in mind that physical processing of roughages can diminish their value with respect to milk quality and the health status of the rumen.

Chemical processing of roughages

The use of alkalis, such as sodium hydroxide, for upgrading straw is not new, but recently additional

benefits from the use of the technique have been recognized.

Essentially, the technique involves adding sodium hydroxide to straw at about 50 kg per tonne fresh weight. The alkali degrades and swells the plant cell wall material, with a consequent increase in digestibility and intake. The benefits are valuable where straw is plentiful and where it comprises a high proportion of the total diet, for example in the case of beef suckler cows.

The residual alkalinity in straw treated with sodium hydroxide can help to reduce the risk of ruminal acidosis in high-yielding dairy cows given diets containing large proportions of concentrates and/or highly acid silages. In these situations, where fibre is needed to maintain milk fat content but the overall energy content is required to be high at the same time, the provision of a source of long fibre of enhanced digestibility is also valuable.

Ammonia (usually added in aqueous form at 30 kg NH₃ per tonne fresh weight) is a useful alternative alkali to sodium hydroxide. It has the advantage of also contributing nitrogen, a valuable feature if the diet is deficient in rumen degradable nitrogen, but a disadvantage if silage of high protein content is the major forage in the diet.

Urea may also be used to upgrade straw, but both the moisture content of the straw and ambient temperature need to be relatively high for the technique to be successful.

The effect of an increase in digestibility of straw on intake can be considerable. Thus a 10 per cent improvement in digestibility can lead to a 50 per cent increase in dry matter intake. Since the feed consumed is more digestible, the increase in ME intake is even greater.

Processing of cereals

Grinding of cereals was traditionally considered essential to achieve complete digestion by cattle. A trade-off was accepted between rapid digestion in the rumen and possible acidosis on the one hand and poor digestibility with undigested grains appearing in the faeces on the other. It is now accepted that the passage of a few undigested grains has no measurable effect on digestibility, but that forage digestibility can be reduced when grain is overprocessed.

The need for cereal processing depends on the size of the reticulo-omasal orifice. In the case of sheep and calves less than 150 kg liveweight, it is difficult for whole barley and whole oat grains to pass through the orifice, whilst it is easy in larger cattle. Thus whole grains may be given to young calves, but some processing is necessary for older cattle. If possible, the extent of process-

ing should be as small as possible: it is sufficient to crack the seed coat. Crimping is better than rolling, but treatment with sodium hydroxide, which has the effect of breaking the seed coat by swelling it, is probably the best method from the animal's point of view. In addition to slowing down the rate of digestion of the starch in the grain, the residual alkali buffers acidity in the rumen.

Feeding management

Successful nutrition of the bovine not only requires an understanding of the principles of nutrient requirement, nutrient supply and animal response; it also involves appropriate management of feed resources. This includes presenting the correct amount of feed to the animal for the appropriate period of time, formulating diets from available resources that meet requirements, taking into account the condition of the animal and the desired direction and rate of change in weight and condition and budgeting ahead so that rapid changes in diet are avoided and performance targets are achieved.

The importance of selective eating

The need to maintain stability in the rumen has led to the presentation of feeds to the animal over a large proportion of the day. This is particularly so with forages and straws, where rate of intake is relatively slow. It is also important that the animal has access to feed for most if not all the time when selectivity is desirable.

At pasture, maximum intake is only achieved when herbage is offered in substantial excess (Figs 9.7 to 9.9). In general, the amount of herbage on offer should be three to four times the amount eaten in order to achieve maximum potential voluntary intake (see section on grazed pasture, p. 101).

Targets for sward surface height at pasture

A simple guide to the amount of herbage on offer is the sward surface height of the grazed pasture. Regular measurement of sward height or sward mass is a useful tactical aid to pasture management. Targets for sward height for growing, lactating and dry cows are shown in Table 9.24.

It is important to measure sward height in grazed areas, since herbage that is rejected due to contamination by faeces, urine or treading is unlikely to be eaten until the height of herbage in grazed areas is well below that at which intake is restricted below maximum.

Table 9.24 Target sward surface heights (cm) for rotational and continuous grazing.

| | Spring | Early summer | Late summer | Autumn |
|-----------------------------------|--------|--------------|-------------|--------|
| Lactating cows and growing cattle | | | | |
| Rotational grazing | | | | |
| Pregrazing | 10–15 | 12–16 | 14–18 | 10–15 |
| Postgrazing | 6–7 | 7–8 | 8–9 | 6–7 |
| Continuous grazing | 6–7 | 7–8 | 8–9 | 6–7 |
| Dry cows ^a | 4–5 | 4–5 | 4–5 | 4–5 |

^a Postgrazing, rotational and continuous grazing.

Buffer feeding

The concept of buffer feeding was developed as a way of reducing losses in output from grazed pasture, especially when herbage allowance was apparently adequate but intake less than maximal due to poor weather, inadequate grass growth, short day length or reduced time of access to pasture.

The buffer feed should be less acceptable than the herbage on offer at pasture, otherwise the buffer acts as a substitute rather than a supplement for grazed grass. Typically, silage or hay are used as buffer feeds, offered *ad libitum* at the farm buildings to dairy cows after each milking or placed in the grazing field for other classes of stock.

Frequency of feeding and ruminal acidosis

It is significant that when cereal concentrates are offered *ad libitum* the animal eats a little at a time. Thus the general practice in feedlots, and in areas of the world where milk is produced from high-concentrate diets, is to allow the animals 24-hour access to all feeds (both concentrate and roughage) to avoid ruminal acidosis, otherwise known as 'feedlot bloat'. This condition is caused by the rapid fermentation of starches and sugars, and can occur as the result of infrequent ingestion of large feeds of concentrates. It can also occur as the result of inadequate long fibre to maintain rumination and saliva production. Essentially, the condition is due to the dominance in the rumen fermentation of lactic acid producing bacteria (p. 829). Ruminal stasis can occur at low rumen pH (less than pH 5.5) and the inability of the animal to eructate leads to the accumulation of gas and the resultant bloat (p. 832).

Cattle given concentrates *ad libitum* should therefore also be allowed access to long forage or a source of roughage such as straw, at about 15 per cent of the total diet dry matter.

Traditionally, dairy cows were given concentrates, usually in the form of milled compounded feeds, in the parlour at milking and forages *ad libitum* for the rest of the day. With ever-increasing milk yields per cow, the pressure on the available time in the parlour meant that the cow had difficulty consuming a large feed of compounds during the milking period. Further, the rapid fermentation of the two relatively large meals (sometimes as much as 5kg/meal) meant that rumen pH decreased, fibre digestion slowed down and forage intake was reduced as a result (see Fig. 9.21). Accordingly, a mid-day feed of compounds or of by-products such as dried sugar beet pulp was introduced to reduce the quantity of compound to be fed through the parlour.

Sodium bicarbonate may be a suitable ingredient of the diet when the cow is suffering from acidosis. However, the problem with bicarbonate is that it is relatively unpalatable and large quantities are required to have a significant effect. Thus the addition of 100 to 150g/cow per day is insignificant by comparison with the 3 kilogrammes of bicarbonate produced in saliva daily. It is better therefore to include feeds, like hay or straw, to stimulate rumination and salivation.

Out-of-parlour feeders

The advent of computerized cow identification has enabled cows to be rationed accurately in the parlour according to yield, and it was a relatively logical step to introduce out-of-parlour feeders to allow the higher-yielding individuals to eat compounds and concentrates during the rest of the day. The nutritional advantages were that higher levels of compounds could be given to those cows that 'deserved' to receive them, and in a relatively large number of meals per day. Feeders could be programmed to deliver equal proportions of the total day's allocation in up to 12 feeds per day; cows not

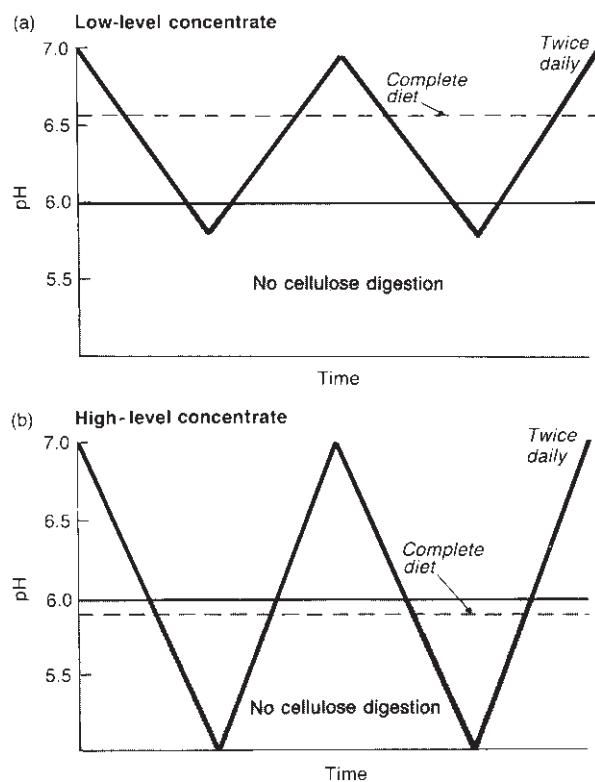

Fig. 9.21 It is important to prevent the pH of the rumen from falling below 6.0 for long periods of time, otherwise cellulose digestion will be greatly reduced. The problem is less at low levels of concentrate feeding (a) than at high levels (b). Reproduced from Orskov (1998) with permission of Chalcombe Publications.

taking their feeds were readily identifiable and could be checked for disease immediately.

Flat-rate feeding

The introduction in Europe of milk quotas placed a limit on output, and the emphasis switched to simplifying the day-to-day feeding management of the dairy herd, especially in those herds where the input of concentrate was moderate and where the supply of grassland for grazing and silage was adequate and reliable throughout the growing season.

The principle of flat-rate feeding is that all cows receive the same amount of concentrate, irrespective of their actual or potential milk production, together with silage *ad libitum*. The system works best when there is a compact calving pattern, with most cows at the same stage of lactation, and when the input of concentrates is relatively low. Silage quality should be relatively high and if necessary the level of concentrate should be reduced when the herd is in late lactation to prevent cows becoming overfat.

In practice, higher-yielding cows in the herd eat more silage and it is important that the silage is on offer *ad libitum* otherwise these animals are underfed. Peak lactation yields tend to be lower than in herds given concentrates to yield, but the rate of decline in yield post-peak tends also to be slower than in herds fed to yield, giving a flatter lactation curve for flat-rate feeding.

Total mixed rations or complete diets

The main principle of complete diet feeding is that the animal receives an intimate mix of slowly and rapidly fermented feeds, thus balancing the inflow to the rumen of feeds with widely differing rates of fermentation and (it is hoped) thereby maintaining stable conditions in the rumen.

However, with high proportions of concentrates in the mix, the level of acidity in the rumen may be so high that fibre digestion is permanently depressed (Fig. 9.21). In this situation, the proportion of propionate in the rumen volatile fatty acids is elevated and as a result cows tend to gain in weight and produce milk of relatively low fat content. Overfat cows with fatty livers were a feature of early mismanagement of herds given complete diets.

Thus, provided cows in late lactation and dry cows are not given the same high-energy mix as higher-yielding animals, complete diets offer a logical approach to feeding management. By-products can be incorporated into complete diets with greater ease than in other feeding systems. Higher voluntary feed intakes are usually achieved than with separate feeding, and milk compositional quality is often improved as a result of the higher energy status of the animal and improved fibre digestion in the rumen. On the other hand, the investment in mixer-wagons can be considerable and there is little evidence of improved overall efficiency of feed utilization by animals given total mixed rations compared to the same diet in separate feeds of forages and concentrates.

Diet formulation

Diets are formulated to meet calculated requirements for major nutrients (see sections on energy and protein requirements, pages 103, 106), taking account also of the needs of the animal for macro- and microelements. Recent research in the USA indicates that formulations for lactation should also take account of dry matter content and the content of NDF (cell wall) in the total diet. The dry matter content of the whole diet should be between 500 and 650 g/kg fresh weight for maximum intake, whilst the content of NDF should be between 350 and 450 g/kg DM for maximal output of milk

Table 9.25 Target condition scores for beef suckler cows. Reproduced from Fuller (1988) with permission of Chalcombe Publications.

| Stage of reproductive cycle | Target condition score | |
|-----------------------------|------------------------|---------------------|
| | Autumn-calving cows | Spring-calving cows |
| At calving | 3 | 2.5 |
| At mating | 2.5 | 2 |
| Mid-pregnancy | 2 | 3 |

| Feed | Budget |
|------------------------|--|
| Grazing | |
| Spring | 5 cows per hectare |
| Early summer | 3.5 cows per hectare |
| Late summer and autumn | 2.5 cows per hectare |
| Silage | 10 tonnes fresh weight per cow at 10.5 MJ ME/kg DM |
| Concentrates | |
| When cows are housed | 1.4 tonnes per cow |
| When cows are grazing | 0.1 tonnes per cow |

fat. Constraints in diet formulation programmes now include dry matter and NDF in addition to conventional prediction equations for voluntary intake and nutrient requirements.

Condition score

Condition scoring cows is relatively easy; there is no fleece to hide the animal's fatness (or thinness). The essential areas for physical examination are: (i) the transverse processes of the lumbar vertebrae at the top of the loin, halfway between the last rib, (ii) the hip bone and (iii) the tail head (see Chapter 2, Fig. 2.1).

Scoring should ideally be carried out by feeling the extent of subcutaneous fat cover at the tail head and at the lumbar area. With practice, visual scoring is possible taking into account the visibility of the ribs and the amount of fat at the tail head. Cows in condition score 1 have no fat at the tail head and their ribs are prominent. The ribs are visible in condition score 2 but not in condition score 3 and above. As condition score rises above 2, the amount of fat visible at the tail head increases.

Target condition scores for cows at different stages of the production cycle are shown in Table 9.25.

| Silage beef (15–16 months) | 6 | 0.8 |
| Cereal beef (11–12 months) | * | 1.6 |

* 0.2 t straw/head to maintain rumen function.

Regular condition scoring helps to identify overthin cows that require preferential treatment (extra feed) and overfat cows, especially those in late pregnancy, that are at risk of dystokia at calving. Scoring in early lactation to monitor the effectiveness of nutrient inputs

to achieve weight gain at mating is an essential part of successful rebreeding. Economies may also be made in high-energy feeds at times when the whole herd is scored as being slightly overfat.

Feed budgeting

Feed budgeting is the extension of daily diet formulation to annual feed planning. Future levels of output are set and a feeding policy is developed which takes into account the home-produced feeds available, or likely to become available during the year, and the type and quantity of purchased feeds required to meet the target level of output. A buying strategy is developed to meet the projected requirements.

Simplified examples of feed budgets for grazing and winter feeding are shown in Tables 9.26 to 9.28 for dairy cows, suckler cows and growing beef cattle, respectively.

Introduction

The main forage crops in the UK and many other countries for cattle are conserved grass in the form of hay or silage, otherwise straw. Economic and nutritional considerations have led to a quest for alternative forages.

Feeding dairy cows, dairy heifers, suckler cows and beef animals is a mixture of science and art. Any ration needs to be balanced for energy, protein, minerals, vitamins and water, to meet the required production objectives. Energy sources will include starches, sugars and digestible fibre, whilst protein will be of rumen degradable and digestible undegradable protein and will contain a wide range of amino acids. The ration must be palatable, digestible, appetizing and free from dirt, stones, harmful bacteria and moulds. Some feeds are enhancers of dry matter intake (DMI), whilst others substitute for existing ingredients in the ration. Thus brewers' grains, sodium hydroxide-treated straw, maize, etc., are enhancers of DMI whereas, for example, barley and wheat substitute for each other.

The UK Ministry of Agriculture, Fisheries and Food and the Agricultural and Food Research Council have published standards for energy, protein and the major

minerals for maintenance and production for lactating and fattening animals. Knowledge is incomplete, and the art of feeding stock relates to adjusting feeds, introducing different ingredients and measuring and observing the results.

The figures shown in Table 10.1 act as a starting point in the compilation of dairy cow rations, particularly as feeds can vary in analysis. Alternative forages will need to fit the criteria laid down for each animal's production. However some forages, such as maize and lucerne, are DMI enhancers and so they can be perfectly satisfactory at lower energy densities in winter rations.

Dairy heifers, calving at two years old, need to grow at 0.7–0.8 kg/head daily to attain a satisfactory calving weight, and beef animals in the final stages of fattening require growth rates in excess of 1 kg/head daily.

Total farm profitability determines whether or not alternative forages feature in a farming system. Factors to be considered include soil type, labour availability, working and fixed capital requirements, value for money, yield variability, rotational considerations and feeding facilities. The majority feature in winter rations, but kale and stubble turnips are often grazed in the summer and early autumn, while lucerne and red clover are versatile protein sources in the summer. They can be grazed (with caution because of bloat) or conserved as silage. Red clover is usually in a grass ley mixture, but lucerne is generally grown as a pure stand.

A brief description will be given of some of the crops available together with their use and integration into cattle rations.

Forage maize (corn)

The typical analysis of forage maize silage per kg dry matter (DM) is:

DM = 28 per cent, metabolizable energy (ME) = 10.8 MJ, digestible crude protein (DCP) = 70 g, neutral detergent fibre (NDF) = 360 g, modified acid detergent fibre (MADF) = 215 g

Minerals: Ca = 3.9 g, P = 1.8 g, Na = 0.2 g, Mg = 2.4 g

Yield on National Institute of Agricultural Botany (NIAB) plots = 12.0 t DM/ha

Table 10.1 Winter ration criteria for Friesian/Holstein dairy cows.

| | Milk yield (kg/day) | | | |
|------------------------|---------------------|------|------|-----|
| | 35 | 25 | 18 | Dry |
| Minimum DM (%) | 38 | 33 | 26 | 22 |
| Energy density | 12.0 | 11.4 | 10.8 | 9.5 |
| Minimum MADF fibre (%) | 15 | 18 | 22 | 25 |
| Approximate DMI | 20.9 | 17.1 | 14.7 | 9.3 |

Note: protein guidelines are 400g DCP for maintenance and 60–65g DCP/kg milk, with sufficient undegradable as well as degradable protein in the ration.

For Jersey cows with milk yields of 25, 18, 13 and 9kg respectively, the protein requirements are 350g DCP for maintenance and 70–75g DCP/kg of milk.

Maize silage is best stored in long, narrow clamps to limit the amount of heating and hence spoilage when the clamp is opened. Most maize is grown in the southern counties of Britain but as more early-maturing varieties are being bred, the frontiers are being pushed further north.

The true value of maize (corn) is often underestimated by conventional equations. Maize silage costs less to produce than grass silage, and is complementary to it. In a dull, wet summer, the ME can be under 10 but is still as good as most grass silages made in similar weather. Generally, it is a high-energy, low-protein conserved forage that has limited fibre and is low in minerals, particularly calcium, phosphorus, sodium, copper, zinc, iodine and manganese. The greater the proportion of maize in the ration, the more deficiencies need to be corrected.

A typical ration for a dairy cow yielding 25kg milk might include 32kg grass silage, 14kg maize silage, 1kg soya bean meal, 5.5kg maize gluten and 0.15kg high phosphorus minerals. Research work, particularly by Phipps (pers. comm.), has shown that by including at least 25 per cent of the silage as maize increases forage DMI, lowers the cost and increases milk production and hence the weight of fat and protein. The response is greater with 63 per cent digestibility ('D' value) silage compared with 68 D grass silage. With a ration based on 40:60 grass:maize silage and 6kg concentrates, DMI and milk yield were increased by 2.8 and 2.9kg respectively compared with grass silage and 6kg concentrates. Maize silage combines well with lucerne silage, but needs an addition of 1–2kg straw to provide fibre.

Maize silage can be used as the sole source of forage for dairy cows. An example ration for a cow producing 25kg milk would be 27kg maize silage, 3.5kg caustic treated straw, 2kg molasses, 2kg sugar beet pulp, 3kg

maize gluten, 2.5kg rapeseed meal, 1.5kg soya bean meal and 0.3kg mineral/vitamin supplement. As the DM of maize silage increases, so does the DMI.

Maize silage can be introduced to young cattle at under three months old, but additional protein, vitamins and minerals are necessary. Typically, a 300kg heifer growing at 0.65kg/day requires 5.1kg DM of maize silage, 0.2kg 50 per cent vegetable protein and one per cent non-protein nitrogen (urea) added to maize silage; 1kg of a 34 per cent protein/mineral/vitamin supplement would also be suitable.

Bull beef animals have higher intakes of maize than grass silage. A beast weighing 300kg needs 6kg DM of maize silage plus 1.5kg of a 34 per cent protein/mineral/vitamin concentrate supplement to gain 1kg/day. This quantity of supplement is kept constant over a range of weights so that the crude protein of the complete ration declines as the animal matures.

Maize fits well into a grass silage system and can be self-fed or forage-box fed. It can be fed as a green crop prior to harvest, and used as a buffer feed in spring for cows at pasture.

Fodder beet

The typical analysis of fodder beet per kg DM is:

DM = 18.3 per cent, ME = 11.9MJ, DCP = 34g,

NDF = 127g, MADF = 83g

Minerals: Ca = 3.9g, P = 1.8g, Na = 2.4g, Mg = 1.4g

Yield on NIAB plots = 14.2t DM/ha (excluding the value of fodder beet tops (leaves), which can add up to 30 per cent to the DM)

Ensiled tops are higher in protein minerals (especially phosphorus) and fibre and can complement the diet, but are difficult to harvest and utilize efficiently. Fresh tops can contain harmful oxalic acid and lead to calcium problems but the problem is reduced with wilting. Thus they can cause scouring and milk fever in freshly calved cows.

Fodder beet is used primarily as a low-cost concentrate replacer for dairy cows, at a maximum of 4–4.5kg DM (22–25kg fresh weight). As a high-energy source, it will need to be balanced by additional degradable and undegradable protein. In limited cases, it can be used as part of the maintenance ration but additional protein, fibre (as hay or straw) and minerals will be required.

For a dairy cow yielding 25kg milk, with 40kg grass silage producing more than maintenance, 15kg of fodder beet, 4kg maize gluten and 2.25kg of a proprietary 20 per cent protein, high-energy concentrate complete the ration. A mix of other dry concentrates such as barley and soya bean meal can replace maize gluten.

Harvested fodder beet can be fed from a hopper or behind an electric fence provided that sufficient feed space is available to avoid uneven intakes between cows in the herd. It is more commonly fed as part of a complete diet in a forage wagon, but the beet must be free from dirt and preferably finely chopped or shredded to integrate in the ration.

Strip-grazing beet in the field produces a multitude of problems: poisoning from tops (even when topped this can be via secondary growth in the spring), waste of feed and foot troubles (see Chapter 31).

When used as a concentrate replacer, fodder beet enhances the butterfat and protein percentages in the milk, but observations suggest that it depletes the compositional quality when used as part of the maintenance ration.

A combination of fodder beet and soya bean meal can add to DMI and hence milk yield and quality, particularly replacing a 10.8 ME grass silage. The grass silage uptake has been shown to decrease from 9.6 to 7.0kg DM/cow per day. When fodder beet was added to a poorer silage and with no soyabean meal, compositional quality was not improved. As well as lowering the ration cost, fodder beet partially acts as a concentrate replacer.

Fodder beet should be finely chopped or shredded in the rations for dairy heifers over one year old when they are changing their teeth. For these animals average grass silage up to 2kg DM (11kg fresh weight) of fodder beet can be fed in place of sugar beet pulp to ensure good growth rates and conception. Using a straw-based ration, a 300kg heifer growing at 0.8kg/day could receive 3kg straw, 14kg fodder beet, 1.2kg barley and 1kg soya bean meal. If ammonia or urea-treated straw is used, 11kg fodder beet and 1kg barley could produce the desired results. Alternatively, 2kg DM from both fodder beet and brewers' grains with *ad libitum* straw should produce a palatable and productive ration. Amounts will, of course, be increased as the animals grow.

Gleadthorpe Experimental Husbandry Farm (1984, 1985) developed a fodder beet system that utilised its low cost when compared with concentrates for Friesian × Hereford heifers and steers. Crushed beet was introduced when the animals weighed 200kg. Both fishmeal and soyabean meal have been used as the protein sources with minerals and straw also added if necessary.

In many cases, fodder beet requires much additional capital for sowing, harvesting, storing, cleaning and chopping the beet, but it can be grown in most areas of the UK and other temperate areas. In a wet autumn on heavy soils, harvesting can be difficult, but it is a relatively cheap source of energy. Mangels, which have a DM of 10–15 per cent, are in the main similar to fodder beet for feeding but crop yield is less.

Swedes

The typical analysis of swedes per kg DM is:

DM = 10.5 per cent, ME = 13.1 MJ, DCP = 64g,

NDF = 140g, MADF = 114g

Minerals: Ca = 3.5g, P = 2.6g, Na = 1.5g, Mg = 1.1g

Yield on NIAB plots = 7t DM/ha

The crop is generally grown in the cooler west and north of Britain. Fungal problems such as powdery mildew and club-root can limit crop yields.

Swedes have a low protein and high energy content, but a relatively low yield of DM. They are used primarily for beef and sheep as well as for human consumption.

Swedes could be utilized by dairy cows on a similar DM basis to fodder beet, but are more costly to produce. Despite their low DM (10.5 per cent) they are likely to be DMI enhancers. Similarly, they can be fed to dairy heifers by incorporation in straw-based rations. The low DM of swedes could assist consumption, but chopping or slicing is advantageous. Swedes may be grazed *in situ*, especially by sheep.

Stubble turnips (leaves and roots)

The typical analysis of stubble turnips per kg DM is:

DM = 8.0 per cent, ME = 11.6 MJ, DCP = 130g

Figures for fibre levels and minerals are not available

Yield on NIAB plots = 3.8DM/ha (relates to the tops and that portion of the root that is above ground)

These quick-growing turnips are a very useful catch crop being sown in the spring as a prelude to a grass reseed in the autumn or after winter barley in July as a break crop.

Stubble turnips are grazed by dairy cows *in situ* behind an electric fence in midsummer and autumn, particularly where grass production is limited. In the summer, stubble turnips and *ad libitum* ammonia-treated straw complement grass, while in the early autumn the same combination can substitute for a limited amount of silage on free-draining soils. Stubble turnips can also be fed to sheep and suckler cows, but are little used for dairy heifers and beef animals because they are unlikely to be constrained by an electric fence. The cost per unit of energy is similar to grazed grass. Fungal problems such as powdery mildew and alternaria leaf spot can limit crop yields.

Kale

The typical analysis for kale per kg DM is:

DM = 13.6 per cent, ME = 12.6 MJ, DCP = 119 g,
 NDF = 208 g, MADF = 161 g
 Minerals: Ca = 12.1 g, P = 3.5 g, Na = 1.2 g, Mg = 1.4 g
 (varieties differ in analysis)
 Yield on NIAB plots = 8.6 t DM/ha

Kale can be grown in most areas of the UK but yields can be adversely affected by dry weather.

Protein and minerals are contained in the leaves and carbohydrates and fibre occur in the stem. Thus, the proportion of leaf to stem influences the feed value of kale.

Kale is a low DM, high-protein feed that is high in calcium, but low in phosphorus, copper, manganese and iodine. Goitrogens can interfere with iodine use in the dairy cow (see pp. 257, 586). Excessive amounts of kale can lead to haemolytic anaemia (see p. 941).

In the past, kale was strip-grazed in the autumn and up to midwinter and, together with hay, provided the maintenance portion of the dairy cows' ration. The practice has been largely curtailed as herds moved towards autumn calving, and a continuity of feed during the winter season became necessary. In addition, foot troubles were very common and udders needed additional washing. Currently, kale is grazed *in situ* in the summer and early autumn in a similar fashion to stubble turnips with ammonia-treated straw. It tends to be fed to mid- and late-lactation cows and should not exceed 30 per cent of the ration. In practice, 3–4 kg DM/head per day are consumed together with 1–2 kg of ammonia-treated straw. Kale can be cut and carted to all classes of stock, and may be strip-grazed by sheep in winter.

Forage rape

The typical analysis of forage rape per kg DM is:

DM = 14 per cent, ME = 9.5 MJ, DCP = 144 g
 (no fibre figures are available)
 Minerals: Ca = 9.3 g, P = 4.2 g, Na = 2.3 g, Mg = 2.1 g
 Yield on NIAB plots = 5.4 t DM/ha

Rape can be grown in most areas of the UK. Forage rape can be used as a catch crop like stubble turnips and kale but is lower yielding than the latter and higher yielding than the former. The principles of feeding and the reservations on use of forage rape are similar to kale. Forage rape can cause taints in milk and should be introduced into the ration slowly. It can be grazed *in situ* from July to December, or be zero-grazed.

Lucerne

The typical analysis of lucerne silage per kg DM is:

DM = 29 per cent, ME = 9.5 MJ, DCP = 134 g,
 NDF = 464 g, MADF = 357 g
 Minerals: it is claimed to be high in minerals, except sodium, and to have good buffering capacity in the rumen. Ca = 17.6 g, P = 3.0 g, Mg = 1.8 g
 Yield on NIAB plots = 14.7 t DM /ha

Lucerne (alfalfa) is now the most important forage crop on a worldwide basis. While some 1 million ha are suitable for the crop in the UK, only around 22 000 ha are cultivated. The crop grows best in areas where the night temperature remains above 10°C and where daytime temperature is in the range 15–25°C. It is an erect, deep-rooting and hence very drought tolerant crop which is well suited to cutting. The exceptionally deep rooting habit requires a well-fissured alkaline subsoil. The soils also need to be free draining as the plant is not tolerant of a high water table. Top soil pH should be maintained at 6.2 or higher, preferably above 6.5 as root nodulation does not occur at pH levels below 6.2. Lucerne is not a competitive crop (Sheldrick *et al.*, 1995).

The advantages of lucerne are its reduced fertilizer requirement (it fixes very high levels of nitrogen); its persistence (it will stand regular cutting for up to 5 years); its drought resistance; its high protein level (up to 24% protein at tight bud stage); its high digestibility; the slow fall in D value; its low level of lignification and its high levels of calcium and vitamins A and E (Koivisto, 1999, pers. comm.).

Its disadvantages are that in the small seedling stage it is frost susceptible. It is not tolerant of wet conditions requiring a free draining soil. It is susceptible to stem eelworm and sitona weevil and some varieties are susceptible to verticillium wilt. In some conditions downy mildew and various leaf spots may occur.

All seed should be checked to ensure that it has been fumigated against stem eelworm and all seed should be inoculated with *Rhizobium meliloti* in areas where it has not been grown in the last few years. A seed rate of 20–25 kg/ha is recommended, except in particularly favourable areas where the rate may be reduced to 15–20 kg/ha. The target seedling density should be 425 plants per square metre, although a mature stand may only have 120–150 plants per square metre. The crop should be sown between late April and the first week in August. Lucerne should not be sown with grass as the latter is too competitive.

Another disadvantage is its low yield in the establishment year, although this can be overcome by undersowing it into a spring cereal crop or a semi-leafless pea crop. After establishing the nurse crop and controlling weeds the lucerne should be broadcast and either rolled or raked in. Alternatively the two crops can be drilled at the same time, although this makes weed control more difficult.

cult. If there is adequate late summer/early autumn rainfall the crop can be established in late summer, no later than mid-August, after a winter cereal crop.

Decaying lucerne roots exude chemicals known as medicarpins which inhibit germination of lucerne so it is not possible to 'stitch in' seed to fill areas where the crop has died out.

Fertilizer requirements are relatively low as there is no requirement for nitrogen after establishment. The main requirements are for phosphate and particularly potash.

Lucerne is ideally suited to a cutting regime. The crop should be allowed to flower before the first cut and should then be cut at intervals of 35–40 days, with the last cut being made in September to allow at least 6 weeks for recovery before the first frost. After the first frosts the crop will normally stop growing, at which time it is safe either to cut or lightly graze the crop. The ideal cutting time is mid-bud stage.

Dry matter yields from a well-established crop of lucerne under ideal conditions could be as high as 14 tonnes dry matter/ha, although average yields will be 10–12 tonnes dry matter/ha. The first cut is normally expected to contribute about 35 per cent of the total, with the second, third and fourth cuts contributing 35, 20 and 10 per cent, respectively.

Ensiling lucerne is more difficult than grass silage as the sugar levels are much lower and for ensiling to be successful it is strongly recommended that the crop is wilted to 30 per cent dry matter. If the dry matter prior to ensiling is much higher than this there is a very real danger that losses will be high as a result of leaf shatter.

Lucerne is not usually grazed because of the risk of bloat, although there are instances where it has been grazed successfully. This requires a slow introduction and all the usual precautions to avoid tympany.

Because of its ability to fix large amounts of nitrogen and its very deep and extensive root system lucerne is well suited to organic systems, although its inclusion in a rotation will extend it considerably.

Red clover

The typical analysis for red clover silage per kg DM is:

DM = 22 per cent, ME = 9.8 MJ, DCP = 135 g

Figures are not available for the fibre levels and mineral content, but like lucerne, red clover has high intake characteristics and the ME is likely to be close to 10 MJ/kg DM

Yield on NIAB plots = 13.5 t DM for first harvest year, and 11.1 t/ha for the second harvest year

The use of red clover declined dramatically to the late 1990s. However, the recent interest in organic farming

has spearheaded a revival of interest in the last five years.

Red clover yields well on a range of soils with a pH of 6 or higher and adequate soil moisture. Summer rainfall is also a prerequisite for good yields. Water-logged soils, on the other hand, should be avoided and heavy soils subject to structural damage from smearing and the use of heavy machinery will shorten the life of the crop. Unlike white clover, red clover does not produce stolons (runners) and has a single crown to the plant that is susceptible to damage.

As a general rule red clover is sown with Italian rye grass and with the more modern varieties a fairly aggressive rye grass is required as the clover tends to take over in the second year. Seed rates are usually around 3 kg/ha with a target plant density of 200/m². It is important that the red clover seed is fumigated against stem eelworm. Modern varieties will usually give two heavy cuts, with a third lighter cut over the first two years. There is a significant decline in productivity in year three, although the new variety Milvus is claimed to give good production over a three-year period. Growing red clover with Italian rye grass will not only give a heavier crop, by up to 30 per cent annually, but also raise overall digestibility. Annual yields of dry matter are usually in the range 9–12 tonnes/ha for pure stands and 11–13 tonnes/ha when grown with companion grasses. Yields in organic systems will be almost, if not as high as in conventional systems because of the high levels of nitrogen fixed. Red clover can fix up to 245 kg nitrogen/ha (Lampkin, 1990).

Red clover is sensitive to soil potash levels as large amounts are removed from the field under cutting. Potash level can be improved by the appropriate use of slurries to which it responds well. If high protein levels are to be achieved in the first cut the use of some artificial nitrogen may be necessary as nitrogen fixation by clovers is temperature dependent and in cold and wet seasons little nitrogen may be fixed before the first cut is made. The protein level in the first cut material is often very low in organic systems where the use of artificial nitrogen is not permitted. However, it has usually increased to around 18–20 per cent by the time the second cut is made.

The low levels of sugar in clover can lead to poor fermentation in ensiled crops of pure red clover. Ensiling grass/red clover is often more successful because of the sugar contributed from the grass. The quality of the fermentation is also likely to be improved by wilting the crop to approximately 30 per cent dry matter whenever possible, but care should be taken not to exceed this as leaf loss due to shattering occurs above this level. If the material has to be ensiled at a significantly lower dry matter the use of an inoculant is recommended.

Weed control can be a problem as red clover is sensitive to many of the herbicides currently available. Control of weeds in organic systems is often achieved by undersowing into a spring cereal nurse crop, a technique which could also be used in conventional systems.

A gap of at least four and preferably five years should be allowed between red clover crops to reduce the risk of pests and diseases, particularly stem eelworm and *Verticillium*.

The risk of bloat in cattle is reputedly higher with red clover swards than white clover swards and as a result red clover is grazed less frequently (p. 833). However, with careful management it can be avoided. The red clover should be introduced slowly and once introduced it should be a consistent component of the diet. The risk is highest in cold wet weather and when the animals are particularly hungry. Lambs in particular grow very well on grass/red clover swards and increased growth rates can also be achieved with young stock and beef cattle (Thomas *et al.*, 1982).

Because of its ability to fix large amounts of nitrogen, red clover is an important part of the fertility building cycle in organic systems.

White clover

In the last few years interest in white clover has increased significantly and it is increasingly being used in grazing swards. Again, interest has been fuelled by the increasing interest in organic husbandry.

Varieties tend to be classified according to leaf size, with the smaller leafed varieties being more suited to sheep grazing and the larger leafed varieties being more suited to cattle grazing and/or conservation. More recently, varieties have been introduced which are more cold tolerant, resulting in earlier growth and nitrogen fixation. Soil pH should again be 6 or higher for good germination and growth, and on some soils this may mean the regular application of lime to maintain this pH.

White clover is much longer-lived than red clover and will typically be expected to survive for six years or more under good management. Typical seed mixtures will contain between 1 and 2kg/ha in a total mix of 12kg/ha (the total seed rate may need to be higher in adverse conditions, e.g. low rainfall and light soils). White clover seed is very small and germinates more successfully if broadcast on to the surface rather than being drilled into the seedbed. Grass varieties need to be chosen with care to avoid either the grass or the clover becoming the dominant species. Work in this area has been done by the Kingshay Trust, from whom recommendations are available to its members.

Production levels from grass/white clover swards are lower than from grass/red clover swards and are likely to be of the order of 6 tonnes of dry matter/ha with no artificial nitrogen input to 7.6 tonnes/ha with 200kg artificial nitrogen/ha. However, at this level the clover content of the second cut will be suppressed (Sheldrick *et al.*, 1995). These same authors state that under ideal conditions herbage yields equivalent to those from grass swards receiving in excess of 300kg nitrogen/ha have been recorded. It is recommended that no more than 50kg of nitrogen/ha is used. In organic systems where the use of artificial nitrogen is not permitted it should be noted that the protein content of the first cut is often very low, particularly in cold and wet seasons when it is typically between 10 and 12 per cent (Weller & Cooper, 2001; Tame, pers. obs.).

The proportion of grass to clover can be managed to some extent by alternating cutting with grazing. The growth of the white clover is light sensitive; allowing the sward to grow will mean that eventually the clover will be shaded out as the grass grows taller. This is particularly so in autumn and early spring when the temperatures are low enough to suppress clover growth but not grass growth. The clover content can be increased by an intensive grazing and/or cutting regime, although the proportion of clover increases naturally through the season (Weller & Cooper, 2001). Ensiling grass/white clover is less difficult than grass/red clover because of the generally lower clover content and higher sugar level contributed by the grass, but even so wilting to around 30 per cent dry matter is again recommended. At dry matter levels much higher than this leaf shatter will be a problem.

Weed control can be a problem in newly established swards, particularly with annual weeds such as chickweed. This can be controlled by the careful use of an appropriate herbicide, although most will have some adverse effect on the clover. In organic systems successful control is achieved by the use of mechanical control or by undersowing into a nurse crop of spring cereals.

Grass/white clover swards are used principally for grazing and it is worth noting that milk production will be 1–1.5 litres/cow higher from a grass/clover sward than from an all-grass sward.

Care needs to be taken in the autumn to ensure that late grazing by sheep does not damage the stolons of the clover as such damage may result in a loss of clover in the following spring.

White clover also plays an important part in soil fertility building in organic systems because of its ability to fix nitrogen even though it fixes less than red clover, 150kg/ha under good conditions (Lampkin, 1990).

Peas

The typical analysis for pea silage per kg DM is:

DM = 25.9 per cent, ME = 8.8 MJ, DCP = 146 g,

NDF = 517 g, MADF = 384 g

Minerals: Ca = 12.7 g, P = 4.4 g, Na = 0.4 g, Mg = 2.0 g

Yield (estimated) = 7 t DM/ha

Pea silage can be a byproduct from the production of vining peas and may be more like straw. Peas can also be grown on their own, but need some physical support and are usually sown in conjunction with spring barley on the basis of 40:60 peas:barley by seed weight. Newman & Luffman (1984) have produced the arable silage mixture (barley was cut at the cheesy stage) with a DM of 43.2 per cent, ME of 10.2 MJ and DCP of 147 g. They observed that the silage yield at 10 t DM/ha was very palatable. Depending on the stage of lactation, when fed to 200 dairy cows in Somerset, it produced rises in DMI between 10 and 20 per cent over grass silage. (Dry matter intake of grass silage tends to be in the range of 7–10 kg depending on the quality and quantity of the silage.) The arable silage mixture can also be fed to dairy heifers and beef animals. Peas are not an easy crop to establish and whole crop cereal silage may be preferred.

Sainfoin

A typical analysis for sainfoin silage per kg DM is:

DM = 24 per cent, ME = 8.4 MJ, DCP = 124 g

Figures for fibre and minerals are not available

Yield (estimated) = 7.5 t DM/ha

Sanfoin is a little grown crop although there has been some revival of interest in the last few years. A research programme is currently under way at the Royal Agricultural College at Cirencester (Lane & Koivisto, 1999). In most aspects the requirements, establishment and management of sanfoin are very similar to those for lucerne.

The main differences are that the most commonly available varieties of sanfoin are significantly less productive than lucerne with fewer cuts. However, some recent varieties that will soon be available from Eastern Europe, notably Hungary, may well be almost as productive as lucerne. Another difference which has significant practical and nutritional implications is that sanfoin has a relatively high tannin level which means that there is no risk of bloat from grazing it. Indeed, very high growth rates have been achieved in lambs grazing sanfoin (Koivisto, pers. comm.). It is also likely that the tannin content of sanfoin may have the

effect of reducing the rate of protein breakdown in the rumen.

Again sanfoin is well suited to organic systems although, like lucerne, its inclusion in a rotation will extend the length of the rotation considerably.

Lupins

Interest in this crop has been growing in recent years particularly as large areas are grown in continental Europe, 60000 ha in northern Germany alone, and particularly in Australia, 1 million ha. While the crop is normally grown as a grain crop it can also be harvested as a forage crop. When cut at ten to twelve weeks post-emergence it gives a high yield of good quality forage. Crude protein levels may be as high as 20 per cent, with a good energy level and up to 20–25 per cent starch.

Recommended types are the white, apically dominant varieties or the yellow branched varieties. The crop is tolerant of a wide range of soil types provided that the pH is within the range 5–7. The crop should be sown from mid-March to mid-April. The seed rate will depend on type and the seed should be inoculated. Weeds need to be controlled in the early stages of the crop. Yields as high as 10 tonnes of dry matter/ha have been reported, although it is too early to know whether this is typical under UK conditions.

Lupins seem to be particularly well suited to organic systems because of the high level of nitrogen fixation and the fact that the crop is in the ground for such a short time means it fits well into rotations.

Rye

The typical analysis for grazed rye per kg DM is:

DM = 23 per cent, ME = 9.5 MJ, DCP = 88 g

Figures are not yet available for fibre and mineral content

Yield (estimated) = 7.7 t DM/ha

Rye is grown on its own or in a mixture with Italian ryegrass to produce an early bite in the spring on light land with a low pH. It is usually strip-grazed by dairy cows once daily and its feed value often decreases rapidly. Zero-grazing is possible. Any surplus can be conserved as big bale silage and used for any class of stock. In some areas it is followed by forage maize and could be drilled after an early maturing variety of maize in the autumn. Many dairy farmers prefer buffer feeding of silage in late spring or other combinations of feed as an alternative to growing small areas of rye.

Triticale

Feed analysis figures are not available for triticale, which is a hybrid of wheat and rye. Triticale can perform a similar function to rye, and is said to have lower DM yields than rye in the earlier part of the season, but its digestibility stays at a higher level than rye as the crop matures. Feeding value is likely to be similar to whole crop silage. If cut in mid June, it can have a DM of 25 per cent and an ME of 9.6 MJ. Both sugar and fibre levels are higher than grass.

Whole crop silage: whole wheat

A typical analysis for whole wheat silage (Newman, pers. comm.) per kg DM is:

DM = 50 per cent, ME = 10.7 MJ,
crude protein = 9 per cent, NDF = 400 g, pH = 8
Yield (estimated range) = 7–10 t DM/ha

There has been a considerable increase in interest in whole crop cereal silage over the last decade both in fermented and in urea-treated form.

The addition of whole crop cereal silage to the diets of both cattle and dairy cows results in a significant increase in dry matter intake, particularly with the urea-treated form. However, there are some very significant differences between the two forms.

The fermented form of whole crop has the advantage that it has a much higher digestibility and results in a larger increase in milk output and a small increase in milk quality, mainly in butterfat. The disadvantage is that it is lower in protein and is aerobically unstable, although this latter disadvantage can be overcome to some extent by adequate chopping, good consolidation and good clamp management.

Urea-treated whole crop has the advantages that there is a large increase in dry matter intake, it is aerobically stable and the added urea results in a higher nitrogen content. However, the disadvantage is that the digestibility, particularly of the starch, appears to be much lower and the large increase in dry matter intake is reflected in only a small increase in milk output and quality (Sutton *et al.*, 1997). As a result urea treatment of whole crop cereal silage is not recommended.

The objective should be to grow the crop as for a good grain yield with winter wheat being sown at a rate of 150–200 kg/ha and spring wheat at up to 240 kg/ha. If a spring crop is to be undersown the seed rate should be roughly half the figure just given. There will of course be a yield penalty with the lower sowing rate. Winter wheat should be harvested at between five and six weeks after ear emergence and at a dry matter of

35–40 per cent (Kristensen, 1995). Winter barley should be harvested slightly earlier at four to five weeks post ear emergence and at a dry matter of 30–35 per cent. However, in the UK the suggestion is that winter wheat can be harvested at up to 45 per cent dry matter (MDC, 1995). Yields for winter wheat are 10–12 tonnes dry matter/ha with conventional systems and 6–10 tonnes in organic systems depending on where it is placed in the rotation and whether it is undersown with grass/clover. If the dry matter is much higher than 50 per cent it is likely that grain will be excreted, undigested, the amount increasing with higher dry matter.

Whole crop cereal is well suited to use as a buffer feed to supplement grazing in the summer, particularly in organic systems where its starch and low protein content can be used to balance the very high levels of degradable protein in the grass/clover swards from mid-summer onwards. Indeed, whole crop cereal silages fit very well into organic systems as a whole as the early harvest allows a grass/clover ley to be established in August. It also allows a degree of flexibility in the system as it can be taken either for grain or for forage depending on the season.

Whole crop cereal with peas

The major disadvantage with whole crop cereal silages is that they are low in protein. This can be overcome to a greater or lesser extent by growing whole crop cereals as a bi-crop with peas. The target should be for at least 40 per cent peas in the crop. The peas should be a short-strawed, coloured, flowered variety. Sowing rate will depend on the proportion of peas required, but with a 50:50 mix the seed rates would be around 125 kg/ha wheat and 270 kg/ha peas depending on variety and seed size.

The crop should be harvested at 14–15 weeks post sowing when the cereal grain is at the doughy stage and the pea seed is at the yellow wrinkled stage. The protein and starch are optimized at this stage (Adesogan, pers. comm.). When harvested at this stage the silage should have a crude protein content of 16–18 per cent, with 40 per cent peas in the mix. If higher crude protein levels are required the proportion of peas should be increased. In the same study digestibility is reported to be higher than grass silage when fed to sheep. A further trial showed that the total intake, milk yield and milk composition of cows fed whole crop/pea silage was higher than or comparable with cows fed first-cut/ryegrass silage and 4 kg more concentrate. As with fermented whole crop, the silage needs to be very well consolidated in the clamp and clamp management at feed-out must be very good.

Table 10.2 Analysis of byproducts fed to dairy cattle.

| Food | DM (%) | ME (MJ) | DCP (g) | NDF (g) | MADF (g) | Ca (g) | P (g) | Na (g) | Mg (g) |
|-------------------------|--------|---------|---------|----------------|----------|--------|-------|--------|--------|
| Brewers' grains | 22.0 | 11.7 | 189 | 572 | 219 | 3.3 | 4.1 | 0.1 | 1.5 |
| Cabbage | 10.6 | 13.7 | 181 | 586 | 140 | 7.2 | 4.5 | 1.2 | 1.5 |
| Carrots | 13.0 | 12.8 | 62 | — ^a | — | 5.9 | 3.4 | 0.8 | 1.8 |
| Parsnips | 15.0 | 13.3 | 67 | — | — | — | — | — | — |
| Potatoes | 20.4 | 13.3 | 80 | 73 | 39 | 0.4 | 2.0 | 0.2 | 1.0 |
| Pressed sugar beet pulp | 25.4 | 12.3 | 60 | 557 | 259 | 9.0 | 1.1 | 0.6 | 2.0 |
| Apples | 13.6 | 12.2 | — | 111 | 101 | 0.5 | 0.9 | 0.1 | 0.3 |
| Apple pomace | 23.0 | 8.7 | — | 503 | 375 | 1.7 | 1.4 | 0.2 | 0.6 |

^a —, no reliable information available.

Yields under a conventional system should be around 11–12 tonnes dry matter/ha, while under organic management it should be 7–10 tonnes of dry matter/ha.

Wet byproducts used in dairy cow rations

The products shown in Table 10.2 can be incorporated in winter rations for dairy cows and other stock. They are likely to be fed with straw and other ingredients for other cattle, and to supplement grass silage and act as a concentrate replacer for dairy cows.

Vegetable waste, e.g. Brussels sprouts, cabbages and cauliflowers from vegetable processing plants, could have a similar feed value to kale. Potato waste, pressed sugar beet, peas and beans are occasionally available. Good storage facilities and the avoidance of waste are necessary for the above products. They will all need to fit in with the ration criteria for the appropriate class of stock.

The clinical attitude

Veterinary clinicians must develop certain special attributes in relation to their environment. They must be inquisitive, questioning, curious and observant. They must notice everything around them, and, if possible, explain it. They must always be critical in the true sense of the word. They spend their lives diagnosing disease and must understand quite clearly that, as health is normality, then disease is simply deviation from normality. From this, it follows that veterinary surgeons will never be able to detect and recognize disease, i.e. deviation from the normal, until they know the normal. They must learn the normal in all domestic species in many different circumstances. For normality is relative, not absolute. It is relative to breed, age, nutrition, the stage of lactation or pregnancy, management and many other factors.

Thus normality is relative to environment. The veterinarian, therefore, must consider the environment as critically as he does the patient. Is it suitable? Does it predispose to, or even cause, the abnormality present in the patient? Does it cause stress? Remember that the environment can only be appreciated if one considers the animal's viewpoint: for example, if it is thought that the ventilation in a calf house is suspect, it may well be advisable to get your head down among the calves!

If it is accepted that disease is often related to environment, nutrition or management, then it follows that in an adverse environment other animals in the group may also be affected. In such circumstances, it is always well worthwhile looking carefully at the rest of the group, if necessary, animal by animal. It may well be that others are showing the same signs albeit to a lesser extent. Such an observation may be very helpful not only in diagnosis, but also from the viewpoints of treatment and prevention.

The veterinarians of today must concern themselves with the health of the herd as well as the individual and it is almost negligent to omit from the examination of the individual cow, a look, however brief, at the other stock in the group.

The other side of the coin is that, in unusual environmental conditions, when you are not certain whether the cow's response is normal or not, it is often very helpful to look at the rest of the group. If they are all showing the same response, then either they are all abnormal, which is unlikely, or they represent normality, in which case, the patient is also normal.

It should be remembered that the owner and his staff are an important part of the patient's environment, and can play a large part in the disease process and progress. They, equally with, or perhaps even more than, other environmental factors, merit critical assessment. Are they competent? Are they humane? Are they interested? Are they truthful? Have they contributed to the disease process? They merit critical study, for the staff are inextricably involved with their animals and the one cannot be considered without the other.

The important diagnostic principles that should always be followed are shown below.

- (1) Be systematic.
- (2) Adopt a routine that is found suitable and stick to it.
- (3) Take nothing on trust.
- (4) Apply continual critical assessment to oneself and monitor one's own attitudes and techniques.
- (5) Consider all the time:
 - (a) Is there a problem?
 - (b) If so, then define it.
 - (c) Having defined it, what is best done about it?

The clinician's approach to the clinical case

There is nothing magical about clinical work. It depends upon care, patience, thoroughness, method and logical routine; a routine of examination that covers all the likely eventualities. Once having evolved such a procedure, there should be no short cuts without good reason, and, however cursory some sections of the examination, for various reasons, sometimes have to be, nothing should be omitted without due consideration.

The clinical examination

The owner's message

The owner's message (usually termed the owner's complaint) should include name and full address, and may reach the clinician by direct word of mouth, by telephone or by mobile or radio telephone direct to his car. The owner's complaint will also include the type of animal and the main presenting syndrome, e.g. a scouring cow, a downer cow, a convulsing cow or a bloated cow. It is important to distinguish between the owner's complaint and his diagnosis. The owner's message will often be in the form of a diagnosis and the clinician must be aware that this will frequently be wrong. For example, a farmer may assume that a recumbent cow and recently calved will be suffering from milk fever. However, a full clinical examination may reveal acute mastitis or calving paralysis.

There are a limited number of main presenting syndromes, and the clinician should learn differential lists for each of them, to include only the major differential conditions, not the rarities. It should be remembered when considering the differential lists that the common things occur commonly; that is why they are common!

The clinician should know the main presenting syndrome and its differential list, and during the journey to the farm should consider the following points.

- (1) The time of year. Many diseases are seasonal, e.g. the coughing calf indoors in November probably has a viral or bacterial based pneumonia, but the coughing calf at grass in August probably has husk.
- (2) The part of the country. Each type of country has its own disease problems, e.g. in the hills one meets malignant catarrhal fever, bracken poisoning and piroplasmosis, while in intensive lowland dairy areas one meets coliform mastitis, milk fever and hypomagnesaemia.
- (3) The individual farm. The clinician will often know that a specific farm has a particular disease problem, e.g. a parasitic problem among the young stock, because they are overcrowded and underfed.
- (4) The type of management. For example, heavily stocked cubicle yards with straw bedding often lead to environmental mastitis.

Such patterns of disease become second nature to veterinary surgeons, and always hold good for the part of the country in which they work, although revision might be necessary in a practice 400 miles away.

The clinician will, therefore, arrive at the farm with a diagnosis already half formed. It will be adaptable, not dogmatic, a *working hypothesis*, to be confirmed or refuted; however, it is quite remarkable how often this hypothesis stands up to the test of full clinical examination, and, more importantly, refutes the presence of any other disease process.

Thus, if the clinician knows that the cow to be visited is showing convulsive signs at pasture, that it is early May, that it is an intensive dairy area in Britain the chances that the disease condition is anything other than hypomagnesaemia are too remote to be significant. Nevertheless, a clinical examination is always necessary.

History

History is all important and the foundation of diagnosis.

- (1) Immediate history is the story of the present illness.
- (2) Past history is anything in the animal's earlier life that may be relevant, e.g. calving and service dates, something similar at the same point in a previous lactation, and so on.
- (3) Herd or group history is important when adverse nutritional or management factors may be relevant to the present illness.

History taking is an art – it does not come naturally, but must be learnt and practised. After a few pleasant

introductory words, questioning can begin while walking to the animal, which may be approached, but should not, if at all possible, be disturbed. First, look. Check the owner's statements mentally by reference to the animal and the surroundings. Do not hurry the owner at first: let him or her talk, then ask your own questions, checking each statement and following a routine that suits you. You are not wasting time for you are, meanwhile, carrying out the next two parts of the clinical routine.

Do not ask leading questions in the hope of saving time, or in the hope of confirming one's half formed diagnosis, for they often produce inaccurate or misleading answers. Human nature being what it is, owners may either agree with you because they think they ought to, or disagree because they are contrasuggestive.

Study the owner or stockworkers. Are they reliable? Are they telling the truth? Are they covering up errors in management? Are they guessing? Every clinician must be interested in the human animal; after all, it is the owner whom you serve, advise, encourage or console. In a way, the owner is as much your patient as the cow. Admittedly, owners seldom deliberately falsify their story, but it is wise to beware the guilty one, the bombastic one, the one who knows it all or the one involved in the sale or purchase of the affected animal.

Description

A formal description is more relevant to the examination of a horse, but it is often very useful for the clinician to classify the animal under observation mentally while the history is unfolding, e.g. a young Friesian cow, recently calved and heavily in milk. It is always dangerous to be uncertain as to the exact type of animal under examination as it may lead to loss of face in discussion of the case and, occasionally, even to serious error.

Preliminary inspection/observation

Like the description, this inspection, *note* inspection not examination, takes practically no time, and is carried out during history taking. The clinician observes the behaviour of the animal or group of animals and makes a mental note of the conditions in the animal's environment.

At this stage, do not touch, do not disturb. Stand well back and observe from a distance, looking over the pen wall or gate. Put the picture in its frame. One is looking for the deviations from normality that constitute disease, so:

- (1) One must know the normal.
- (2) If the animal is frightened, pushed about or even handled, abnormalities may appear due to annoyance and fear. The minutiae that might have given a diagnostic lead will be masked. Condition, vigour, demeanour, respiratory pattern, appetite, rumination, faecal passage and type, and response to environment should all be noted.

Preliminary examination

The animal may now be touched but it is essential to proceed quietly, with as little fuss as possible. This stage of the examination includes the rate and character of the pulse, the temperature and a check on skin, eye, membranes, udder and ruminal movement. Although pulse character and rate are very important, it is frequently quite impossible to examine the pulse properly in a modern dairy cow that has been separated from the others, driven into a crush and clamped by the neck. It is usually not possible to do more than check the heart and heart rate with a stethoscope.

The clinician may well have arrived at a diagnosis at this stage, but if not is probably aware of the system of the body involved. In this case, he may only need to confirm his views, by examination of that system and by checking out the other systems quickly, even mentally.

Nevertheless, the position may still be far from clear, and the clinician will then have to embark upon a systematic examination. The procedure so far described will have taken no more than a few minutes, but if a full systematic examination becomes necessary, the case becomes much more time consuming.

Systematic examination

This includes all the manual and instrumental techniques necessary as part of such an examination, even including surgical intervention in some cases. The clinician, according to training and inclination, may interpret the word systematic as meaning (i) thorough, starting at the nose and finishing at the tail or (ii) system by system, in which case a mental list of the systems or sections that should be examined can be ticked off mentally when satisfied.

There is merit in adopting the second routine. It enables one to examine first the system or disease section that seems most likely to be affected from the preliminary evidence. Should the provisional diagnosis be confirmed, then a great deal of time will be saved, for it will only be necessary to check the remaining systems briefly, even, in some cases, mentally, to make sure that there is no other disease or lesion present. If there is no provisional diagnosis in mind, then it is reasonable to begin the systematic examination with the

digestive system. In cows, this is the most likely cause of illness in obscure cases. Subsequently, the less important systems and sections can be examined as necessary.

A logical list of systems and disease groups for examination is as follows:

- Digestive system
- Respiratory system
- Circulatory system
- Urinary system
- Genital system
- Locomotory system
- Nervous system
- Skin
- Sense organs
- Lymphatic system
- Liver
- Udder
- Parasite problems
- Metabolic disease
- Allergies.

The last five headings on this list are, of course, not systems: nevertheless, they are very important disease sites (liver and udder) or disease groups that are logically considered as entities on the clinician's list.

A rectal examination is an important and useful aid to diagnosis and must always be included if the presenting signs are not conclusive. The bladder, uterus and ovaries, kidney and rumen are easily palpable, as are the caecum and small intestines if dilated.

Laboratory and special examinations

These are very important today, although increasing costs and the decline of dairying have unfortunately decreed that most laboratory work, apart from statutory Ministry investigations, or that done in the practice, is limited to the diagnosis of herd problems, rather than individual cow disease.

It is important that the clinician should never become a slave to the laboratory. The laboratory investigation is intended to confirm or refute the provisional diagnosis (working hypothesis) already in your mind.

Clinical examination comes first. Laboratory results can be inaccurate, irrelevant and confusing as well as expensive, but if used logically and critically they can be of great help.

Laboratory investigations include: haematology, biochemistry, bacteriology, virology, parasitology, serology, biopsy (histology) of tissues or fluids and, finally, necropsy.

Even after full examination, one may not have a complete diagnosis. However, there should be sufficient evidence to make a provisional diagnosis, which will allow

a logical course of treatment and, where relevant, prevention. The clinician must be prepared to think, form a working programme even on insufficient evidence, have enough confidence to convince the owner and enough adaptability to modify the programme tactfully if, and when, new evidence appears.

Owners, of course, are only partly interested in diagnosis. Prognosis is much more important to them. Will the cow get better? Will she be fully productive again? Is she worth treating? And today, unfortunately, another factor enters the equation. Will it be inconvenient to treat the cow; will she need nursing or extra care? If so, she is likely to be slaughtered, provided that she has antibiotic clearance and is likely to pass meat inspection.

The main presenting syndromes

It is not intended to discuss here the detailed techniques of the clinical examination of the various body systems. Every clinician has learnt these techniques as part of basic training, and there is excellent coverage in many textbooks, e.g. Boddie's *Diagnostic Methods in Veterinary Medicine* (1970). Instead, this chapter sets out to consider the differential diagnosis of some, although by no means all, of the main presenting syndromes that occur from day to day in the dairy cow.

Drooling at the mouth (kiddling, slobbering)

This is due to factors causing excess salivation, or factors preventing normal swallowing or combinations of both.

Bacterial or viral lesions in mouth

In countries where foot-and-mouth disease (FMD) has not occurred for a number of years, the possibility of infection must always be considered (see Chapter 43c). Thus the UK outbreak of 2001 shows how important it is that the disease is always remembered in differential diagnosis. Its occurrence was 33 years after the last major outbreak. The consequences of failure to recognize this disease are quite terrifying. Any salivating bovine animal, whether lame or not, whether pyrexic or not, must be treated as a possible case of foot-and-mouth disease until the clinician is satisfied that it is not. Other pyrexic diseases with oral lesions may give cause for concern, particularly bovine virus diarrhoea (BVD)/mucosal disease (see p. 853), infectious bovine rhinotracheitis (IBR) (see p. 289) and occasional cases of malignant catarrhal fever (see p. 935), but, fortunately, the mouth lesions and signs caused by these three diseases are usually relatively superficial and mild.

Actinobacillosis causes mechanical difficulty in tongue movement. The lesion is obvious, but painless even when ulcerated (see p. 824).

Calf diphtheria is limited to the young animal, causes pain as well as difficulty in mastication or suckling and produces inflammatory swelling with necrosis of the mucous membrane of the cheek (see pp. 250, 822, 825).

Foreign bodies

These are rare in the mouths of cattle, but the lids of cans occasionally become wedged between the lower molars and the cheek. Rarely, a stick becomes impacted between the rows of lower molars, or a molar itself loosens (see p. 825).

Interference with swallowing

This may be due to paralysis of the fifth or seventh cranial nerves which, in turn, may be due to listeriosis, meningeal abscesses or, particularly in the case of the seventh nerve, to trauma to the side of the head or face.

Fifth nerve paralysis makes the cow unable to close her mouth completely. The lips are in apposition but the teeth are not, a fact which is easily checked by flicking the lower jaw upwards, when the clicking together of upper and lower molars may be heard. Fifth nerve paralysis may often lead to accumulation of partly masticated food or cud in the pharynx, producing marked discomfort and gagging.

Seventh nerve paralysis causes unilateral or bilateral paralysis of the lips and cheek, and if of central origin, as in listeriosis (see p. 904), also causes flaccidity of the eyelids, with resultant keratitis and drooping of the ear on the affected side. This condition also leads to dropping of the cud bolus out of the mouth on the affected side and thus, ultimately, to loss of condition.

Oesophageal choke, particularly in the high oesophageal position, causes anxiety, even distress, with arching of the neck and profuse salivation. Choke may also cause varying degrees of ruminal tympany (see p. 826).

Dilatation and diverticulum of the oesophagus, particularly in the low cervical position, may produce similar, though milder, signs, as accumulation of food in the diverticulum may eventually lead to blocking of the oesophageal lumen, with resultant accumulation of food and saliva above the lesion.

Actinobacillosis of the oesophageal groove may lead not only to low-grade ruminal tympany but also to reflux of ruminal and reticular fluid into the mouth, so that in shippen-housed (i.e. tied) cows, a pool of such fluid may be found in the manager in the morning (see p. 823).

Excess salivation of CNS origin

This may be seen in lead poisoning, for the toxin affects the salivary nucleus. Blindness and aimless wandering in the cow, abdominal pain and convulsions with bellowing in the calf, should help the diagnosis.

In the 'licking mania' ketotic complication of milk fever or in 'nervous acetonaemia' (see p. 794) excess salivation is due to the compulsive chewing so characteristic of the disease.

Rhododendron poisoning

This may cause profuse salivation, and even vomiting, as well as diarrhoea (see p. 943).

Organophosphorus compounds

These may also cause salivation and diarrhoea (see p. 940).

Acute photosensitization syndromes

These may well cause profuse salivation, as well as lacrimation, jaundice and, later, the onset of necrosis of the non-pigmented skin areas (see p. 884).

Acute dyspnoea

This condition, as in very severe pneumonia, may cause obvious salivation as a result of mouth breathing.

Acute anaphylactic shock

This often causes profuse drooling of saliva as well as tachypnoea, subnormal temperature, cold extremities, oedema, and a very rapid heart (see p. 927).

Vomiting (see p. 825)

Vomiting is very rare in the cow and, to all intents and purposes, only occurs in *laurel* and *rhododendron poisoning* (see p. 943). Very occasionally a peptic ulcer of the abomasum will cause problems (see p. 844). Regurgitation of rumen fluid or content (false vomiting) may occur in cases of acute bloat (see p. 852), acidosis (see p. 829) or where there are lesions in the oesophageal groove (see p. 147), e.g. actinobacillosis or a foreign body ('wire') (see p. 837).

Occasionally, cases of oesophageal dilatation and diverticulation may accumulate material above the obstruction until it overflows into and out of the mouth.

Acute abdominal pain (colic)

It is interesting that acute colic pain of the type seen in the horse is relatively rare in cattle, and several of the

syndromes that cause the most acute pain are not, in fact, obstructive gut lesions, as one would expect, and may not even involve the alimentary tract at all.

Acute gut obstruction

This may be due to the following causes:

- Abomasal torsion (see p. 842);
- Torsion of caecum, colon, or ileum or common mesentery (see p. 847);
- Strangulated mesenteric hernia (see p. 1113);
- Strangulated scrotal hernia (see p. 1113);
- Gut tie: the entrapment of gut in peritoneal tears at the edge of the internal inguinal ring due to castration by traction in the slightly older animal (see p. 1113);
- Intussusception (see p. 847);
- Obstruction of ileum by the stalk of a lipoma (see p. 849).

Abomasal or large gut torsion produces a degree, sometimes very considerable, of right-sided abdominal distension, not normally seen in small gut obstructions. In gut tie, there may be considerable distension in the inguinal region, whilst scrotal hernia obviously produces distension of the scrotum on the affected side. It is, however, very easy for the clinician to overlook scrotal or inguinal swelling unless aware of the possibility. These acute obstructive conditions cause the most acute colicky abdominal pain in the very early stages, but such pain is often very transient and by the time the case is presented to the veterinary surgeon, temperature is falling, pulse rate is rising, body surfaces are becoming cold and even clammy, and a dull toxæmic and shocked appearance develops as circulatory obstruction, necrosis and gangrene of the obstructed gut supervenes. Intussusception is sometimes an exception in that many cases of bovine intussusception, particularly if large gut is involved, show little more than depression and dullness even in the early stages. Rectal examination is a useful diagnostic procedure.

Acute enteritis (Chapters 14, 15, p. 850)

Acute enteritis, particularly salmonellosis (see Chapter 15), is similar to acute cereal overeating, e.g. barley poisoning, in that some cases show spectacularly acute abdominal pain, often with some degree of tympany, which remains noticeable for a considerable time, often several hours, before the characteristic profuse diarrhoea begins. Laparotomies have been performed on a number of occasions at this stage of the disease in the belief that the condition was one of acute gut obstruction. Once diarrhoea appears, temperature falls often to normal or below, while signs of dehydration, electrolyte imbalance and shock appear.

Acute fermentative colic

This condition, involving the caecum and colon and producing right flank tympany, may occur on rich pasture, particularly in wet weather, and may be difficult to differentiate from acute obstructive conditions. Fortunately, these conditions generally respond to analgesics and antispasmodics before serious diagnostic errors occur (p. 847).

The passage of a calculus down the ureter

This may produce the most spectacular colicky pain, which fortunately is usually relatively transient. Diagnosis is obviously extremely difficult (see p. 263).

Photosensitization involving teats

Acute photosensitization (see p. 884) in cattle, e.g. Ayrshires with sparingly pigmented teats and udders, can produce an inflammatory exudative lesion of teats and skin of the udder that is so painful that the cow behaves exactly as if suffering from an acute abdominal catastrophe. Diagnostic error will only be avoided if the clinician remembers the invariable rule that whatever may seem to be affecting a cow, the udder and teats must always be examined.

Acute abdominal distension

This is one of the important and relatively common presenting syndromes in the cow. All causes of abdominal distension in the cow are covered by the memory rhyme (the seven Fs), which runs as follows: fat, fetus, fluid, flatus, faeces, food or foreign body. Severe abdominal distension may originate at several sites.

Ruminal

Dietary ruminal impaction: This occurs in housed fattening cattle on store diet, hay or straw, with limited water (see p. 236). The massive ruminal impaction, absence of ruminal movement, raised temperature and pulse rate, painful frequent abdominal grunt, and hard scanty faeces produce a syndrome requiring differentiation from *acute traumatic reticuloperitonitis* ('wire') (see p. 837) in its very early stages, although the impactive mass in the 'wired' rumen is never so great.

A similar condition, although much less severe, may occur in dairy cows tied in shippens during the winter should the water bowl cease to function, a mishap that frequently escapes the attendant's notice, and is always worth checking. Modern systems of building and management have markedly decreased the incidence of these two conditions.

Impaction of the rumen with grain (see p. 829) occurs in cows that have broken into a food store and eaten greedily, but even when the attendant is unaware of this, or will not admit it, the nature of the case generally becomes apparent in two to three days when profuse diarrhoea, staggering, recumbency, subnormal temperature, rapid pulse rate and other evidence of toxic effects occur in severe cases. In cases seen soon after ingestion of large quantities of grain, palpation of the left sublumbar fossa may produce the same sensation as handling a sack of grain. If, as is generally the case in Britain, the grain is barley, the interim period of impaction, with arched back, grunt, depression and moderate tympany is usually transient, and within a few hours the profuse diarrhoea so characteristic of barley poisoning appears.

Vagus indigestion (see p. 855): This condition is usually a complication of 'wire' that has produced adhesions, involving the medial wall of the reticulum and the cranial sac of the rumen, interfering with the function of the vagus nerve receptors in their walls. The atonic rumen, gradually filling with water and saliva, eventually produces a massive left-sided fluid distension in a cow steadily losing body condition.

Acute ruminal tympany (see p. 832): Acute ruminal tympany presents relatively little diagnostic difficulty. The condition includes clover and kale bloat and oesophageal obstruction (choke). The history, environmental circumstances, season of the year and the gagging, retching and salivating associated with most cases of choke are generally reasonably conclusive, although in very acute cases, of course, it pays to relieve the tympany via the left sublumbar fossa before worrying too much about the aetiology.

It is worth remembering that a thirsty cow, housed overnight in old-fashioned accommodation and released to drink its fill of very cold water, may easily become, transiently, quite alarmingly tympanitic, due presumably to the chilling effect of the frosty water on the rumen musculature.

The acute ruminal tympany of a cow that, for one reason or another, e.g. milk fever, has collapsed into lateral recumbency should not require mention. It is, however, surprising that it is still quite commonplace to find that such a cow has not been supported in sternal recumbency, as the condition demands.

Peritoneal

Acute diffuse peritonitis (see p. 849): This condition occurs when the special ability of the bovine peritoneum to withstand and localize peritoneal infection

fails for various reasons, allowing a virulent diffuse exudative process to spread across the peritoneal cavity. Usually, the condition stems from the breakdown of the defensive mechanisms isolating 'wire' in reticular diaphragmatic adhesions, but the leakage or rupture of a superficial liver abscess may produce the same result.

The peritoneal cavity fills with thin evil smelling pus of *Arcanobacterium* (*Actinomyces*; *Corynebacterium*) *pyogenes*: there are widespread adhesions, temperature falls, pulse rate rises, scanty diarrhoea develops, body condition falls away and the cow is toxic and in pain. The fluid wave is very obvious and confirmation by paracentesis is easy. The condition most likely to cause confusion is the massive milky ascites that may follow extensive liver damage and obstruction to the portal circulation. Inspection and examination of peritoneal fluid provides straightforward differentiation.

Peritoneal tympany: A gas-filled abdominal cavity may occur following perforation of an abomasal ulcer at a point free of attached omentum, causing acute pain over much of the anterior abdomen, particularly on the right side. Grunting, tooth grinding, falling temperature and rising pulse rate are followed by progressive peritoneal tympany due to leakage of gas from the abomasal lumen into the abdominal cavity.

Abomasal

Dilatation and/or torsion of abomasum (see p. 842): Dilatation and/or torsion of the abomasum on the right produces right-sided distension, very marked in cases of torsion, which also causes acute and even colicky pain.

Acute left abomasal displacement (see p. 839): This condition produces significant abdominal distension of the left flank, but such cases are exceptional. All abomasal cases are amenable to diagnosis by normal auscultation methods.

Intestinal

Acute tympanitic fermentative intestinal colic: This condition, which usually resolves without too much difficulty, can produce massive right-sided distension.

Torsion of caecum and colon on the common mesentery (see p. 847): This serious and usually fatal complication of fermentation and atony also produces massive right-sided distension. Differentiation depends upon demeanour, rectal examination, pulse rate and upon progress of the case following initial medication.

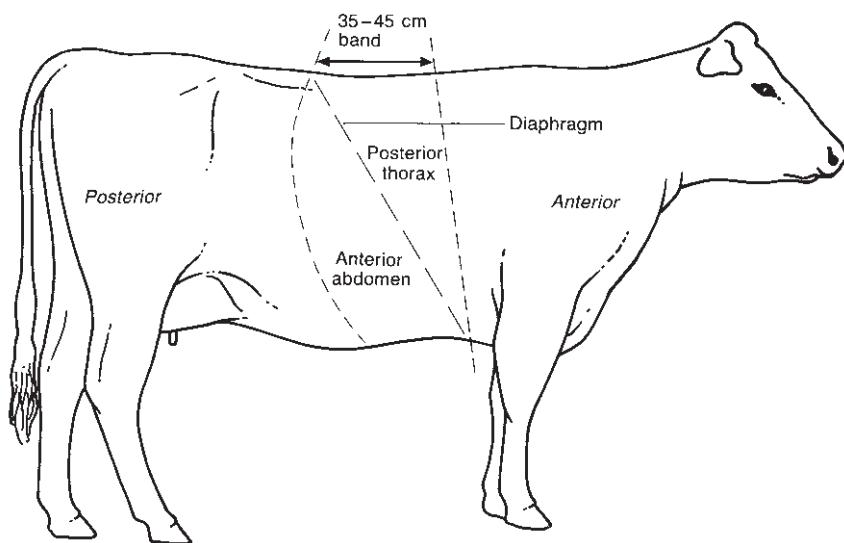

Fig. 11.1 Lateral view of cow showing anterior abdominal/posterior thoracic area.

Uterine

Hydrops amnion and allantois (see p. 1119): These conditions produce very marked abdominal distension. Diagnosis is helped by rectal examination. Uterine rupture producing extra-uterine pregnancy in the last third of pregnancy is marked by the formation of much fibrinous exudate in an abdomen filled with free uterine fluid and containing fetus and membranes. Such an abdomen is distended and shows a fluid wave which, on rectal examination, appears to be unassociated with the uterus. There is abdominal pain, rapid pulse and often severe illness. Diagnosis depends upon an accurate history and the ballottement of a fetus in the lower abdomen, even though rectal examination reveals a partially involved uterus.

Anterior abdominal/posterior thoracic pain

The organs and structures enclosed within a 35–45 cm band encircling the cow immediately behind the withers provide a group of diseases of great importance to the bovine clinician. Viewed from a lateral position, the diaphragm divides this area into the posterior thorax anteriorly and dorsally, and the anterior abdomen ventrally and posteriorly (Fig. 11.1).

The band described encircles lungs, mediastinum, heart, pleural cavity and great vessels in front of the diaphragm, and rumen, reticulum, omasum, abomasum, liver, gall-bladder, spleen and the anterior part of the peritoneal cavity posteriorly with much of the greater and lesser omental sheets. Differential diagnosis is often difficult and is not helped by the fact that both thoracic and abdominal lesions occur within this imaginary belt.

Traumatic reticulo-peritonitis

The classical and traditional condition affecting this area is traumatic reticulo-peritonitis ('wire') (see p. 837) and it is very convenient to use this condition, less common nowadays, but well known and recognized, as a yard-stick with which to compare the numerous other conditions of the posterior thorax and anterior abdomen.

The possibility of overlooking a penetrating foreign body, a serious mistake for both patient and clinician, is always at the back of one's mind when examining a bovine abdomen. It is always a considerable relief if one can eliminate the possibility of a foreign body and its complications, and such a process is, of course, very important to the surgeon when considering the site of a possible exploratory laparotomy. Nevertheless, neither the confirmation nor the refutation of a provisional diagnosis of traumatic reticulitis is easy without exploratory laparotomy. Thus, the clinical syndrome presents such wide variations in both the extent and intensity of signs that it is probably true to say that the only constant clinical sign is the presence of some degree of pain in the anterior abdomen. The range of differential diagnoses is therefore wide and includes several groups of clinical conditions, each capable of confusion by virtue of exhibiting one or more of the signs associated with reticulitis.

The acute clinical syndrome not infrequently encountered at the onset of the condition includes complete inappetence, and ruminal and reticular atony, resulting in ruminal impaction and slight tympany, with absence of ruminal movement and cudding. Constipation may also be a feature. Temperature may be 40–40.5°C (104–105°F) with a pulse rate of 80–90/minute. There is

a marked drop in milk yield. The painful focus in the anterior abdomen results in general rigidity with arched back and protruding neck, disinclination to lie down and spontaneous grunting accentuated by movement, defaecation and micturition, and very marked on pinching the withers or applying upward pressure to the xiphisternal region.

This acute syndrome is by no means constant, even at the onset of reticulitis, and when present usually abates in 24–36 hours as the intensity of pain lessens and varying degrees of ruminal and reticular motility return. Temperature tends to fall into the 39–39.5°C (102–103°F) range, pulse rate may be in the normal range or slightly raised, appetite, although poor, is not completely absent, ruminal impaction and tympany largely disappear and faeces regain normal consistency. The painful rigid stance relaxes and although the back remains somewhat stiff and arched, pain may require elicitation by the clinician rather than being obviously spontaneous. Rumination, however, nearly always remains absent, or irregular and occasional.

In some cases the only clinical signs are slightly depressed appetite and rumination, subnormal milk yield and indications of pain so slight that they amount to no more than unwillingness to depress the back, so that even mild and painless diseases such as acetonæmia have to be considered in differential diagnosis.

Localized peritonitis

The acute and subacute syndromes described above are, of course, essentially those of localized peritonitis, and pictures similar in broad outline will result from other causes of localized peritonitis, although the veterinarian may be able to differentiate the focus of pain.

- (1) Penetration of the involuted uterus or the vaginal fornix by a catheter or damage to the anterior vagina at service may produce a picture similar, save for considerably less interference with alimentary motility and for pain response on pressure over the posterior abdomen or on rectal examination. Such injuries frequently evoke straining, indicating the need for vaginal examination.
- (2) Postoperative peritonitis may well provide a syndrome similar to that of moderately acute traumatic reticulitis, but the fact of recent operation and the possibility of peritonitis resulting therefrom will be obvious to the clinician, particularly after procedures such as trocharization for the relief of bloat.
- (3) Perforation of an abomasal ulcer (see p. 844) may present a picture broadly similar to that of acute

traumatic reticulitis if seen in the early stages before diffuse peritonitis, collapse and death occur. However, there is likely to be acute pain over a much wider area of the anterior abdomen, particularly on the right side, than is the case in reticulitis. Any temperature rise is likely to be transient only, but the pulse rate will be considerably in excess of that expected in reticulitis and may exceed 100/minute. There will be grinding of the teeth and loud groaning as well as grunting of a similar type to that seen in acute reticulitis. The cow will not eat, is greatly depressed and remains largely recumbent. In a proportion of cases, though by no means all, the abdomen becomes distended with gas, presumably by leakage through the perforation, and a state of true peritoneal tympany develops. This syndrome must also be considered in the differential diagnosis of acute abdominal distension.

- (4) A peritonitis syndrome varying from a very acute picture associated with shock to a subacute picture sometimes associated with straining is occasionally met with as the result of penetration of the rectum by a foreign body, usually a broom or pitchfork handle, introduced through the anus by a person with sadistic tendencies. Such a lesion is always detectable by rectal examination.
- (5) The more acute lesions of tubercular peritonitis (see p. 863), as seen in the breakdown forms of the disease, occasionally produce an abdominal syndrome similar to that of traumatic reticulitis. Unless there are obvious coincidental signs of tuberculosis, diagnosis is made only on opening the abdomen with the intention of performing rumenotomy when the blood-streaked, caseating and even exudative lesions of the acute disease may be only too obvious. This syndrome is now rare in more developed countries but might occur should the disease again break out.

Having considered the differentiation of traumatic reticulitis from other causes of peritonitis, one must now be prepared to differentiate moderately severe forms of the disease from conditions which, although not involving peritonitis, cause pain in the anterior abdomen or posterior thorax. This question of pain in the anterior abdomen or posterior thorax is, of course, very important in the diagnosis of reticulitis. One must remember that the reticulum, diaphragm, liver, abomasum, omasum, heart, pleurae, oesophagus and the posterior lung areas all lie approximately along the vertical line between the point at which one pinches the withers and the point at which one applies the bar.

Bacterial endocarditis (see p. 726)

Classically described and reviewed by Rees Evans (1957), bacterial endocarditis obviously requires differentiation from other cardiac diseases, but it is not generally realized that, in its earlier stages, before signs of venous congestion and circulatory stasis supervene, endocarditis can easily be confused with traumatic reticulitis. Pain, often intermittent in nature, and causing rigidity of stance with abduction of the left, or both, elbows, and discomfort when pressure is applied to the withers, xiphisternum and left ventral aspect of the chest, is probably due to infarction of the lungs or myocardium. This is not unlike that due to a foreign body penetrating the reticulum. Once venous congestion is clinically obvious, the fact that the heart is diseased becomes apparent and from this point the clinician must eliminate other cardiac diseases, particularly traumatic pericarditis.

Previous to the development of venous congestion, accelerated respirations with dyspnoea and coughing on exercise, the peculiar 'shifting' lameness of endocarditis, the tendency towards a markedly high pulse rate even when temperature is responding to antibiotics and the presence, in some cases, of recognizable abnormality of heart sounds may all help in differentiating endocarditis from reticulitis. The author is cautious on the subject of heart sounds, for although he has frequently been assured by skilled cardiologists that a murmur will always be audible in this disease, he has frequently failed to detect one in cases with a right-sided lesion. It is noticeable that endocarditis cases tend to retain a relatively bright demeanour and reasonable appetite until the late stages of the disease. The white cell picture is of limited value as many cases present total and differential counts similar to those produced by a penetrating foreign body, although there is a tendency for both total white cell count and neutrophil percentage to be higher than in that disease.

Certain cases of pneumonia and pleurisy

(see Chapter 49a,b)

These conditions, particularly the latter, exhibit signs of posterior thoracic pain that may simulate reticulitis and careful auscultation of the chest is necessary in an attempt to confirm the presence of abnormal thoracic sounds. Pleurisy is very painful in the early dry stages, but becomes painless as effusion develops. Respirations are rapid and shallow, but as effusion builds up, they become deep and swinging.

Impaction of the abomasum (see p. 844)

Impaction of the abomasum, involving primarily the pyloric outlet with large quantities of fibrous foodstuffs,

sand or gravel, may occur very occasionally. There is a slow diminution in appetite and milk yield and progressive ruminal impaction comprising solid food material with, occasionally, a little gas. Rumination ceases and constipation occurs. Temperature is never more than slightly raised, but pulse rate may eventually exceed 100/minute. At first, there is slight anterior abdominal pain only, but as the disease progresses, pinching of the withers and pressure over the xiphisternum are resented markedly. Pain may, in contradistinction to the case in reticulitis, be evoked by pressure over the anterior part of the right flank. The white cell picture may be in the normal range or similar to that of 'wire'. Although the patient becomes much weaker and more depressed than is the case in reticulitis, it is doubtful whether differentiation will be made before exploratory laparotomy reveals the distended doughy abomasum.

The author believes that true abomasal impaction is very rare, and that most of the cases described as abomasal impaction in the past have shown distension of the fundic portion of the abomasum with material like dry rumen contents and an accumulation of fluid within the rumen, which suggest very strongly that they are, in fact, cases of 'vagus indigestion' (p. 855). Lymphosarcoma can cause the problem (p. 693).

Painful conditions of the liver (see p. 147)

These obviously present a problem in differentiation within the group of diseases causing pain in the anterior abdomen or posterior thorax. The liver is a very difficult organ from the clinician's viewpoint. It is anatomically inaccessible and, in spite of the considerable volume of work carried out in recent years, there are still no entirely satisfactory tests of liver function in the bovine species.

The cow has large reserves of liver tissue, and very considerable damage may occur without the production of a clear-cut syndrome. Liver biopsy is of limited value in that the portion of liver obtained may be quite unrepresentative of the whole. The author prefers to make an incision behind the last rib, in the right sublumbar fossa, sufficiently large to allow a manual examination of the liver and even, using a small torch, limited visual examination. A biopsy specimen can, if required, be obtained through such an incision with the minimum of risk.

Pyelonephritis (see p. 725)

In its more severe forms pyelonephritis produces pain that, although not sited in the anterior abdomen, can easily lead to confusion with traumatic reticulitis, particularly as the white cell count is also usually raised. It may be said that, in spite of the raised temperature and

pulse rate, the arched back and the grunt not infrequently present, urine examination leaves the diagnosis beyond doubt. Nevertheless, failure to observe the urine may easily lead to error. Rectal palpation will reveal an enlarged kidney or differentiate cystitis from pyelonephritis (p. 725).

Impaction of the omasum

Another confusing condition, which is practically impossible to diagnose in life, is impaction of the omasum. The disease, which is fortunately very rare, produces slow weight loss, inappetence, low-grade anterior abdominal pain and general dullness. Ulceration and necrosis of the abomasal leaves are found at post-mortem examination.

Diaphragmatic hernia (see p. 848)

In cattle diaphragmatic hernia produces signs much more suggestive of anterior abdominal pain, particularly reticulitis, than of any thoracic involvement. It is, in fact, probable that many cases arise due to weakening of the diaphragmatic muscle by previous foreign body ('wire') damage. The hernial ring is usually small, involving parts of the reticulum and sometimes the omasum. The resulting low-grade pain may actually be due to areas of peritonitis caused by the original 'wire'. The interference with reticulum and omasum, due to the constriction of the hernial ring and the development of adhesions, sometimes leads to 'vagus indigestion' (p. 855).

Uterine torsion (see p. 1118)

It is worth remembering that the occasional cow which develops uterine torsion very early in parturition may show subacute or chronic abdominal pain with progressive inappetence and constipation. Such a case may show little or no further signs of developing labour.

Cases of acute traumatic reticulitis (see p. 837) with ruminal impaction requiring differentiation from other conditions presenting this feature

These conditions are discussed in the section on ruminal impaction and include dietary ruminal impaction in yarded cows on fibrous feeds, e.g. hay or straw, with limited access to water. A less spectacular ruminal impaction may occur in dairy cows tied in ship-pens during the winter should the water bowl cease to function or in groups when the water supply is reduced or ceases, e.g. freezing, bursts in piping, etc.

Impaction of the rumen with grain shows varying degrees of ruminal distension and discomfort for varying periods before diarrhoea supervenes (p. 829).

Subacute and chronic ruminal tympany (see p. 832): These do occur in traumatic reticulitis, particularly in the early stages, and often superimposed on a degree of ruminal impaction. A number of other conditions also result in slight ruminal tympany, which forms a differential group in its own right (see chronic bloat, p. 832).

Cases of traumatic reticulitis (see p. 837) requiring differentiation from other causes of anterior abdominal pain and conditions causing stiffness and rigidity of stance

Tetanus (see p. 733): This is not infrequently misdiagnosed as reticulitis in the first instance. Not only is there subacute tympany, but the arched back, stiff unbending stance and marked constipation of tetanus can be quite confusing.

Bilateral solar ulcer (see p. 417), *laminitis* (see p. 420) and *other hind foot lesions* (see Chapter 31): Similarly, but with less justification, cases of bilateral solar ulcer, laminitis (coriosis) and other painful bilateral hind foot lesions may cause similar confusion.

Injury to lower cervical vertebrae: Occasionally, cows suffer injury to the lower cervical vertebrae, resulting in pain, stiffness and reluctance to bend the lower neck or back, and such cases have sometimes been diagnosed as traumatic reticulitis.

Complications of, and sequelae to, traumatic reticulitis (see p. 837) causing confusion in diagnosis of anterior abdominal/posterior thoracic pain

- (1) Cases are encountered where a piece of wire loose in the reticulum, by reason of its shape, repeatedly pricks the reticular wall and is then dislodged, producing minor episodes of pain and localized peritonitis that rapidly resolve. By the time operation has been decided upon, the animal is substantially normal and surgery is withheld, only for the syndrome to be repeated after varying intervals of time. It is possible that such 'pricks' should be included with transient phases of abomasal displacement as the reason for many of the 'non-specific inappetence' cases so well known to every bovine clinician.
- (2) A difficult problem is the case where traumatic reticulitis is strongly suspected and rumenotomy carried out, only to find that in spite of the presence of definite reticular adhesions, no foreign body can be found. There are three possibilities. Firstly, the adhesions may be longstanding and bear no relation to the present illness, i.e. the diagnosis is

incorrect. This possibility can be checked by applying digital pressure to the adhesions – if pain is provoked, they are probably pertinent to the present ill health. Secondly, the foreign body may have become dislodged and passed down the gut, or even regurgitated, in which case prognosis is good. Thirdly, the foreign body may have passed completely through the reticular wall and be buried in adhesions and reactionary tissue beyond. Here the prognosis is obviously grave.

One can only advise a wait-and-see policy, but such cases do present difficulties in the management of clients who expect the production of a foreign body and, in its absence, are frequently inclined to doubt the diagnosis and regard the operation as an error on the part of the clinician.

- (3) An occasional, but nevertheless difficult, case is the cow from whose reticulum a foreign body has previously been removed and which now, weeks or months later, is showing a clinical syndrome suggestive of 'wire'. Has there, in fact, been a penetration by a further foreign body or are the signs due to further infection or abscess formation in the old adhesions? In cases that do not respond promptly to antibiotic therapy it is always wise to re-operate, for even if no further foreign body is involved, an abscess may be found that can be drained into the reticulum.
- (4) A further group of conditions occurs where a foreign body penetrating the reticulum has since penetrated another organ. Signs, in these cases, are usually related largely to this secondary occurrence and the signs, all-important prognostically, of the primary foreign body aetiology tend to be masked. The classical example of this type of condition is traumatic pericarditis, producing a syndrome very well recognized, but presenting considerable difficulty at times in differentiation from endocarditis.

Penetration of the thoracic cavity to produce suppurative pneumonia or pleurisy also occurs, tending to produce a subacute thoracic syndrome with progressive loss of condition. It is of considerable importance prognostically to know whether such a condition is due to a penetrating foreign body or not and it is often extremely difficult, in the presence of pain in the posterior thorax, to decide whether pain exists in the anterior abdomen as well. The white cell picture will not help, and exploratory laparotomy may be necessary as a diagnostic aid.

Similarly, foreign body penetration of the liver may occur causing a large area of suppuration, which may produce a clinical picture similar to the acute liver fluke

syndrome previously mentioned, but with reticuloruminal interference as well. Extensive liver lesions of this type occasionally interfere sufficiently with the bile ducts to cause jaundice.

- (5) Occasionally, traumatic reticulitis leads to acute diffuse peritonitis, the abdomen filling with pus and producing abdominal distension, toxæmia, depression, weakness and diarrhoea, leading to death (see abdominal distension, p. 140).
- (6) Vagus indigestion is also a complication of traumatic reticulitis (see abdominal distension, p. 855).

Chronic bloat (chronic and subacute ruminal tympany) (see p. 852)

All conditions producing low-grade ruminal tympany must fall into one or other of two main groups: (i) those affecting normal rumino-reticular tone and motility and (ii) those causing partial obstruction to the escape of gas from the rumen, motility and tone remaining normal.

Conditions affecting normal rumino-reticular tone and motility

Chronic inflammatory lesions of the mucous membrane and wall of the reticulum and the oesophageal groove: Actinobacillosis of these sites is the most important condition of this group (see p. 823). The smooth painless fibrous plaque of this disease interferes with both eructation and rumination, producing a mild tympany most obvious after feeding. If the oesophageal groove is badly affected there is often a prolonged retching gurgling noise as the cow makes laboured attempts to bring up the first bolus of a new period of rumination. There may be drooling from the mouth.

Therapeutic response is normally rapid enough to be considered diagnostic.

Occasionally, inflammatory thickening and *A. pyogenes* abscessation of the area resulting from foreign body lacerations and partial penetrations may occur, also affecting eructation and rumination. Chronic ruminal atony can occur in calves with oesophageal groove problems.

Inflammatory changes (peritonitis): Inflammatory changes involving the serous lining of rumen, reticulum or even abomasum are more important, leading to poor motility and even atony of the rumen-reticulum. The classic syndrome in this group, as already mentioned, is *traumatic reticulo-peritonitis* ('wire', p. 837). Even in longstanding cases, where some degree of rumen movement has returned, there may well be chronic ruminal tympany often superimposed on low-grade ruminal impaction.

A *peptic abomasal ulcer* (see p. 844) sufficiently advanced to involve the peritoneal lining may well form omental adhesions, and may even perforate among these adhesions, so that there is no leakage into the peritoneal cavity itself. Such a cow, instead of dying within 24–36 hours of acute diffuse peritonitis, toxæmia and shock with massive peritoneal tympany, as described under abdominal distension, will pass into a state of intermittent low-grade pain, abnormal or negligible rumino-reticular movement with slight and intermittent ruminal tympany. There will be lethargy, weight loss and intermittent diarrhoea.

Acidosis (see p. 829): This shows its classical features in barley poisoning, but many recently calved high-yielding cows on a high-energy diet develop mild acidosis after each feed. The slight ruminal tympany plus near-diarrhoeic faeces in a lethargic cow with sub-optimal appetite and milk yield is familiar in intensive dairy herds.

Vagus indigestion (see p. 835): Occasional cases of vagus indigestion (see complications of traumatic reticulitis, p. 837, and abdominal distension, p. 140) show an accumulation of ruminal gas forming a marked, but chronic, tympany that may even mask the fluid present.

Tetanus (see p. 733): Tetanus frequently produces a moderate tympany (see rigidity of stance and gait, p. 145).

Cold water: Under ruminal distension, the effect of cold water on the ruminal musculature is mentioned. In some herds, in which all the cows drink water from troughs in the yard, the whole herd may show a degree of post-drinking tympany.

Botulism (see p. 721): With its generalized muscle weakness, botulism shows subacute tympany as a minor part of a fatal progressive disease.

Conditions causing partial obstruction to the escape of gas from the reticulo-rumen

Motility and tone being normal, these conditions will cause low-grade tympany.

Oesophageal wall lesions (see p. 825): Usually traumatic in origin, these include oesophageal stricture, oesophageal wall abscesses, oesophageal dilatation and oesophageal papillomata, which are usually sited at the cardia.

Lesions causing external pressure on the oesophagus (see p. 832): These lesions will also produce chronic tympany. They include thymic lymphosarcoma in young

cattle (p. 698) and enlarged posterior mediastinal lymph nodes in the adult. Such enlargement is an important cause of chronic tympany and is usually due to one of three infective organisms: *A. pyogenes*, *Actinobacillus lignieresii* and, occasionally, *Mycobacterium bovis*.

Diaphragmatic hernia (see p. 848): This condition also not infrequently leads to chronic tympany.

Diagnosis of chronic and subacute ruminal tympany

Diagnosis depends firstly upon a careful clinical examination to decide whether the tympany is related to a specific alimentary condition or whether it is due to loss of gastric tone as a result of a more general disease. If the condition is primarily alimentary, and one believes there is no oesophageal obstruction, then auscultation should be carried out to check that the left flank tympany is ruminal and not abomasal (i.e. left displacement). Auscultation should leave one in no doubt, although it is not always easy to distinguish between a gas-filled abomasum, early vagus indigestion (p. 855) and reticular actinobacillosis (p. 823).

The liver

The liver is practically impossible to examine clinically by normal methods. It is unfortunately true that unless one adheres to a strict routine, it is only too easy to examine a cow without even thinking about the liver. The liver has many functions and failure, therefore, may produce a variety of signs.

Signs include lethargy, slow weight loss, anaemia, low-grade or acute abdominal pain, massive abdominal haemorrhage, ascites, abdominal distension, chronic venous congestion, ataxia, ventral oedema, photosensitization, endocarditis, encephalopathy, dyspnoea with pulmonary thrombosis, massive nasal haemorrhage and, occasionally, jaundice. All these conditions may originate in hepatic disease. Also, one must consider the diverse problems of the high-yielding cow calving down with a very fat liver predisposing to metritis, coliform mastitis, ketosis, low solids, milk fever and even infertility.

The liver, it seems, not only is the site of specific disease conditions in its own right, but also may be a background factor predisposing to disease in other organs and systems. In the face of this diversity of signs, all one can suggest is that the clinician should always consider the possibility of liver disease when examining a cow. He/she is then unlikely to miss liver pathology when it occurs.

Laboratory tests, e.g. haematology, serum proteins, serum enzymes (aspartate aminotransferase (AST), serum alkaline phosphatase (SAP) and particularly

gamma-glutamyl transferase (γ GT)), may be helpful, though by no means conclusive. Paracentesis may occasionally help in the presence of ascites, while liver biopsy is at least theoretically useful. Unfortunately, these techniques are expensive and the farmer of today is very unwilling to authorize them in any but the most valuable of individual cows.

So consideration of the liver must be as rigid a rule as checking the udder, and a mental list of the syndromes involved in hepatic disease can be a great help.

Abscessation (see p. 830)

This is usually due to *A. pyogenes* or *Fusobacterium necrophorum* en route from the rumen, and is probably only clinically significant when extensive. Obviously, cereal overeating and other conditions likely to damage the rumen wall will predispose to liver abscesses. Bacteraemias also come from navel infections and pyaemias.

Complications of hepatic abscessation may be very serious:

- Rupture into the abdominal cavity leading to an acute diffuse peritonitis.
- Rupture into a major vessel, leading to major haemorrhage, shock and sudden death.
- Vena cava thrombosis, usually where the vena cava passes through the diaphragm. This produces hepatic portal obstruction leading to abdominal distension and ascites; however, it may produce pulmonary thromboembolism leading to pulmonary abscessation. There will be a painful cough, and dyspnoea, with rupture of abscesses into blood vessels producing severe and often recurrent haemorrhage via the nose and mouth (see p. 867).

Hepatic necrosis

Hepatic necrosis due to *Fusobacterium* invasion causes pyrexia, inappetence, lethargy, rapid pulse, weight loss, ataxia and occasionally signs of anterior abdominal pain. The presence of jaundice is variable, but is diagnostically helpful when it occurs.

Cholecystitis

This condition is rare and difficult to diagnose. Such cases show ataxia, anterior abdominal discomfort and jaundice, with lowered appetite and milk yield. Temperature may be raised.

It is interesting that jaundice is much more likely to occur in obstructive hepatic conditions than in parenchymatous change.

Cirrhosis

Cirrhosis in cattle, for all practical purposes, means liver

fluke infestation (p. 276). This condition must never be forgotten. It occurs in adults as well as young stock, in herds as well as individuals, and although wasting, submaxillary oedema and anaemia may well be present, the disease may merely cause chronic unthriftiness and sub-optimal yield during the winter months, thus needing differentiation from a nutritional energy deficit. In fact, both problems may occur in the same herd, particularly between parturition and peak yield.

It is worth remembering that in severe fluke infestation, constipation is more likely than diarrhoea, and that during the migratory stage of the young flukes, a low-grade abdominal pain syndrome may occur that requires differentiation from 'wire'.

Liver fluke infestation (see p. 276) has far-reaching effects. It may lead to infertility, presumably due to weight loss, to low milk solids and to salmonellosis, or to endocarditis due to bacteria passing to the liver and then into the circulation.

Cirrhosis also results from ragwort poisoning (p. 945), causing weight loss, ataxia, encephalopathy, occasional jaundice and terminal tenesmus in the affected animal. The encephalopathy produces blindness, head pressing and dragging of the hind fetlocks reminiscent of lead poisoning in the adult cow. Ragwort poisoning during the grazing period may well trigger photosensitization.

Other syndromes involved in liver disease

Tuberculosis (see p. 862) and *neoplasia* of the liver are relatively rare. Neoplasia includes lymphosarcoma and adenocarcinoma and is, to all intents and purposes, impossible to diagnose in life, while fatty livers may follow bacterial or chemical toxicity, but are much more common as the result of overfeeding or inappropriate feeding.

The fatty liver syndrome (see p. 801), resulting from excessive weight gain pre partum, has gained prominence in recent years, but is probably less common today. The syndrome may be involved in many diseases in early lactation.

Constipation

Quite apart from the acute gut obstruction syndromes, constipation may occur in diverse circumstances in cattle.

- (1) Unsuitable fibrous diet, e.g. straw, may produce ruminal impaction.
- (2) Insufficient water intake may produce ruminal impaction.
- (3) External pressure on the gut, e.g. fat necrosis (see p. 849), lymphosarcoma (see p. 693), adhesions.

- (4) Pain:
 - (a) Postoperative pain.
 - (b) Injured back – faeces dry out in rectum.
 - (c) Injured anus and rectum – painful bladder.
- (5) Weakness or paresis: milk fever, broken back. Constipation is, of course, a very useful differential sign of milk fever (p. 781).
- (6) Some poisons, e.g. lead (see p. 944) and ragwort (p. 945).
- (7) Pyrexia.
- (8) Anaemia. e.g. fluke (see p. 276), piroplasmosis (see p. 748). In both these diseases, constipation becomes very marked in long-standing cases.
- (9) Ketosis: mild constipation is a frequent clinical sign (see p. 793).
- (10) Hypocalcaemia (see p. 781).
- (11) Peritonitis (see p. 849).

Constipation is, of course, rare in dairy cattle and if faeces are completely absent, acute gut obstruction (p. 1113) caused by intussusception (p. 847), caecal or intestinal torsion (pp. 846, 847) will be the most likely reason.

Diarrhoea

Varying degrees of diarrhoea are normal today in intensive dairy herds feeding concentrates and silage.

Not all conditions causing diarrhoea originate primarily in the digestive tract, but from the viewpoint of differential diagnosis, it is best to consider all conditions causing diarrhoea together.

Acute diarrhoea

- (1) Most toxæmic conditions produce diarrhoea, e.g. diffuse peritonitis (p. 849), acute mastitis (staphylococcal, coliform or *A. pyogenes* (Chapters 23, 24)), acute septic metritis (p. 519), traumatic pericarditis. These conditions all involve damage by bacterial toxins, and the diarrhoeic faeces tend to be relatively scanty, but dark and sticky with a fetid odour.
- (2) Several acute septicaemic diseases are associated with acute enteritis and diarrhoea, e.g. anthrax (see p. 717), transit fever (see p. 286) and other forms of acute pasteurellosis (see p. 728), and, of course, salmonellosis (see Chapter 15).
- (3) Some virus diseases, e.g. malignant catarrhal fever (see p. 935) or the BVD/mucosal disease complex (see p. 853).
- (4) Several plant poisons, e.g. solanin from green potatoes (see p. 943), water dropwort (see p. 943), and rhododendron (see p. 943).
- (5) Several chemical poisons, e.g. arsenic (see p. 941) and certain organophosphorus compounds (see p. 940).

Chronic diarrhoea

- (1) Johne's disease (see p. 857): the classical form of chronic diarrhoea with loss of weight, particularly from the hindquarters, ventral and submaxillary oedema and anaemia.
- (2) Tuberculosis of the intestine (see p. 862), very rare today, is always secondary to pulmonary lesions, and is similar, clinically, to Johne's disease.
- (3) Ulceration of the abomasum (see p. 844) produces scanty and intermittent diarrhoea in a cow losing weight, becoming anaemic and showing signs of low-grade anterior abdominal pain. Erosion of such an ulcer into a blood vessel in the abomasal wall produces more profuse, tarry faeces and may cause death.
- (4) Amyloidosis is very rare indeed (see p. 928).
- (5) Lymphosarcoma of the large gut is also very rare in cattle (see p. 693).

Herd diarrhoea

- (1) Winter scours, or winter dysentery, has long been recognized as an acute, pyrexic and occasionally slightly dysenteric condition, which races through a housed dairy herd in winter conditions and then dies out with minimal long-term damage. There has been discussion as to the aetiological organism, various viruses and *Campylobacter* spp. having been incriminated (see p. 852).
- (2) Various nutritional diarrhoeas:
 - (a) Spring grass.
 - (b) Frosted roots or kale.
 - (c) Fodder beet poisoning, the leaves of which causes a hypocalcaemia-like syndrome and diarrhoea.
 - (d) Acidosis (see p. 829), whether due to excessive root feeding or more commonly due to excessive cereal overload. The classical acidosis syndrome is that of barley poisoning with its acute abdominal pain and low-grade tympany, followed by profuse diarrhoea (see p. 830).
- (3) Mineral deficiencies, e.g. copper (see pp. 254, 298) and cobalt (see p. 295) deficiency, producing chronic diarrhoea with weight loss and anaemia.
- (4) Parasitic diarrhoea, e.g. parasitic gastroenteritis (see p. 267) and coccidiosis (see p. 282), largely affecting young stock.
- (5) Toxicity, e.g. antibiotic contamination of the feed.

There is no easy way to diagnose the diarrhoeic animal. It is necessary to consider all environmental factors, including nutrition, stage of lactation, season of year, housing or pasture; whether the condition is an individual animal or herd problem and whether it is acute or chronic in nature.

Other signs besides diarrhoea may indicate whether the faecal changes are due to a primary gut problem or are secondary to a systemic disease.

Finally, one must utilize whatever laboratory tests for bacteria, parasites, viruses or minerals are available under the circumstances. Even so, there will be one-off conditions, rarely met with in one's practice area, which will, from time to time, elude the diagnostic net!

Tenesmus (straining) (see p. 838)

This condition occasionally occurs in cattle. *Coccidiosis* (see p. 282) in calves is an excellent example due to painful inflammatory changes in the hindgut. The *BVD/mucosal disease* (see p. 853) complex in young stock may have the same effect. Straining is also seen in the late stages of *ragwort poisoning* (see p. 945), in occasional cases of *terminal intussusception* (see p. 847) and sometimes in *urolithiasis in the male* (see p. 263).

It may also follow *sadistic human behaviour*, when sticks or broom handles have been forced into the rectum, frequently penetrating the wall of the hind gut some 30–45 cm (12–18 inches) proximal to the anus.

Occasionally, there will be sufficient straining to pass hard dry faeces in the cow with milk fever of some hours duration, to produce transient doubt in the attendant's mind as to the possibility of there being a further calf *in utero*. Obviously, the most frequent causes of straining in the cow are obstetrical, e.g. parturition, dystokia (p. 1115) or vaginal injury (p. 519).

Rectal examination may make things much worse if tenesmus is marked, but a look at the mucous membrane just within the anus with a pencil torch may be very helpful. In coccidiosis, cryptosporidiosis and the BVD complex, particularly, the acutely inflamed nature of the hindgut often spreads right to the anus itself.

The unthrifty or emaciated cow

Starvation

Even in developed countries today, starvation can still be seen in poorer areas as a primary condition, but much more frequently appears as a relative energy deficit in high-yielding cows near peak yield. In the period from parturition to peak yield, it is frequently associated with ketosis.

Ketosis (see p. 793)

Ketosis is nothing more nor less than energy deficit and may if untreated produce very severe weight loss.

Liver fluke infestation (see p. 276)

Liver fluke infestation, reaching its most dangerous in terms of liver damage in the late autumn and winter

months when autumn-calved cows are at peak yield and possibly in energy deficit, accentuates the whole picture of energy deficit and ketosis.

Chronic hypomagnesaemia (see p. 787)

In cold windy weather in late winter, heavily pregnant cattle develop a state of chronic hypomagnesaemia as a result of low food intake and cold, becoming thinner and poorer until some additional stress triggers off the acute convulsive phase.

These four conditions, interconnected to varying degrees, account for much of the unthriftness found in dairy herds. A further condition, which may also be involved, is copper deficiency (p. 298).

Copper deficiency (see p. 298)

Copper deficiency may be either in its own right or resulting from molybdenum excess. In the latter case, there will be diarrhoea, but many herds exist in a low-grade copper deficiency, particularly at the beginning of the grazing season when the rapid grass growth dilutes the copper uptake, with weight loss and infertility the only signs.

Other conditions leading to weight loss

On an individual animal basis, Johne's disease (p. 857), which does not always cause diarrhoea in the early stages, and, historically, tubercular emaciation (p. 862) are important causes of weight loss, as are abomasal disorders such as left displacement (p. 839) and ulceration (p. 844). Chronic liver disorders, e.g. ragwort toxicity (p. 943) or multiple abscessation (p. 829), may also result in poor thriving to the point of emaciation before clear-cut aetiological pointers appear.

A number of other conditions lead to weight loss and suboptimal yield, but reasonable and sensible clinical examination should produce a definitive diagnosis without real problems. These conditions include the following.

- Lameness (laminitis, solar ulcer and white line lesions) (Chapter 31), often ignored by farmers who completely fail to realize the serious nature of the long-term effects.
- Chronic pyelonephritis (see p. 725), which should be obvious provided the clinician remembers to examine the urine.
- Actinobacillosis of the tongue or oesophageal groove area, already discussed on pp. 823–6.
- Paralysis of the fifth or seventh cranial nerve.
- The long-term toxic and depressing effects of mastitis, metritis, or postoperative peritonitis with adhesions and peritoneal abscessation.

The 'downer' cow (see pp. 439, 797)

A 'downer' cow used to be defined as a cow that remained recumbent after treatment for milk fever due to a continuing hypophosphataemia (p. 791). But, by general usage, the term has come to mean any cow recumbent at, or near, parturition, and thus there is a large differential list.

Preparturient

- Liver fluke (see p. 276) and/or starvation (see p. 796). These cows may have cirrhotic livers. They are thin, weak and lethargic, but not ketotic.
- The fat cow syndrome (see p. 796). Occasionally, grossly fat preparturient cows with pathologically fatty livers may become recumbent.

Parturient

- (1) Prolonged dystokia may lead to exhaustion.
- (2) Rupture of cervix or uterus leads to recumbency through shock and is quickly fatal.
- (3) Traction injuries.
 - (a) Sacroiliac disarticulation (see p. 448).
 - (b) Sciatic nerve paralysis (see p. 439).
 - (c) Torn adductor muscles (see pp. 439, 459).
 - (d) Fractured pelvis (see p. 446).
 - (e) Fractured femur (see pp. 441, 444).
 - (f) Peroneal paralysis, which is much more likely to occur after milk fever than after parturition, because it is secondary to muscle atony in recumbency (see p. 438).

Parturient and postparturient

- Complications of milk fever (see p. 781)
- Fractures, dislocation and muscle injuries (see Chapter 32).
- Ruptured gastrocnemius (see p. 451).
- Peroneal paralysis (see p. 438).
- Sciatic nerve paralysis (sensory and motor) (see p. 439).
- Pressure ischaemia of hindleg or legs, which may lead to ischaemic muscle degeneration, particularly the semimembranosus and semitendinosus muscles. Serum AST and creatine phosphokinase levels rise markedly (see p. 439).
- Ketosis and licking mania (see p. 793).
- The cows seems bright and well, but stays down. Never attempt to make a cow with milk fever get up before it is entirely ready to do so (see p. 797).

Notice that the following conditions are all important in the differential diagnosis of the 'downer' cow (see pp. 439, 797).

- Acute staphylococcal (see p. 332) or coliform (see p. 334) mastitis.
- Acute septic metritis (see p. 519).
- Hypomagnesaemia (see p. 787).
- Cereal over-eating: acidosis (see p. 829).
- Fodder beet poisoning (see p. 149).
- Botulism: a condition increasing in frequency and associated with the feeding of big bale silage. Diagnosis is aided by a normal temperature, slow pulse rate and slowly progressive generalized muscular weakness affecting both voluntary and involuntary muscle (see p. 721).
- Internal haemorrhage, with fast pounding heart, white membranes, rapid respirations and often a subnormal temperature.

Diagnosis of the 'downer' cow is never easy, unless there is an obvious major fracture.

It is important that every 'downer' cow should be given full doses of calcium and phosphorus, and possibly also magnesium. It may be very logical to argue that a particular cow cannot possibly be a case of hypocalcaemia, but it is easy to be wrong. It is much safer to treat, just in case. With reasonable care no harm can be done.

Once satisfied that metabolic possibilities have been covered, a careful examination of the available parts of the skeleton should be carried out, but may not be very fruitful. It is not easy to assess injuries to the legs of a 'downer' cow deep in sludge or slurry!

It is vital that the udder and the uterus should be properly checked and, as far as the udder is concerned, every quarter must be examined however difficult access may be.

The cow ill during or after calving

There is no excuse in cases of periparturient illness for the taking of any form of short cut. The clinician must be satisfied that the cow has not developed any form of milk fever, and even when satisfied, it may be wise to give calcium/magnesium mixture subcutaneously as a precautionary measure.

The uterus must be examined to make sure that it is not infected and not damaged and, above all else, that there are no more calves within. Even after removing the third calf, the uterus should be checked for the fourth!

It is essential that the udder is properly examined. A parturient dairy cow may be very ill and dangerously toxæmic before the udder shows more than a small crepitating area just above the teat, and that may be all that is noticeable in some cases.

Pyrexia of unknown origin (PUO)

Obviously, many conditions may cause a marked rise of temperature in a cow, but a lethargic cow with a

temperature of 40.5–41°C (105–106°F) is more likely to be a case of incipient mastitis (Chapter 23) than anything else, and should always be treated as such in the absence of other signs.

The next possibility is an active pulmonary hyperaemia as an early stage of pneumonia, while an acute septicaemic condition, such as salmonellosis (Chapter 15), may show pyrexia and little else for some 8–12 hours before diarrhoea supervenes. A rectal examination may discover diarrhoea in the early stages that will not have been seen by the stockman. During this period, the total white cell count may be as low as 1500–2000 per mm³, with a neutrophil percentage of less than 10 per cent.

One should remember that *anthrax* (see p. 717) is also an acute septicaemic condition, and there have been many cases of early anthrax where lethargy and a temperature of 41–42°C (106–108°F) are the only signs present. In young stock, severe diarrhoea, often bloodstained, with injected membranes, may supervene within a few hours to be followed by ataxia, collapse and death. In the adult cow, it is not infrequent for the hyperpyrexic early anthrax picture to be followed by collapse, subnormal temperature, clammy skin, cyanotic mucous membranes, restlessness and anxiety, followed quickly by coma and death. The clinician must beware of a stage in this process when the cold recumbent cow is easily mistaken for a severe milk fever case. Realization will come when it is seen that injection sites are trickling dark blood, while spreading haematomata appear where a vaginal examination has been performed, the teats have been handled or the stockworker has gripped the cow's nose.

Sudden death

This is a dangerously misleading heading. Very many cows that the owner regards as cases of sudden death are in fact cows found dead, which is quite a different matter. A cow found dead may well have taken 12 hours or more to die, depending on the diligence of the stockworker and when the cow was last seen.

If one can assume that sudden death means that a cow has collapsed and died, if not immediately then within the hour, then the differential diagnosis is fairly clear-cut.

Acute infections

- Anthrax: every case of sudden death is anthrax until proved otherwise (see p. 717).
- Blackleg (see p. 723): usually young stock but may occur in young adults. The lesion is usually obvious at post mortem. The causal organism is *Clostridium*

chauvoei and bruising of muscle groups predisposes to the problem (see p. 723).

- Wound gas gangrene infections: other clostridial organisms involved in wound infections, usually obvious at post mortem (see p. 724).

Occasional cases of acute coliform (see p. 334) infections, salmonellosis (see Chapter 15), pasteurellosis (see pp. 281, 728) and RSV pneumonia may produce a very rapid, sudden and unexpected death.

Acute pasture conditions

- Bloat: classical signs and environment, with a reasonably clear post-mortem picture, provided that the carcass is examined within an hour or so of death (see p. 832).
- Hypomagnesaemia: classical convulsive syndrome on spring grass. The carcass is often covered with debris, sweat and mud, with signs of convulsive movement in the grass for a considerable distance around (see p. 787).
- Fog fever: occurs in late summer or early autumn. As it is a herd problem there are usually other animals with signs. The lungs show a fairly characteristic post-mortem picture (see p. 866).

Electrocution and lightning strike (see p. 930)

There may be no signs whatsoever on the carcass, particularly in electrocution cases. The behaviour of neighbouring cows, if there is any witness, may help in electrocution, while it goes without saying that if a cow is to be struck by lightning, there must be a thunderstorm.

Accident or catastrophe

Road traffic accidents do occur but strangulation and asphyxiation as a result of faulty yokes and feed trough fittings are probably more common.

Catastrophes also include such events as a wire in the reticular wall being forced in one movement into the heart. The perforated abomasal ulcer leading to shock, peritoneal tympany and toxæmia is also included in this grouping.

Acute haemorrhage

This may result from the following:

- Wire penetration into a great vessel.
- Mammary vein rupture following injury.
- Teat vessel haemorrhage following injury.
- The rupture of a coronary vessel.
- The erosion of an abomasal ulcer into an artery in the abomasal wall.

- Damage to uterine or vaginal vessels after forced traction in dystokia cases.
- The erosion of a hepatic abscess into a major vessel.
- A thromboembolic pulmonary lesion originating from liver (see p. 867).
- A superficial haemangioma, often sited dorsally in the lumbar sacral area.
- Occasional acute cases of the pyrexia, pruritis and haemorrhage syndrome (see p. 884) bleed from the gut, and all other tissues. They also show raised temperature, severe general pruritis and aggressive behaviour before collapse and death.

It should be noted that all these haemorrhagic syndromes, with the exception of rupture of a coronary vessel, may not necessarily produce immediate death, but may instead produce a cold, staggering and severely anaemic animal with rapid pulse rate, rapid respirations, loudly beating heart and subnormal temperature. Early anthrax, peracute salmonellosis, acute babesiosis and acute bracken poisoning may produce the same collapsed and anaemic syndrome.

Acute anaphylactic reactions (see p. 927)

There may be much saliva around the mouth with oedema of the larynx, pharynx, eyelids, skin of face and head, etc. On the other hand, the only lesions may be pulmonary.

Poisons (see Chapter 54)

Theoretically, a number of poisons may cause sudden death in the cow but, practically, sudden death by poisoning will be due to one of the following:

- Yew (see p. 947);
- Water dropwort (see p. 943);
- Bracken: acutely haemorrhagic (see p. 946);
- Strychnine: rarely found today in Britain;
- Arsenic: rarely found today (see p. 941);
- Lead: may cause sudden death in calves, but not usually in cows (see pp. 906, 944);
- Copper (see p. 948).

Jugular stasis (cording)

Care must be taken in the interpretation of jugular stasis. There is often confusion between jugular stasis and jugular pulsation, and it must be emphasized that jugular pulsation may occur in perfectly normal cows, especially if the head is held low as while grazing.

Jugular stasis may occur in conditions involving space-occupying lesions in the anterior mediastinum, e.g. thymic lymphosarcomata in young stock, mediastinal lymphosarcomata in the adult (p. 693) or large mediastinal abscesses.

Nevertheless, the more common causes of jugular stasis (distension) stem from the heart itself.

Traumatic pericarditis (see p. 731)

Previously the most common form of cardiac disease in the cow, this condition has now become relatively rare in Great Britain.

Chronic vegetative endocarditis (see p. 726)

This condition has become much more frequent. It is probable that, 30 years ago, many cases of endocarditis were missed completely for the clinician was so used to 'wire' and pericarditis that all cases of congestive heart failure were diagnosed as pericarditis and sent to the knacker's yard after the most superficial examination.

There are a number of important clinical differences. The pericarditis case is much more toxæmic and therefore more depressed. Transition from relative health to acute illness is much more sudden, although there may, of course, have been low-grade reticulitis signs at some previous stage. Pain is more marked and very readily elicited by wither pinching. Cardiac sounds start with slight friction sounds synchronous with the heart beat, which is usually more than 100/min. Within a day or so, the tinkling splashing sounds indicative of gas/fluid production within the pericardium can be heard, and in a further day or so the sac is grossly distended with pus, and splashing and tinkling have ceased. The heart sounds are now muffled and may, in fact, be louder on the right side because the pressure of the distended pericardium against the left thoracic wall tends to extend the whole structure across to the right.

Gross jugular and mammary engorgement and dependent oedema will now be present at jaw, neck, brisket and lower abdomen. Pulse rate may well reach 140/min.

Endocarditis, on the other hand, runs a more gradual course. For some time, the picture may be one of low-grade anterior abdominal pain, plus a temperature rise to 40–41°C (104–106°F). Pain is felt over a much wider area of the chest. The pulse rate is not generally very greatly raised at first. The cow is often relatively bright and may even eat a little, but exercise tolerance is very poor. Heart sounds, at first, are often no more than loud, and even later in the disease it is not always possible for ordinary mortals to hear the cardiac murmur that is stated to be invariably present in this disease. The reason for this seems to be that, in most cases, the lesion is right-sided.

At first, therefore, and for several days at least, vegetative endocarditis falls within the anterior abdominal/posterior thoracic pain grouping and is easily mistaken for 'wire'. There may even be a wire, for

although most cases derive the valvular infection from the rumen via the liver, from the udder, uterus, pharynx or feet, occasional cases are met in which the primary pyogenic focus is a penetrating reticular foreign body. It is interesting that, in most cases of vegetative endocarditis, the white cell count and the temperature fall during antibiotic treatment, but the pulse rate is unaffected.

Eventually, jugular congestion, shifting lameness, dependent oedema, pulmonary signs, and even haematuria may all appear.

In right-sided cases, pulmonary thromboembolism may cause marked thoracic pain, whilst ascites and engorged mammary and jugular veins are very noticeable. In left-sided cases, pulmonary congestion causes dyspnoea and coughing with less pain, but haematuria due to renal infarction is more likely.

Myocardial abscesses

Myocardial abscesses of considerable size may sometimes occur, producing a clinical picture similar to that of endocarditis, but with lower temperature rises and a slower course.

Other causes of jugular stasis

Fatty degeneration of the heart, and tubercular pericarditis, are usually masked by more obvious systemic signs of the respective diseases.

'Redwater' (blood or blood pigments in urine)

With very few exceptions, disease of the urinary tract in cattle produces significant urinary haemorrhage, and the differential diagnosis obviously includes the numerous haemolytic conditions producing urinary haemoglobin.

Obviously, therefore, when presented with a 'redwater' case, the first stage in diagnosis is to decide whether the case is one of haematuria or haemoglobinuria. Microscopical examination or centrifuging the urine will supply the answer, but usually the simple expedient of standing some urine in a container for a few minutes, while clinical examination is proceeding, will give a satisfactory answer. The clinician must remember that many cows with redwater are not presented as such, for stockworkers rarely notice or even see a cow urinate, except by chance. If asked whether the urine is normal, the invariable answer is that it must be or it would have been noticed. This is wishful thinking, upon which no reliance can be placed.

Once differentiation between blood and blood pigment has been made, diagnosis becomes much easier.

Haematuria

- Chronic cystic haematuria (enzootic haematuria (see p. 947) or chronic bracken poisoning (see p. 946));
- Pyelonephritis (see p. 725);
- Calculi (see p. 263);
- Neoplasia other than is involved in the first list point.

These four conditions show primary lesions within the urinary tract.

Enzootic haematuria (see p. 946) has a regional incidence dependent upon the prevalence of bracken. It tends to occur in older home reared cows and the blood in the urine, slight at first and slowly increasing, contains very little pus or exudative material.

Pyelonephritis (see p. 725) is much more likely to be encountered in dairy herds, but is, for some reason, a rare disease today in Britain compared with its incidence in the 1950s and 1960s.

There are systemic signs varying from very acute to very mild, but diagnosis is greatly assisted by the presence of pus, debris and renal casts, as well as blood, in the urine. Rectal examination may help and the presence of pain is another differential point, for enzootic haematuria is painless and afebrile. Bacteriology on the urine of pyelonephritis may, in fairly early cases, produce a culture of *Corynebacterium renale*, which is the primary causal organism. Remember that the pain, the temperature and the arched back invite confusion with 'wire' unless the clinician keeps pyelonephritis in mind in such cases, particularly in the first third of lactation, and insists on inspecting a urine sample.

Urolithiasis (see p. 263) occurs largely in the young male, and other signs such as straining, the absence of significant amounts of urine and, eventually, 'water belly' overshadow the presence of blood spots in the urine.

Neoplasia of the urinary tract, other than that due to chronic bracken poisoning, is very rare.

A number of conditions occur in which haematuria is but one of a number of fairly obvious systemic signs, so that the urinary blood, when present, is not important in diagnosis:

- Vegetative endocarditis (see p. 726).
- Septicaemic conditions, e.g. anthrax (see p. 717) and acute pasteurellosis (see pp. 286, 728).
- Acute bracken poisoning: a disease with markedly raised temperatures and generalized haemorrhages, which behaves like an acute septicaemia and probably is one (p. 946).

It is worth remembering that very high doses of sulphonamides may theoretically produce crystalluria and

haematuria, but sulphapyridine, the sulphonamide that most frequently produced these signs, is no longer used.

Haemoglobinuria

Piroplasmosis is an acute, pyrexic, and acutely haemolytic tick-borne disease of certain areas of Britain and other countries caused by *Babesia divergens*. The clinical signs include profuse diarrhoea, followed by stubborn constipation in a non-preimmune cow, progressive anaemia, with very rapid pulse rate, loudly pounding heart, and deep port wine coloured urine (see p. 748).

Bacillary haemoglobinuria is a peracute and rapidly fatal pyrexic disease due to *Clostridium haemolyticum* (now renamed *Cl. oedematiens* type II). It affects young stock in certain rough hill areas, but is of relatively little importance overall (see p. 719).

Postparturient haemoglobinuria is seen during the weeks following parturition in cows in certain parts of eastern Scotland and occasionally in England. It is non-febrile, but progressive and frequently fatal due to very severe anaemia, and is possibly associated with root and straw feeding and abnormalities in phosphorus metabolism. It is too rare today to be of real significance (see p. 792).

Kale and rape poisoning are too well known to merit detailed consideration. Large quantities are required and wilted kale is much less likely to cause problems. It is worth remembering that rape in excess may also produce abdominal pain, nervous signs and/or dyspnoea (see p. 941).

Leptospira icterohaemorrhagiae produces haemoglobinuria in the calf, but this is most unlikely to occur in the adult (see p. 735).

Very cold water, thirstily drunk, may cause haemoglobinuria in the calf, but not in the adult.

Copper toxicity, increasing in the UK, may apparently produce haemoglobinuria (see p. 948).

Cows breathing badly (hyperpnoea and dyspnoea)

The clinician must not assume that rapid respirations in cattle necessarily indicate the presence of pneumonia. Cattle 'blow' for many reasons.

Physiological

Cattle breathe more rapidly when full after feeding, after exercise, in hot and humid weather and when they are nervous or frightened. A herd coming in for milking on a hot summer afternoon after a mile walk from lush grazing may all appear dyspnoeic! When asked to

comment on a cow's respiratory pattern, it is always worth comparing it with that of neighbouring cows.

Pathological

Respiratory rates:

- (1) Increase markedly in many diseases due to pyrexia.
- (2) Increase and become jerky in acutely painful conditions, e.g. septic feet, acute laminitis (see p. 417).
- (3) Increase in acute toxæmic conditions, e.g. summer mastitis (Chapter 24), coliform mastitis (see p. 334) and acute septic metritis (see p. 519).
- (4) Increase in metabolic disease, e.g. hypomagnesaemia (see p. 787) or acidosis (see p. 829).
- (5) Increase markedly with a much shallower thoracic excursion in conditions that prevent full pulmonary expansion, e.g. ruminal tympany, ruminal impaction and pleural effusion.
- (6) Increase in conditions in which the upper respiratory tract is blocked at least in part, e.g. malignant catarrhal fever, IBR (see p. 289) and pharyngitis.
- (7) Increase and become shallow in conditions that interfere with the function of the respiratory muscles, e.g. tetanus (see p. 733).
- (8) Increase very markedly in severe anaemic conditions, e.g. piroplasmosis (see p. 748) and haemorrhage.
- (9) Increase and become laboured in conditions that, for various reasons, decrease the amount of active lung tissue, for example:
 - (a) active pulmonary congestion prior to pneumonia (see p. 860);
 - (b) chronic venous congestion, e.g. vegetative endocarditis (see p. 726);
 - (c) acute anaphylactic conditions (see p. 927);
 - (d) 'fog fever' (acute pulmonary oedema and emphysema) (see p. 866); and
 - (e) pneumonia (see p. 864).

Acute nervous and convulsive syndromes

Nervous signs occur relatively frequently in cattle of all ages, and vary from mild signs of ataxia and head pressing on the one hand to hyperesthesia, circling, muscular tremors, aggression, collapse and convulsions, on the other.

Acute hypomagnesaemia (see p. 787)

This condition occurs in dairy cattle on heavily fertilized high-protein pasture at turn-out in spring, and again in the autumn. It also occurs in winter and early spring in beef cattle on exposed pasture. Hyperesthesia, with muscular tremors of face, eyelids, ears and

muscles of the head and neck, is followed by strabismus, generalized muscular tremors and collapse in generalized clonic convulsions.

Transit tetany

This occurs during transport, largely in preparturient cattle under stressful conditions. Signs are similar to those of hypomagnesaemia, but blood may be low both in magnesium and calcium.

Bovine spongiform encephalopathy (BSE) (see p. 909)

This shows more slowly developing hyperaesthesia with ataxia and behavioural changes prior to collapse. These changes include apprehension occasionally amounting to panic, obsessive licking of nose and lips, semaphoring of ears, refusal to pass through doorways, kicking off the milking clusters in the parlour, reflex kicking at other times and muscular tremors of neck and shoulders.

Hepatic encephalopathy

Hepatic encephalopathy, occurring as a complication of certain forms of liver disease, e.g. ragwort (see p. 945) or other forms of plant poisoning, is due to the effect upon the brain of ammonia released from the damaged liver. Signs are ataxia, dullness, slow circling, head pressing and collapse. Occasional periods of excitement are seen.

Tubercular meningitis (see pp. 251, 862)

Not to be forgotten in these days when bovine tuberculosis is on the increase, tubercular meningitis may be seen in half-grown cattle as a sequel to congenital tuberculosis or the consumption of milk from cows with mammary tuberculosis. Ataxia, stumbling, bellowing and an inco-ordinate aggression with head pressing followed by collapse were frequently seen in this condition. In the days of horned cattle, fracture of one or both horns often occurred as a result of head pressing. Blindness in one or both eyes might also occur.

Lead poisoning (see p. 944)

In the adult lead poisoning produces blindness and aimless wandering, often complicated by trauma due to collisions with walls, trees, etc. Bellowing frequently occurs.

Rape poisoning (see p. 941)

Rape poisoning may produce excitement, aggression, blindness and bellowing, a nervous syndrome, which

may be complicated by dyspnoea, haemoglobinuria and constipation.

Listeriosis (listerellosis) (see pp. 251, 904)

Listeriosis occasionally occurs in silage-fed cattle, producing an initial pyrexia followed by hyperaesthesia, a tendency to aggression, circling, head pressing, facial paralysis with drooping of one or both upper eyelids and a dry keratitis. One or both ears may also be involved, and occasionally the fifth cranial nerve as well as the seventh is affected so that chewing and swallowing are impaired and food becomes impacted in the pharynx and mouth.

Ketosis (acetonaemia) (see p. 795)

Ketosis is normally a sign of energy deficit in high-yielding dairy cattle between two and six weeks after calving. The condition may well be subclinical, doing no more than reducing yield. At its worst, it produces inappetence for concentrates, lethargy and constipation, with a normal or subnormal temperature and pulse rate.

Occasionally, a nervous form occurs producing ataxia and excitement, with marked head signs, the patient licking itself and anything within reach in an obsessive fashion, holding the bars of the shippen or parlour in its teeth and chewing to such an extent that tongue and lips may bleed forming a bloodstained froth. Ketone bodies are present at high levels in blood, milk and urine.

Occasionally, this licking frenzy may occur as a complication of milk fever. It is known as 'licking mania' and is believed to be ketotic in origin.

Acute inflammatory, exudative and/or haemorrhagic lesions in the brain

Acute inflammatory, exudative, and/or haemorrhagic lesions within the brain may cause marked excitement bordering on mania before collapse occurs. This picture may occur in anthrax (see p. 717), in which case diagnosis will be helped by generalized haemorrhage and oedema, and is also sometimes seen in malignant catarrhal fever accompanied by marked nasal and ocular discharge, with heat and pain over the sinuses of the head. Horns, if present, feel hot and in cattle with white horns they become very reddened and may, in fact, become loose. There is usually profuse diarrhoea.

Convulsive syndromes that are relatively frequent among calves

Lead poisoning (see pp. 906, 944): This is still common, causing abdominal pain, blindness, salivation and con-

vulsions, with marked bellowing and leading rapidly to death.

Magnesium tetany (see p. 255): In beef calves fed dam's milk alone without supplement magnesium tetany appears at 12–16 weeks of age, producing star gazing, stilted gait, muscular tremors and hyperesthesia leading to convulsions and death. Abdominal pain, blindness and bellowing are not features of magnesium tetany.

Gammexane (gamma BHC) poisoning (see p. 942): This condition is due to feeding milk in buckets contaminated with gammexane, after mixing insecticides, and causes very severe clonic convulsions and death.

Linseed poisoning (see p. 941): The acute dyspnoeic picture with gasping and muscular spasm that follows the feeding of warm wet linseed to calves may look much like a convulsive picture unless one is aware of the signs of prussic acid poisoning.

Muscular dystrophy (see pp. 258, 302): Calves dying of heart failure due to the cardiac form of muscular dystrophy will normally be housed calves fed only on dam's milk. Vitamin E intake may therefore be low, and at two to three months of age any sudden excitement, such as the arrival of the dam at feeding time, may trigger off a cardiac failure episode with cyanosis and anoxia which, nevertheless, may superficially resemble a convulsive syndrome.

Cerebrocortical necrosis (see p. 261): Cerebrocortical necrosis (CCN) occurring in housed or yarded calves may produce star gazing, hyperesthesia and ataxia but, occasionally, leads to a severe convulsive picture.

Introduction

Genetics in hereditary diseases corresponds to the microbiology of infections. Before Pasteur's contribution to bacteriology, infections were crudely controlled by isolation, but his work greatly improved preventive measures. Similarly, genetics greatly improves the precision in controlling hereditary diseases.

Many genetic problems are complex and exhibit a spectrum from being entirely genetic to entirely environmental. The genetic component may be divided into major gene and polygenic effects. Polygenes each have a small effect and produce continuous variation. Most disease due to major genes is, however, also influenced by minor genes and many diseases currently considered polygenic may in reality be affected by relatively few major genes.

Observations and experimentation indicate that, like the well-studied *Drosophila*, cattle carry a genetic load of deleterious major genes producing gross abnormality and of deleterious polygenes producing subfertility, increased disease susceptibility and poor physique. With current knowledge many polygenic constitutional defects can only be studied biometrically, but the final aim is to recognize individually every gene and its location on specific chromosomes. Recombinant DNA technology now makes this theoretically feasible.

Deleterious major genes

Every body system is subject to abnormal inheritance. Indeed, if, as the embryo unfolds, a defect occurs early, several subsequent systems may be involved, producing a syndrome. Environmental disturbances, or other genes sometimes inherited differently but affecting the same developmental pathway, can produce identical diseases or syndromes.

Genetic diseases affect all ages from conception to senility. Congenital malformations, observed at birth, may be genetic or due to maternal effects such as infections, nutritional deficiencies or drugs. Genes control the synthesis of proteins and, when defective, generally result in an enzyme reduction or deficiency.

Molecular genetics has developed the concept of control genes, influencing structural genes, but most genetic diseases are still thought of in terms of structural or chromosomal mutations.

Genes and disease in different species

The basic genetic physical structure of all species from worms and fruit flies to humans is similar. For example, the control homeobox genes, the molecular architects organizing other genes and switching them on and off at the correct time, are universally responsible for the division into head, thorax and abdomen. The gene that controls eye development in humans, when inserted into a fly, produces normal fly development. This common, genetic, evolutionary heritage implies that genetic malformations present in one species will often also be present in others. The luxate gene in mice, humans and Galloway cattle is an example. Further genes can be transferred from one species to another. Using transgenics, most known human genetic diseases have been transferred to mice.

Mammalian species probably have around thirty thousand genes and yet only three hundred are thought to separate mice from men. Different species are therefore likely to suffer from similar infections and infestations. Tuberculosis and the influenzas illustrate the point. Studying genetic disease similarities and dissimilarities between species constitutes comparative genomics.

Genetic epidemiology

All cattle breeds possess several genetic diseases, some common to many breeds, others specific to individual breeds. Several hundred have been described and many more are known.

Most persist at a low frequency. Some appear almost sporadically in many different herds over the years. Others are concentrated in a few herds in sudden outbreaks. Occasionally, a defect increases until individual or collective action reduces its frequency. If breeders relax, its frequency increases again, producing a cyclical pattern.

Economic loss

Calf loss may reach 20 per cent within a herd for several years, as in Galloway tibial hemimelia (p. 176). Maternal mortality may be high as in prolonged gestations in many breeds (p. 183). Difficult parturitions reduce yield and late abortions result in long dry periods. In later developing defects, e.g. hip dysplasia (p. 453), only cull value is obtained. The bull has to be replaced, the breeding programme is disrupted and pedigree sales drop. Counterselection substantially reduces economic selection.

Few breeders escape genetic disease at some time. Economic data are not available on either the direct loss due to major deleterious genes or the greater indirect loss from counterselection. Genes capable of producing defects are, however, abundant and most cattle probably carry several. Only fear of inbreeding and continual selection against defects prevents more frequent outbreaks.

Modes of inheritance

Inheritance is duplicate: each individual has two genes (units of inheritance) for a particular character or function at each locus on the chromosomes. A parent passes one on a random basis to an offspring, the other coming from the second parent. Chemically, genes are deoxyribose nucleic acid (DNA) and the fine structure of the gene has been elucidated, but for most clinical purposes the gene may still be regarded as the unit of inheritance.

Dominant genes

In regular dominance every carrier is affected. The disease is generally inherited from one parent and half its offspring are affected. A new dominant gene producing a severe effect tends to be lethal and produces single isolated effects. Surviving dominants produce relatively minor defects, e.g. notched ears in Ayrshires.

Irregular rather than regular dominants are more common in cattle. An individual may carry the gene but not manifest it due to intangible environmental effects or modifying genes (incomplete penetrance). Half of its offspring also carry the abnormal gene but a proportion similarly do not manifest it, producing irregular segregation ratios.

Hereditary ataxia (p. 178) in Aberdeen Angus illustrates this inheritance. Transmitting bulls mated to non-carrier cows leave around 25–40 per cent of calves affected instead of the expected 50 per cent, so penetrance is from 50 to 80 per cent.

Some late-developing defects, such as arthritic conditions in bulls (p. 176), could, in theory, be due to dominants. The bull would not exhibit the disease until old, and bred from, and because of culling, the relationship and ratios between bull and offspring might not be easily noticeable.

Semidominant genes

These are quite common in cattle. A single gene produces a defect but a double dose increases its severity. In the single dose, the abnormal gene converts a Kerry into the small, more desirable, Dexter, but a double dose produces monsters. Matings of Dexters produce on average 25 per cent Kerry types, 50 per cent Dexter types and 25 per cent bulldog monsters (see p. 175).

Many dwarves exhibit this inheritance. Often, as in snorter dwarves in Herefords, the carrier conformation is only slightly different from normal and slightly better (heterozygote advantage). Selection for carriers then spreads the disease. At the limits, one-quarter of the calves are defective.

Recessive genes

A single gene does not show in a carrier because of the normal dominant gene. The defect only appears with a double dose. Neither parent is affected yet the defect has come from both parents.

In carrier matings one in four of the offspring are normal (RR), two are carriers (Rr), and one will be affected (rr). This is true on average but not for individual or small groups of matings. Moreover, pure recessives giving exact ratios are rare, even with the traditional genetic model of *Drosophila*.

The abnormal gene is usually considered neutral in carriers but in some cases, probably more than is currently understood, it may be detected biochemically. Carrier recognition is a major field of genetics and should always be sought in major recessive outbreaks in cattle.

Recessive defects may also have reduced penetrance. Since the frequency of recessive homozygotes is generally low, if further reduced by incomplete penetrance, inheritance is best described simply as irregular, and calculating the penetrance of a recessive is generally unprofitable.

Recessive defects often appear following line breeding. A breeder obtaining good daughters from one bull is often tempted to use related bulls on these. These related males may carry the same recessive gene derived from a common ancestor. Some second matings are thus between carriers, and defects appear. The pedigrees of affected animals often reveal common ancestors within a few generations.

Sex-limited and sex-linked genes

Many cattle diseases are limited to one sex, for example, testicular hypoplasia (p. 182). The other sex, however, plays an equal role in inheritance and the defective genes are in the non-sex autosomes. This inheritance must be distinguished from sex-linked recessive inheritance where the abnormal gene is carried on the X chromosome and a carrier cow transmits the disease to half her bull calves, and leaves half her heifer calves as carriers; a cow with a double dose of the harmful gene would show the disease. Since sex-linked recessives are not transmitted by unaffected bulls, they are rare in cattle.

Multiple alleles

Each locus on the chromosome may have not just two but several genes present. Various combinations of these genes may produce a gradation of severity of a condition. For example, a series of multiple alleles reducing melanism successively dilutes coat colour from normal agouti to albinism. Multiple alleles may contribute to the variation in clinical expression of many diseases. They are also a common form of inheritance in many disease-related biochemical variants.

Irregular inheritance

Many, indeed most, genetic diseases of cattle are inherited irregularly. They do not provide simple genetic ratios and are characterized by sporadic incidence and occasional concentration within families. Arthrogryposis in Charolais characterized by calves with twisted limbs (see p. 177), cleft palates and a twisted spine, illustrates the problem. More than half of all artificial insemination (AI) bulls produce a few defective calves but a few (about 5 per cent) leave around five per cent of affected calves.

Cryptorchids provide another example of non-Mendelian inheritance. Cryptorchidism is frequently sporadic (p. 182). Most extensively used sires leave some cryptorchids. Many cryptorchids leave mainly normal offspring and most cryptorchids have normal parents. Occasionally, however, affected or normal bulls sire a higher proportion of affected offspring than average. Their incidence also increases markedly on inbreeding. Cryptorchidism thus has a genetic component and probably both male and female contribute to its occurrence.

Such defects result from unknown environmental factors and genetic susceptibility, either recessives or dominants, exhibiting a very sensitive threshold of manifestation.

Genetic polymorphism

This is a discontinuous variation which persists in a population apparently more or less at random. Cattle blood groups are an obvious example. Their relative proportions are not maintained by a balance between mutation increasing the defect and selection removing genes in affected animals. Most, however, will probably be ultimately shown to affect fitness. Many may be relicts of resistance mechanisms to much earlier plagues.

Chromosomal abnormalities

Structural chromosomal mutations, such as duplications, deficiencies, inversions, translocations (p. 184) and alter-

ations in chromosomal number, are not uncommon in cattle. Large chromosomal breakages produce complete sterility and small breakages subfertility. Both are inherited like irregular dominants. Bulls with low conception rates due to minor chromosomal abnormalities pass the defect directly to their sons.

Many chromosomal defects, often difficult to detect, are probably present in early embryos, and account for a considerable proportion of early embryonic mortality and some reduction in conception rate. The uterus, however, acts as a clearing house for such defects and few progress to birth.

Epidemiology and control

Breeds are generally organized hierarchically. A few top herds supply bulls to less influential breeders who in turn supply commercial producers. If a harmful gene spreads in the top strata these bulls spread carriers through the breed. Similarly, if the defect is eliminated from the top herds then sires free from the defective gene slowly reduce the defect in the other herds. The origin and increase of a harmful mutant in the top herds is probably due to mutation and genetic drift.

Control is the sum of the control efforts of individual breeders. Affected herds select against the gene, and breeders soon learn from which herds to reduce their purchases. The distribution of non-carrier bulls reduces the incidence.

The desirability of control will vary with the severity and frequency of the defect. A defect causing dystokia justifies considerable counterselection, but a minor defect such as colobomata very little. Strong selection against a defect may also relax selection for important economic characters.

Controlling dominants

A regular dominant spreads directly down through a breed but such direct transmission is rare in cattle except for minor defects such as some forms of polydactyly. If required, culling all affected animals eliminates the defective gene.

Dominants exhibiting incomplete penetrance, however, commonly spread directly. The lower the penetrance, the greater the likelihood of this occurring. If penetrance is high a few offspring will pinpoint a carrier parent and transmitters can be culled. If penetrance is low, control is more difficult, since many offspring are required to detect carriers.

Controlling recessives

At breed level, epidemiology and control of recessive genes will depend on the gene frequency. This is simply

the proportion of genes of a particular type in the population. Since each animal has two of these genes, the proportion of carriers is approximately twice the gene frequency, and the incidence of affected individuals is the square of the gene frequency. Thus, if the incidence of a recessive defect is 1 per cent, the gene frequency is 10 per cent and the proportion of carriers about 20 per cent. Even a low incidence of defects thus implies large numbers of carriers.

Moreover, this gene frequency will be the average for the whole breed and much higher frequencies will occur in farms that have used carrier males recently. Thus the outbreaks and frequencies will be patchy with some farms heavily affected and others with few or no defects. This often renders measurement of the incidence of a defect in a breed difficult. A useful guide is that a defect attracts notice when around 1 per cent of calves are affected in the breed so that about 18–20 per cent of animals are carriers.

Reduction in frequency can be rapid if the initial frequency is high but is slower as the frequency decreases or if the initial frequency is low. Thus breeders can rapidly reduce a recessive defect at high levels but eliminating it completely is very difficult.

The main difficulty in selecting against a recessive is the large number of carriers that cannot be recognized on visual inspection. However, if all bulls and cows producing defects are culled, experience shows the incidence of the defect soon drops to acceptable levels.

Controlling an irregularly inherited defect

In a disease such as arthrogryposis (p. 177) all bulls leaving defects cannot be culled but only bulls transmitting most frequently. Similarly, in defects such as cryptorchidism, control is based on not using affected animals or close relatives and this is effective in maintaining a low frequency.

Irregular defects such as cryptorchidism (p. 182) would only increase if affected animals were continuously used. Why they persist at a low level despite generations of natural and artificial selection is unknown although carrier advantage may be suspected.

Genes exhibiting good and bad effects

Some pleiotropic genes or closely linked gene complexes produce both desirable and undesirable effects and selection for the good effects may spread the gene. For example, some genes producing desirable coat colours also cause infertility. Selection for the coat colour may thus spread infertility or maintain it at a low level, as in white heifer disease (p. 183).

A gene may be beneficial when single but harmful in a double dose as in selection for the desirable conformation in American beef breeds resulting in unconscious selection for carriers.

Inheritance involving advantageous and disadvantageous effects may be much more common in cattle than suspected.

Assessing controls

Excessive controls, such as compulsory recording of all abnormalities, are sometimes advocated. Controls are essential, particularly where a defect has become a problem, but they should be kept in proportion. They should be kept to the minimum level necessary, so that selection for efficient production can proceed as rapidly as possible.

Investigating genetic diseases

Inheritance may be suspected when other factors are excluded, the defect runs in families and previous reports implicate genetics. Since environmental defects may simulate genetic conditions and similar clinical defects have different genetic causes inheritance in the affected herd should be investigated.

Inheritance exists when one bull has sired all the defects and another contemporary bull has left none when mated to similar females in a similar environment. However, such controls are often not available and a properly designed experiment may be necessary.

If line breeding is being practised a new defect is probably genetic. If recessive, both sexes are affected equally and the incidence within a herd seldom rises above 15–20 per cent. The disease may disappear as unaffected males are brought in. Since environmental changes are often made simultaneously confusion may arise.

Simple recessive defects resemble each other fairly closely – one dropsical calf tends to be similar to another. Where considerable variation in clinical appearance or age of onset is present a simple recessive is unlikely.

In cattle, and especially in a small herd, establishing the exact inheritance may be difficult. Often all that can be said is that the disease runs in families and comes from either one parent only or, alternatively, the genetic factors are present in both parents.

Breed differences are also suggestive of genetic disease but not conclusive because of possible confounding between breed and environment. This is particularly true where infections or mineral deficiencies are involved.

Pedigree analysis

A few generations intensively studied are better than long pedigrees. A list of normal and affected animals born during and immediately prior to the outbreak, their sex, sire, dam and maternal grandsire is generally adequate. This list will indicate if simple genetic ratios exist.

With recessives one out of four offspring of carriers are affected, but in practice the common ratio obtained is one in eight. This occurs when two carrier males are used successively. The first carrier leaves on average half of his daughters carriers (as well as half his sons). In mating the second carrier bull to the carrier daughters, one out of the four offspring are defective. About one in two × one in four, i.e. one in eight of the second bull's offspring are defective.

Care has to be taken with pedigrees since as many as 10 per cent may be inaccurate. Few pedigree investigations fail to produce anomalous cases.

DNA analysis

Almost weekly a new gene for a human disease, located by deciphering the genome, is recorded and some breast cancers are already subject to routine screening, particularly in patients with a family history. Although mapping the genome in cattle is being pursued in some laboratories, financial restraints limit progress. Moreover, reliable results require great technical skill to narrow down the suspected DNA sequences, which may involve several hundred genes, to the required gene and to assure the specific gene is involved. Until more progress is made reliance for diagnosis and control in livestock has to be placed on the more standard but still relevant procedures such as pedigree analysis outlined previously.

Predicting future diseases seems to cause substantial ethical and insurance problems in humans, but in livestock, while similar problems will arise, they are relatively trivial. In contrast, predicting future diseases in livestock is one major way ahead in reducing disease incidence.

Differentiating genetic and infectious diseases

Genetic and infectious diseases may, on occasion, be confused. Their epidemiology can be similar, with deleterious genes or infectious agents radiating out from heavily diseased foci. Moreover, many infectious diseases through close contact are familial and genetic resistance may be present, enhancing the familial aspects. Pathology may even be similar, since an invading organism can affect the same developmental

pathway as a deleterious gene. The crucial distinctions are the isolation of an infectious agent and experimental transmission of the disease or the establishment of fairly clearcut genetic ratios, preferably the former.

Genetic counselling

In the event of a genetic disease a breeder should be advised to change the bull immediately, thus eliminating the appearance of the defect and reducing the carrier incidence in offspring. Continuous use of non-carrier bulls gradually reduces the number of carriers.

If a carrier male has had only restricted use all his daughters should be culled. However, where the herd has many carrier females, culling should be gradual to avoid decimating the herd. Known carriers and low-producing females should be culled first. Where the abnormal gene occurs in a particularly good strain its frequency should be reduced rather slowly so as to preserve the strain intact, i.e. some defects should be suffered to maintain production qualities.

In a serious outbreak a breeder might test a male on about 20 of its daughters or half sisters, or on 10 known carrier females. Generally, however, test mating is expensive and best avoided.

Control of defects inherited as irregular dominants or in a non-Mendelian fashion, follows the same principles. The bull should be changed and transmitting females culled.

When a defect rises in frequency, the breed society should seek veterinary advice. After ensuring that the disease is recognizable, both clinically and pathologically, its mode of inheritance and methods of control are then explained to breeders so they can counterselect most effectively. Prenatal diagnosis and selective abortion, although feasible, should only have limited application in valuable animals in cattle practice.

Genetic defects and artificial insemination (see Chapter 39)

Artificial insemination centres seldom suffer outbreaks of genetic disease because they avoid inbreeding, particularly in the larger units, and rapidly withdraw bulls transmitting defects. Although most bulls carry several defective genes, few leave many defects in their progeny since their cow population is unlikely to have a high gene frequency for the same defect. While a carrier bull leaves half his daughters carriers, each time a non-carrier is used on the succeeding daughter's generations, the carrier incidence is halved.

Automatically eliminating bulls leaving three or so affected offspring is rather rigid. Selection against bulls leaving calves causing maternal mortality, late developing defects, or leaving three affected calves in their first 100 offspring should be more intense than against bulls producing unimportant defects, or producing a few abnormalities among several thousand normal calves. Again, a few defects among several thousand normal calves is tolerable from a bull transmitting efficient production.

When an undesirable gene is increasing, an AI centre should buy bulls from sources thought to be incidence free. Even with limited numbers of offspring and a low gene frequency, carrier bulls should soon be detected. For a serious condition, bulls might be progeny tested on known carrier females.

Testing all bulls on their daughters would test for any deleterious gene. Since most bulls probably carry several such genes, the bulls available would be limited. Where older bulls are being used, the test might be of some value, although low production in the inbred daughters would be a disadvantage.

Generally, AI, because of its scientific basis and monitoring procedures, is an agent for reducing rather than increasing defects.

Genetic defects and egg transplanting

Routine egg transfer permits intense selection among females and potentially concentrates even further the genetic base. It thus enhances the risk of spreading genetic defects. Provided proper surveillance is instituted and donors transmitting defects rapidly withdrawn, like AI, it should however decrease rather than increase genetic disease.

Polygenic deleterious genes

There is very marked individual variation in fertility, in susceptibility to infections and metabolic diseases and in conformation and physique. The genetic part of continuous variation is considered to be due to many additive genes, each with a small effect. They produce a bell-shaped distribution whose mean can be shifted by selection.

Multifactorial inheritance, particularly from field data, is measured by a heritability estimate – the ratio of genetic influences to all influences (genetic and environmental). Heritability estimates tend to vary widely according to the method of calculation and the particular field data chosen and are commonly averaged to obtain a generalized more reliable estimate. Individual estimates have to be treated with great

caution, especially when used to predict rates of progress under selection. Strictly speaking they apply only to the population from which they are obtained and their predictive value is limited to a few generations at most.

Sterility and infertility genes

Infertility genetics is little understood. Although there is substantial automatic natural selection present for fertility, the marked decline in fertility with inbreeding and its restoration on crossbreeding demonstrates the existence of many infertility and subfertility genes.

Difficulties and inaccuracies in statistically measuring fertility, and the different indices used, have produced very different estimates of its heritability. Most studies suggest the heritability of pregnancy rate in cattle is low, almost zero. Some based on sire/son comparisons, however, suggest figures as high as 40 per cent.

Intense selection for yield is thought by some workers to lower fertility. It can be argued that a few per cent decrease in pregnancy rate might be overestimated in comparison with high yield. Lengthening calving intervals, however, markedly reduce profitability and selection for fertility should remain a high priority with some culling of sons of bulls with low pregnancy rate.

Semen volumes and sperm numbers, concentration, motility and morphology show marked age, breed, weight and individual variation (see p. 604). Semen characteristics are considered to be moderately heritable (15–20 per cent) and should respond to selection to improve semen quality but progress would be slow. The correlation between sperm characteristics and fertility is, however, not entirely clear and some semen standards may be unnecessarily high, leading to reduced selection for other characters. Specific sperm defects which are common, e.g. knobbed sperm, are often due to single genes and should be strongly selected against. Testicular size and conformation are also influenced considerably by genes. The difference in libido between beef and dairy bulls is sufficient to indicate the strong genetic influence in libido.

At the herd level most infertility problems are transient and non-genetic. Similarly, repeat breeding in individual cows is usually of environmental or management origins. Oestrous expression, however, plus time of onset of post partum cyclicity, probably has a considerable genetic component associated with hormonal differences.

Calving difficulties

Genetic selection for yield and growth rate increases body size and larger cows inevitably have increased

calving problems. Friesians, for example, have more difficulties than Jerseys or Ayrshires. At the extreme limit in pure, large, continental breeds cows can only produce a few calves before becoming sterile. Counterselection is impossible as long as growth rate is given priority and the only remedy is Caesarean section.

Susceptibility and resistance genes

Susceptibility and resistance genes are widespread and genetic variation in disease resistance has always been demonstrated when adequately sought. Animals relatively resistant to one disease are often susceptible to another. Resistance is sometimes polygenic but, with increasing research, it has often been found to be dependent on relatively few genes.

In natural epidemics an invading organism frequently spreads rapidly causing heavy mortality. Some genetically resistant animals almost invariably survive and subsequently multiply. After initial oscillations, host and parasite settle down to coexist. Initially acute diseases tend to become chronic as genetic immunity develops.

Before control, selection for resistance genes must have been intense. This effect is still obvious in tropical countries, for example, where Zebus are markedly more resistant to local disease than exotic breeds. In grading up by crossbreeding, a proportion of Zebu genes has to be retained and indeed in high-disease areas improvement of indigenous cattle may be preferable. For many large countries resistance genes dictate a stratified breeding programme from pure exotics to pure indigenous cattle. In tropical countries genotype–environment interactions are of prime significance.

In European cattle the most obvious example of genetic resistance is in mastitis. There are marked breed differences. Heritability estimates vary enormously but are probably around 10–15 per cent. Daughters of infected dams are more susceptible and some bulls transmit substantially more mastitis than others. In one extensive survey most mastitis cases were daughters of relatively few AI sires.

Selection to raise the frequency of mastitis-resistance genes, even with AI, although feasible, would be difficult. Many daughters, perhaps 250, would be required to classify the bull. Currently sires' daughters are classified mainly on first lactation yield when mastitis is less frequent and the effect of AI on mastitis incidence is probably neutral. It is dangerous to assume that selection for high heifer yield automatically implies selection for health, as many diseases occur in later lactations.

Calf scours and pneumonia also have a genetic component, associated with colostral antibody. This varies

genetically, as does the vitality of the calf, influencing its suckling ability.

BSE is another infectious disease where mouse research published and some unpublished research on scrapie and BSE's epidemiology suggest there are strong genetic and familial factors operating. Research has been hindered by the need to prevent its spread to humans. Since safety in humans can only be guaranteed by its elimination in cattle, the genetic factors involved justify much further research.

There are marked species and individual differences in the severity of foot-and-mouth disease and selection could probably enforce this resistance, but vaccination would seem the best approach in such an infectious, rapidly spreading disease involving many viral strains. Isolating the experimental animals could also prove a major, although not insuperable, problem.

Parasitic infections, however, are emerging as a very possible candidate for scientific counterselection. They tend to be chronic, natural selection resistance already exists and regular treatment is expensive. This field is likely to develop, perhaps particularly in tropical livestock development centres (LDCs).

The greatest progress in artificially selecting for disease resistance depends on detecting biochemically resistant and susceptible animals. Considerable progress is being made on this front, centring around immune response genes. These control the ability of the animal to produce antibody against certain specific antigens. The *Ir* genes are on the part of the chromosome that contains the genes controlling the acceptance of tissue grafts, the histocompatibility genes. These latter can be detected serologically and both *Ir* genes and histocompatibility genes form a multiple allelic series.

As knowledge of this gene complex increases and the genetic basis of immunity is understood in finer detail, positive selection for resistance to disease may become more feasible. Artificial insemination, egg transplanting and, ultimately, gene transfer are the obvious instruments.

Selection for disease resistance is likely to be profitable, however, only where vaccines are not available, although in some cases genetically more resistant animals respond more effectively to vaccines. Both approaches may in some circumstances be complementary.

Metabolic disease genetics

Individual variation in susceptibility to metabolic disease is well demonstrated by milk fever. It has a heritability estimate of around 20–25 per cent and a repeatability of about 20 per cent, indicating how sus-

ceptible cows can be. There are also breed variations, Channel Island breeds being particularly liable. Breed variation in hypomagnesaemia and acetonaemia also exists.

The anaemia common in high-yielding cows provides one of the best experimental examples of the strength of biochemical individuality. In one unpublished twin study, despite marked prolonged nutritional and weight differences, haemoglobin, red blood cells, packed cell volumes and mean haemoglobin concentrations were all so highly determined by individuality that pair members closely resembled each other in blood pattern, despite the nutritional differences within and between pairs. Individual differences overshadowed the nutritional effect.

Such individual differences indicate the need for caution in interpreting disease status from blood analysis in individuals. Because of individual variation normality is difficult to define. A single animal with a low haemoglobin may not be anaemic but merely exhibiting a normally determined low value. Blood tests are generally most valuable at the herd level in preventive medicine.

Selection for increasing yields is putting dairy cows under increasing stress and metabolic diseases are steadily increasing in developed countries. Both milk fever and acetonaemia are basically diseases of high yielders and almost unknown in less-developed countries.

Disease genetics and cattle improvement schemes

These are essentially interwoven. Improvement schemes carry risks as well as rewards. Those based on AI and egg transplants steadily to improve rates of progress involve the risk of inbreeding depression.

Inbreeding depression

Since relatively few males are required to avoid inbreeding, in theory it presents little problem in improvement schemes.

As technology reduces bull numbers and AI sires are followed by their sons more care will be necessary. Using a few score bulls for several million cows should not cause serious inbreeding provided sons are not chosen repeatedly from only the very best sires, causing an undue concentration on very few sires. However, after many decades, such a system could cause a serious accumulation of inbreeding effects. Remedies would include importations, using stored semen or splitting the breed into small units and exchanging bulls. Simi-

larly, with egg transplanting overconcentration on a few mothers has to be avoided.

In practice, however, more inbreeding may be occurring than is generally suspected and with inadequate recording the risks may be being underestimated.

Intense single-character selection

Single-character intense selection in all species reduces fertility and frequently produces other undesirable correlated responses. The balanced homeostasis of the animal is upset. At the extreme it often uncovers major defects, e.g. pygmies in downward selection for weight.

Intense selection for yield in dairy cattle increases mastitis, udder oedema and metabolic diseases. The genetic, early, high-peak yields in dairy cows, much higher than in any other species, induces stress. High yielders also suffer increased digestive disorders, foot problems and calving difficulties. High yielders, although more profitable, thus require expensive health care, particularly to maintain mammary function.

The genetic reduction in fertility associated with high yield is probably sufficiently serious to reassess current selection programmes in dairy cattle. Increased efficiency of production, rather than yield alone, should be the objective.

Balanced selection

In future, greater emphasis is likely to be placed on balanced selection. Factors such as growth rate and mature size, body conformation and composition, food intake and efficiency and perinatal mortality and disease resistance are likely to be built into selection indices. Selection will probably also occur under controlled conditions as well as using field data. The aim will be better balanced and healthier animals and hence more profitable dairy cattle.

Positive selection for health

Selection and longevity in dairy cows

The very short lifespan of dairy cows (and bulls) is probably due to poor management and particularly inadequate fertility control. Genetic selection for health and longevity could, however, contribute substantially to better health. In livestock, positive eugenics is possible.

Longevity has a considerable genetic component independent of yield. The heritability of survival to the sixth lactation may be around 20 per cent. Theoretically,

selection for longevity at the end of the first lactation is possible but would require too many daughters and measurements to be economically feasible. As biochemical individuality is explored in greater depth it may become possible.

Bull mothers

A simple approach to improving health, and longevity is to place a much greater emphasis on older bull mothers, cows that have successfully over five or six lactations resisted mastitis, metabolic disease and infertility. This approach is now being implemented.

Crossbreeding

Crossbreeding schemes, even those where the primary objective is blending different maternal and paternal characters, greatly improve health and vigour.

The simplest explanation of hybrid vigour is that the load of recessive deleterious genes, which can be exposed on inbreeding, are covered up by normal alleles on crossbreeding. Crossbreeding is extensively used in beef production, particularly where hardiness is vital, as in exposed hill areas.

Systematic crossbreeding schemes are being used in some Scandinavian, eastern European and tropical countries but generally have been little developed in western Europe.

The best schemes of cattle improvement, maximizing both health and efficiency, are probably based on combining crossbreeding and selection and using selection indices. Dairy cattle improvement is only in its infancy and with increasing research and development such schemes are likely to develop in the West.

Health recording schemes

Another approach to genetically improving health is a greater emphasis on health recording schemes. Currently, the most effective of these are devoted to improving fertility control, particularly regular calving and improved heat detection and, to a lesser extent, early detection of metabolic breakdown. With improved design, however, they are likely to detect bulls transmitting undesirable qualities such as mastitis susceptibility and poor heat expression.

Recent advances

The full significance and utility of the two fundamental genetic achievements of the last decade, the human

genome project and cloning, are only now being explored, but the genetic revolution will have a major impact.

Cloning

Livestock cloning, when a relatively reliable success rate is achieved, should greatly advance medical science, enabling the rapid build-up of flocks and herds containing specific genes for generating pharmaceutical products, as in various Roslin Institute research projects. Investigation of the current reproductive and malformation difficulties should also enhance our understanding of cell differentiation, and cell multiplication and division, with implications for genetic diseases and even ageing and cancer.

Commercial cloning to achieve rapid once and for all improvement may require greater caution. Widespread use of identical animals could leave them exposed to new, rapidly spreading, emerging diseases and without biological diversity, whole populations could be affected. The Irish potato famine was basically caused by cloned potatoes. Moreover, the aim is to improve animals every generation rather than stabilize current populations with prize-winning livestock. In certain circumstances, however, where scientifically improved animals have been developed, limited commercial cloning could prove worthwhile. Cloning valuable animals before they succumb to infertility or disease could be regarded as dysgenic.

One underestimated benefit would lie in exploring nature and nurture. Currently, field heritability studies tend to produce lower values than twin studies, and the problems of nature and nurture are far from being satisfactorily resolved. In twin research the existence of only two identical twins reduces replication and requires very complex experimental designs. Clones would greatly simplify this. In field studies the introduction of clones into different herds and environments would also greatly improve the measure of genetic variation. Apart from specific genetic studies, readily available clones would improve nutritional and disease research, raising the whole standard of cattle research, as pure lines have done in mice.

The genomics revolution

The most significant result from the human genome project is a reduction in the gene count from an estimated hundred thousand or so to nearer thirty to forty thousand. Since there are probably hundreds of thousands of proteins, the one gene, one enzyme hypothesis

is, therefore, untenable and each gene must encode for several proteins – estimates vary from the tens to several hundreds.

This conclusion leads to a switch in emphasis from genomics to proteomics as the fundamental key to understanding the body and attempts are now being made to produce a comprehensive catalogue and map of all the proteins. This will be very difficult since proteins are complex, may interact with other proteins, once created may be modified and can be transient.

This changing emphasis is having a major effect on drug development and therapy. Although in a fluid state, the new concepts are already tending to emphasize the importance of individual drug treatment, and helping to explain why different drugs act differently in different patients and the occasional side-effects in block busters and vaccines. The key seems to lie in genetic individuality producing genetic variation in individual proteins and hence different responses to different drugs. Medicine, at present, could be regarded as a diverse collection of symptoms and empirical treatments, but is slowly being converted into a science. The day when each valuable animal has its own genetic profile and can be treated accordingly, however, is a very long way off, but that is the direction in which genomics and proteomics seem to be leading pharmacogenetics.

Not only some mammals but many infectious agents, such as the cholera bacterium, have been successfully sequenced, work which should lead to more effective vaccines. Likewise sequencing biting insects such as the mosquito should ultimately lead to better insecticides. With infectious agents and parasites evolving rapidly to overcome current therapies, sequencing should provide a better understanding of the resistance mechanisms they are developing (they are fairly well understood in bacteria already) and this in turn should help provide better control systems.

In evolutionary terms the reduction in gene numbers seems to imply that the vast variation in life forms, including the domestic species and their parasites, may be due more to control genes, switching genes on and off, rather than a large number of genes producing different proteins.

In animal breeding terms it is difficult to overestimate the significance of genomics and proteomics. Currently improvement is largely based on biometrics, particularly heritabilities. In the future this is likely to be supplemented and possibly finally replaced by screening the DNA and looking for genes, particularly major genes, which influence production and disease. In the even longer term such genes are likely to be inserted into the genotype – after all, all genes in different species can be regarded as part of one vast

network – and the future of livestock improvement lies in genetic engineering.

Perhaps after a long latent period, during which the immense successes of microbiology has dominated medicine, the old-fashioned subject of medical diathesis or constitutional medicine, rejuvenated by Mendelism, is now reasserting itself.

Conclusions

Thus in cattle improvement, the future is likely to see a greater emphasis on selection for survival and efficiency as well as production, and genetics will become a core subject in cattle preventive medicine. With gene transfer enabling resistance genes to be built in to cattle, a new Pasteurian age is developing and the prospects seem limitless.

Introduction

Most farmers will, at times, have calves that show defects of a varying degree at birth. Such defects, although congenital, may be due to genetic or environmental factors or their interaction. The overall level of incidence of congenital defects ranges considerably in surveys from 0.2 to 3.0 per cent. It should be remembered that genetic defects are not always apparent at birth. The incidence of all specific defects is very small, but detailed investigation of any anatomical system will often show slight deviations from the norm. Genetic causes can be inherited on a dominant, recessive or additive basis and often they are influenced by the environment. In many cases all that can be said about a particular condition is that it is familial. Factors connected with the environment are many-fold. Other problems are the result of bacterial or viral infections, nutritional deficiencies, chemical poisoning and physical insults. If the condition occurs in the early stages following fertilization (i.e. up to day 14 after fertilization), death of the embryo occurs and it is resorbed. During the embryo and organogenesis stage (15–44 days after fertilization) the effect is variable. In many cases there is death of the embryo with resorption or abortion, whereas in others the embryo remains viable and there is congenital absence, deficiency or disturbance in function. Once the fetus stage is reached (day 45 to birth) then again death can occur resulting, if early, in resorption, otherwise mummification or abortion and, if later, in stillbirth. In other cases the fetus survives and may be normal or suffer growth retardation, reduction in size or organic function, or the animal may become weak.

It is often difficult to diagnose the problem and to decide whether a congenital condition is inherited or not, and if it is, whether control of the condition is necessary. Often it is hard to ascertain the frequency of a problem, as farmers are reluctant to admit its presence and also how frequently it is occurring. In many cases

with large herds and limited labour, abortions or deformities are often missed. When the condition is present in the offspring of bulls used in artificial insemination the frequency may again be hard to determine because of the disinclination of farmers to report the problem. An indication as to whether or not a problem is of genetic origin may be obtained from the type of defect apparent and the knowledge already available about the condition. Other evidence may be a sudden outbreak of a defect following the use of a new sire and which only affects calves of his parentage. In some cases there is evidence of a gradually increasing number of similar abnormalities that occur over a number of years. Following an investigation, it may be shown that a defect is confined to a particular family within a herd or to the progeny of certain dams.

In most cases the history will show a much lower incidence of any inherited defect in crossbred animals than in pedigree ones. Some genetic problems are noted as being very common in certain breeds or families within the breed and this aids a tentative diagnosis of the condition, e.g. hip dysplasia in Herefords (see p. 453). The history should be indicative of a relationship between the condition and mating systems rather than the time of year, disease incidents, etc. The reuse of the same bull in repeat sire-dam matings may also indicate the inherited nature of the condition and its mode of inheritance, as also can sire-daughter or sire-half-sister matings, but these involve a considerable period of time before any mode of inheritance can be suggested or confirmed.

Some of the more common conditions are described under generalized headings of the systems involved.

Cardiovascular system

Ectopia cordis

This is an uncommon congenital abnormality where the heart is present outside the thoracic cavity. The cause is unknown. The heart is usually positioned in the region of the lower neck and can be seen pulsating when some distance from the calf. Some cases are displaced into the abdominal cavity.

Ventricular septal defects

These are the most common form of congenital heart lesion in calves. They vary in their size, which determines the severity of the signs and their location, but they are often high on the septum. In some cases the animal survives for many years with nothing untoward being suspected. The defects can be single or combined with abnormalities of the blood vessels. The defect allows blood to pass from the left to the right ventricle.

The signs mainly depend on the size of the defect. If it is small the animal may grow normally, have a normal exercise tolerance and a normal life expectancy. Such cases are usually only detected when the animal is examined for some other reason. Occasionally, calves will suddenly drop dead with no premonitory signs at a few weeks to several months of age. In severe cases there will be some stunting in growth, decreased exercise tolerance and a varying degree of listlessness. Other calves will remain recumbent at birth and die soon afterwards. In the uncomplicated case there is no cyanosis, but on auscultation all animals have a systolic murmur that is very obvious and can be heard on both sides over a wide area of the chest. At necropsy there is an interventricular defect and this is often just ventral to the aorta. In some cases there may be an enlarged liver.

Multiple cardiac lesions

There are many of these but all tend to be uncommon. In most cases the animal is born dead, weak or stunted. Often other congenital defects are also exhibited. Tetralogy of Fallot is probably the most common and involves a ventricular septal defect with pulmonary stenosis, a dextroposed aorta and a secondary ventricular hypertrophy. Eisenmenger's syndrome is relatively similar to tetralogy of Fallot with a ventricular septal defect, a dextroposed aorta but there is no pulmonary stenosis. Other multiple cardiac lesions include a double aortic arch and a double outlet to the right ventricle.

The affected animals usually die. Those that survive show a very poor growth rate, severe dyspnoea when exercised, and lassitude. Cyanosis is present in many cases, particularly after exercise, although in Eisenmenger's syndrome, cyanosis may not develop until late. Auscultation of the heart will reveal a murmur.

Patent foramen ovale

This normally takes about seven to ten days to close completely in the normal calf. Patency is relatively common. In many cases there is little blood transport, but if it does occur it is usually from left to right and so there is normally no cyanosis. Hypertrophy of the right ventricle may sometimes arise. There are usually no signs unless other defects are present. Cyanosis is absent unless there is subsequent right ventricular hypertrophy.

Patent ductus arteriosus

Although patent during intra-uterine life, the ductus arteriosus closes within a day of birth and at least by

five days old. The condition is relatively common and the cause is unknown. Blood passes from the aorta to the pulmonary artery. Signs are often limited other than poor exercise tolerance and lassitude. There is no cyanosis, but there is a continuous murmur often known as a machinery murmur as it increases and decreases with each cardiac cycle. The condition can be corrected surgically.

Aortic stenosis

This is very uncommon and is just below or at the aortic semilunar valves' attachments. Some animals show few signs, others show dyspnoea. There is a systolic murmur. Death can occur suddenly with respiratory distress.

Persistence of the right-sided aortic arch

This is rare, but when it occurs the oesophagus is encircled by blood vessels, causing constriction. There is usually regurgitation of milk after feeding and this normally starts at birth or soon afterwards.

Persistent truncus arteriosus

This condition occurs very rarely.

Abnormal origin of the carotid arteries

This may affect one or both arteries, which may derive from the pulmonary artery instead of the aorta. This results in weakness of the myocardium in the ventricle of the affected side due to anoxia, and leads to congestive heart failure.

Aortic coarctation

This is a constriction at the site of entry of the ductus arteriosus and results in a systolic murmur and poor pulse.

Cardiomyopathy

A condition often with polydipsia, hyperpnoea and dyspnoea for one to seven days before death has been described in Australian Poll Hereford calves with a tight curly hair coat. At post-mortem examination there is vascular congestion of the liver, spleen and lung with diffuse streaking of the entire myocardium. It appears to be a genetic condition, possibly associated with a simple autosomal recessive mode of inheritance.

Blood disorders

Factor XI deficiency

The main congenital coagulation deficiency reported in cattle involves factor XI (plasma thromboplastin antecedent). It has been reported in North America and recently in Britain. It has been shown to be present in some Holstein–Friesian breed lines and is transmitted as an autosomal recessive trait. Factor XI protein is concerned at an early stage of the contact or intrinsic activation pathway of blood coagulation. This pathway converges with the extrinsic one due to tissue damage, resulting in the activation of factor X. Following activation the factor converts prothrombin to thrombin, which in turn changes soluble fibrinogen to an insoluble fibrin clot. Bleeding problems can vary from minor to profuse with haematuria and post-injection haemorrhage.

Bovine leucocyte adhesion deficiency (BLAD)

This is a genetic problem caused by an autosomal recessive gene type of inheritance in Holstein cattle which came into prominence in the 1990s. It is characterized by a deficiency in the Mac-1 (CD11b/CD1S) cell surface receptor of the integrin family. The lack of adhesion results in an inability to combat disease effectively. The problem is seen in certain genetic lines of Holstein bulls, some of which have been very widely used by AI for their increased milk production characteristics.

Animals involved are not easy to detect initially as they are more susceptible to infections and so suffer more enteric and respiratory problems and growth rates are poor. There is usually oral ulceration, which is recurrent, and on post-mortem examination some have peritonitis. Most animals die between two and about seven months old, although some have survived longer. Many of the signs are similar to BVD infection, BIV, mineral deficiencies and parasitic problems including coccidiosis, cryptosporidiosis and parasitic gastroenteritis. Diagnosis is often difficult, but if BVD is eliminated and the animal has a marked leucocytosis it is likely to be the cause. This can be confirmed by laboratory examination of blood to show the presence of the genetic defect and looking at the pedigree to determine the presence of certain affected bulls. Many reputable cattle semen companies will indicate the presence of the BLAD factor within their bulls. Treatment has been successfully undertaken by bone marrow transplant but is not recommended as it is helping to perpetuate a genetic defect. If a mating does produce an affected calf

then it should not be repeated and bulls should be used which do not carry the BLAD gene.

Simmental hereditary thrombopathy

A bleeding disorder resulting from impaired aggregation of platelets has been diagnosed in Simmental-sired cattle. The signs may not be manifested early in life, although later it causes a prolonged bleeding time after even minor trauma. These animals become severely debilitated or die. The problem has mainly been recorded in Canada, where it is recorded sporadically in the cattle population. The data available suggest that the inheritance is the result of the inheritance of at least two genes rather than a simple Mendelian recessive.

Skeletal defects

Achondroplastic calves (bulldog calves, chondrodystrophy fetalis)

Although it has been associated with the Dexter breed, it can also occur in the Friesian, Hereford, Jersey and Guernsey. It is basically a defect of interstitial growth. The condition is mainly a recessive gene except that it is dominant in the Jersey. When Dexters are mated together 25 per cent of the offspring are bulldogs, 50 per cent are Dexters and 25 per cent are Kerry-type Dexters with long legs. Most calves are aborted at about seven months' gestation. The calves usually have very short limbs, flattened skulls with a foreshortened face and short nose. There are often abdominal hernias and anasarca. In many animals there is hydrocephalus due to the deformed cranium.

Complex vertebral malformation (CVM)

A problem recently discovered by Danish scientists. It involves the Holstein breed and appears to have a genetic basis, possibly with a recessive-type inheritance pattern. It appears to have been carried by some bulls widely used for AI across the world. The problem is of malformed calves which appear visually to have a foreshortened neck and thorax; the spinal cord may be twisted, with deformed carpal and metacarpal joints. It appears that there can also be an increase in abortions, heart and lung abnormalities and low birthweight. Control is obtained by ensuring dams are not mated to known carrier bulls or other bulls descended from the same bloodlines.

Congenital joint laxity and dwarfism syndrome (CJLD)

The condition is also known as long bone deformity/chondrodystrophy syndrome and in Canada

'acorn calf syndrome', as it occurs at a time when acorns are around. The condition is seen mainly in the calves of suckler cows and very occasionally dairy heifers. The calves are mainly born in the spring from dams which have usually been fed only pit or clamp silage or rarely big bale silage with no other feeds. Various causes have been suggested but it appears to be nutritional in origin, directly or indirectly, as the addition of another feed such as straw, hay, cereals, etc. to the diet usually prevents or greatly reduces its occurrence.

There are various forms of the condition which have been grouped together and may be variations on the same problem or different problems. In the dwarfism syndrome animals are born at full gestation but have long bone shortening. Other signs can include increased (laxity) or decreased joint movement (chondrodystrophy) and some of these can improve. The fetlocks are often involved. The head may be domed or the face dished, there may be superior brachygnathia. The fore limbs may show lateral bowing or the hind can be sickle hocked. Severely affected calves are unable to rise and may have kyphosis. Post-mortem reveals the skeletal abnormalities; there may also be hepatic fibrosis.

The cause is unknown although silage feeding is critical. There appears to be an interference in normal bone metabolism: it may be a calcium/phosphorus imbalance, or vitamin D, A or copper deficiency. Manganese problems have been suggested but supplementation does not improve the problem. There appears to be no genetic link.

Osteopetrosis (*metaphyseal dysplasia*)

This has been recorded in black and red Aberdeen Angus and Hereford calves. It is thought to be due to an autosomal recessive gene. The calf may be born prematurely. At birth it is small and of low weight, with brachygnathia inferior (shortened mandible), protrusion of the tongue, impaction of the molar teeth, misshapen coronoid and condyloid processes, open fontanelle, thickened cranial bones, shortening of the long bones and a lack of bone marrow. Radiographs show the homogeneous bone shaft.

Atlanto-occipital fusion

This is rare and is due to a failure of the first cervical vertebra to separate from the occiput and thereby form a joint. It need not necessarily be apparent at birth. The main signs are ataxia with inability to coordinate limb movements. There are then abnormal flexures of the cervical region and recumbency.

Mandible and face abnormalities

The terms 'overshot' and 'undershot' are often used for these conditions, but they have variable definitions. Abnormal length of the upper and lower jaws is better termed superior or inferior prognathia and shortening of the upper or lower jaw is superior or inferior brachygnathia respectively. Most newborn calves show a degree of inferior prognathia, but this condition resolves. However, persistent inferior prognathia is more common than inferior brachygnathia (parrot mouth). The conditions are thought to be inherited. Problems can arise from impaction or non-apposition of the molar teeth. Extreme hypoplasia or agnathia are rare. Lateral deviation of the face with normal development of the mandible (campylognathia) is occasionally seen.

Vertebral column defects

Various abnormalities have been reported including spirabifida, lordosis (ventral deviation), kyphosis (dorsal deviation) and scoliosis (lateral deviation). Occasionally, there is partial or total agenesis of the posterior part of the spinal column; screwtails are reported in Red Polls and wrytails in Jerseys and Holsteins. Ankylosis of the intervertebral joints has been recorded.

Defects of the limbs and claws

Occasionally, duplication of all or part of the limb occurs and in other animals the whole or various bones of the limb are absent. One problem recently described is tibial hemimelia in Galloway cattle. Polydactyly or extra digits have occasionally been seen. A quite frequent abnormality is the partial or complete fusion of the digits (syndactyly or mule foot). The condition is reported in the Holstein, Aberdeen Angus, Hereford and Chianina. It occurs more commonly in the front than the hind legs and the right limbs are more often affected. It can be inherited as a simple autosomal recessive trait. Duplication of the whole limb (polymelia) is very rare. It can be attached to the thigh of the normal limb by soft tissue and a pseudoarthrosis may develop between the femoral head and the pelvis.

Osteoarthritis

Although it can be nutritional in origin, it can also be inherited in Jersey and Holstein Friesian cattle. There are two main conditions, namely degenerative arthropathy, which mainly involves the hips, and degenerative osteoarthritis, which primarily affects the stifle joints. The latter condition develops in older cattle over a period of one or two years. The stifle shows

crepitation and the limb is not raised much off the ground when walking. The articular cartilages show degeneration.

Arachnomelia

This condition involves the limbs having very long, thin distal extremities like a spider and the bones are brittle. It has been recorded in the Simmental breed. Often there is spinal curvature and inferior brachygnathia, which often affects other body systems.

Displaced cheek teeth

The lower mandible tends to be shorter and narrower than normal with abnormal eruption or impaction of the cheek teeth.

Lymphatic system

Inherited lymphatic obstruction

This has been reported in Ayrshire calves and is caused by the autosomal recessive condition. The lymph nodes tend to be small and the lymphatic vessels are large and tortuous. The condition results in oedema, which varies from slight to severe. The calves may be born dead. The oedema may be so gross as to cause dystokia. Oedema can be of the head, neck, ears, tail and legs. In slight cases there is oedema of the legs and these animals may survive. Accessory lobes may be present at the base of the ears.

Alimentary tract defects

Cleft palate (palatoschiasis)

This can occur as an individual condition but is normally associated with other conditions, particularly arthrogryposis.

Harelip

This has been recorded in cattle but its mode of inheritance is not known. Occasionally, ingestion of lupin (*Lupinus sericeus*) can result in the condition.

Smooth tongue (epitheliogenesis imperfecta linguae bovis)

This is seen in the Holstein–Friesian and Brown Swiss. It is the result of an autosomal recessive gene and leads to the filiform lingual papillae being small. The animals

tend to be in poor condition with a poor coat and increased salivation.

Atresia ilei

This condition has occasionally been reported and there is disruption of patency. The signs are of a distended abdomen and this may lead to dystokia. Some cases are due to a recessive gene.

Atresia coli

This has been recorded in Aberdeen Angus and other breeds. The calves survive only a few days.

Atresia ani

This may be inherited and is seen in several breeds including the Friesian. The animal is usually born bright, but will usually die within a week unless surgical relief is provided.

Muscular system defects

Congenital flexure of the pastern joints

This is common and present in most breeds. In the Jersey it is considered to be caused by an autosomal recessive gene. The calves show knuckling over on one or both front fetlocks, and occasionally the hind limbs are also affected. The condition is usually reversible and most calves recover within about six weeks. In some cases it may be necessary to splint the limbs. Manganese deficiency in the dam can also lead to the condition as can locoweed or poison vetch (*Astragalus* and *Oxytronitis* spp).

Arthrogryposis ('curled calf disease')

(see pp. 451, 925)

By definition this is a permanent joint contraction. The condition is normally bilaterally symmetrical and the forelimbs are affected more than the hind limbs. The muscles show marked atrophy, they are pale in colour and there is replacement of many muscle fibres with fat. Cleft palate is often also present. The condition is common in the Charolais breed where it is a recessive gene. The gene is probably more prevalent than it should be because carrier dams appear to have advantages in improved longevity and fertility. Infection of the fetal calf by akabane virus can result in the condition, as can lupin (*Lupinus sericeus*) ingestion.

Muscular hypertrophy (double muscling, muscular hyperplasia, culard)

This is a characteristic with some production potential in that some muscles have increased numbers of muscle fibres. The condition is seen in the South Devon, Limousin, Charolais and Belgian Blue and the degree of skeletal muscle involvement varies. It occurs most commonly in the hind limbs with a rounding of the hindquarters. The muscles affected have deep grooves along the intermuscular septa and this may be seen in the muscles of the shoulder, back, rump and hindquarters. Many of the animals tend to stand in a stretched position. The calves tend to be less viable at birth and because of the increased muscle size dystokia is common. In the Belgian Blue dystokia results partly from a narrowing of the dam's pelvis.

Multiple tendon contracture

This has been recorded in Shorthorn cattle and results in dystokia due to the calf's limbs being fixed in extension or flexion. There is a lack of mobility of the limbs and often positioning is abnormal. The problem involves the tendons and there is limb muscle atrophy. The calves are born dead or are destroyed because they are unable to stand. The condition is thought to be inherited by a single recessive gene.

Joint hypermobility

The cause of the condition is unknown but in Jersey calves it is a single autosomal recessive gene. The joints are very mobile and can be bent into very abnormal positions with overextension and flexion of all or most of the upper fore and hind limb joints.

Achondroplastic deviation

Most cases appear to be inherited as a single recessive characteristic and involve the Aberdeen Angus and Hereford breeds but cases have been reported in the Holstein and Shorthorn. The calves have short legs, a wide, short head and the mandible protrudes far in front of the dental pad. The eyes bulge and the tongue protrudes. Breathing is stertorous with the forehead protruding and the maxilla distorted.

Nervous system defects (see Chapter 51)

Hydrocephalus

This is uncommon in calves and can be inherited or congenital. It is often associated with other deformities. e.g. congenital achondroplasia. The condition is seen in

the Holstein and Hereford and is in-herited. Infection of the fetus with akabane virus can produce the problem and it is thought vitamin A deficiency can contribute to the condition. It can result from obstruction to the drainage of cerebrospinal fluid from the ventricles or cranial malformation. In both conditions the animals are born dead or die in a few days. There are usually ocular defects.

Cerebellar hypoplasia

This is also known as Hereford disease, but is seen in the Holstein and Shorthorn and appears to be genetic. During pregnancy, infection with BVD or *Neospora* can produce the condition (see p. 900). The cerebellum tends to be small, tough and leathery or even absent. Most calves are obviously affected at birth; there is swaying of the neck, with inability to stand and blindness occurring in severely affected animals. Less badly affected calves have exaggerated and incoordinated limb movements. The animals are conscious and able to drink. Some will survive for several months.

Inherited cerebellar ataxia (see p. 893)

This condition is described as being due to a single autosomal recessive gene. It is seen in the Holstein, Jersey and Shorthorn and the signs are similar to cerebellar hypoplasia, although they are not apparent at birth. The gross lesions are minimal and consist of a wet glistening appearance to the cerebellar white matter, which appears on histology to be reticulate.

Cerebellar abiotrophy (premature ageing)

This condition is seen in Hereford and Simmental calves and appears when four to eight months old. There is the sudden onset of ataxia, which then progresses slowly. The animals are not blind. Calves remain strong but become recumbent or decline slowly into a spastic ataxia. Histologically, there is ageing or degeneration of the cerebellar neurones (see p. 893).

Congenital spasms

The condition has only been reported in the Jersey and there is a continual tremor of the head, neck and limbs. The animal cannot walk and it may die in a few weeks.

Familial ataxia and convulsions (see p. 893)

These have been reported in Aberdeen Angus calves and appear to be an incomplete dominance. The signs are seen within a few hours of birth but can occur when two or three months old with the sudden onset of

tetanic spasms, which last for three to twelve hours. In mild cases there is a stiff, exaggerated movement but in the severe form there may be convulsions with recumbency, opisthotonus and paddling of the forelimbs. Following the initial signs there is a residual ataxia with a goose-stepping action, which lasts weeks or months. Necropsy shows lesions of degeneration of the cerebellar cortex Purkinje cells. Diagnosis depends on age, signs and their remission.

Progressive ataxia (see p. 894)

This has been recorded in the Charolais in Britain and subsequently in France. The signs do not develop until the animal is about a year old and they are seen as a progressive ataxia. The animal has increasing difficulty in rising until it may become permanently recumbent. Histologically, there is a myelin degeneration of the white matter of the cerebellum and internal capsule.

Bovine progressive degenerative myeloencephalopathy (Weaver syndrome)

The condition is inherited, appears to be linked with high milk production and occurs in the Brown Swiss breed, although a similar condition has been described in the Murray Grey. Signs usually develop between five months and two years, with the occasional one starting after that time. The problem is one of a progressive (it often stretches over one to one and a half years) bilateral hind limb weakness with the animal showing an increasingly broad-based stance when standing, ataxia and dysmetria. Thus the animal gradually has increasing difficulty in rising, a weaving action and often goose stepping of the fore limbs while starting to drag its hind legs. Although there are proprioceptive deficits, limb reflexes are normal. The animal is bright and alert throughout the condition. At post-mortem examination there are lesions in the white matter of the cerebellum and at all levels within the spinal cord. The lesions include axonal degeneration and vacuolation of the white matter due to large intercellular spaces and axonal spheroidal degeneration. There may be muscular wasting but without muscular dystrophy. Chromosomal examination confirms the defect.

Inherited neurodegenerative disease (shaker calf syndrome)

This syndrome, which has been described in Canadian horned Hereford cattle, is evidenced by a severe muscular tremor and shaking of the head, body and tail. The animal has difficulty in rising, a wobbly spastic gait and

an inability to bellow. Histological examination reveals accumulations of neurofilaments within the neurones of the central, peripheral and autonomic nervous systems.

A similar clinical syndrome has been recorded in Holstein male calves and is probably caused by a sex-linked recessive mutation. On histology, there are spinal cord changes with spongiform lesions with cavitation.

Idiopathic epilepsy

This condition occurs when the calves are a few months old and mainly involves the Brown Swiss. It is inherited as a dominant characteristic. The convulsions are epileptiform and are seen when the calf is stimulated. They disappear once the animal is one to two years old.

Lysosomal storage diseases (see p. 892)

There is a generalized glycogen storage problem in beef Shorthorns with muscle weakness, incoordination of gait and eventual recumbency. In the Friesian there is a GM₁ gangliosidosis where there is an accumulation of ganglioside (GM₁) in the nervous tissue due to reduced activity of the enzyme β-galactosidase. At about three months old the animal begins to grow more slowly, is blind and has a staring coat.

Mannosidosis

The condition has been recorded in Aberdeen Angus and Murray Grey cattle in New Zealand, Australia and recently in Britain (see p. 892). It is inherited as an autosomal recessive trait and is a deficiency of a specific lysosomal hydrolase enzyme, α-mannosidase, and this causes the accumulation of mannose and glucosamine in secondary lysosomes. The signs develop from one to fifteen months old and most animals die by one year. There is, at first, slight hind leg ataxia, then a fine lateral head tremor, slow vertical head nodding, aggression and loss of condition. Diagnosis is based on reduced tissue and plasma levels of α-mannosidase. Histologically, accumulations of mannose and glucosamine are seen in the nerve cells, fixed macrophages and epithelial cells of the viscera. Tissue and plasma levels of α-mannosidase are about half the normal level in heterozygous animals and can thus be detected.

Spastic paresis (see p. 458)

There is an extension of the stifle and tarsal joints of one or both hind limbs. The condition is seen in the Friesian, but other breeds can be affected. Signs are not usually present until the animal is several weeks or months old, when they start to progress. Contraction

of the Achilles tendon, gastrocnemius and superficial flexor tendons overstraighten the hock joint, so that the os calcis is moved cranially towards the tibia. Usually, one leg is more affected than the other and this limb may appear shorter. In the later stages of the severe cases, the leg may swing backwards and forwards like a pendulum. The condition is considered to be inherited. However, the genetic influence is considered to be small, and it is thought that the phenotypic expression as a probably multifactorial recessive genotype depends on mostly unknown environmental factors. Where only small numbers of an AI bull's offspring are affected and the animal is of high genetic merit, it has been suggested that it should still be used as a sire (see p. 166). Surgery can relieve the condition but the animals should not be used for breeding. Recently, analysis of cerebrospinal fluid concentrations of homovanillic acid, the main metabolite of dopamine, has shown levels to be lower in spastic paresis calves than normal contemporaries. The possibility of a disorder in dopamine metabolism has therefore been suggested as a possible cause of the condition.

Neonatal spasticity

This condition involves a single recessive characteristic in the Jersey and Hereford. The animal is born normal but within the first week it develops convulsions of the head, neck and limbs, preceded by neck deviation and bulging eyes.

Periodic spasticity

This has been recorded in the Guernsey and Holstein breeds. It appears to be a single recessive character with incomplete penetrance and is often not noticed until the animals are adult. Early signs involve the hind end, with difficulty in rising; the hind limbs are stretched backwards and the back depressed. The back muscle may fasciculate and the condition progresses from a few seconds duration to last up to 30 minutes. The animal cannot walk during the attack.

Inherited congenital myoclonus

The condition does not involve oedema of the central nervous system and is therefore described as inherited congenital myoclonus (see p. 893). It is inherited as an autosomal recessive gene and is seen in America, New Zealand and Australia to affect Hereford and polled Hereford-cross calves. It has also been reported in Britain in the Hereford, Jersey and South Devon. Animals are usually produced after a shorter than normal gestation period. They are bright and alert but

recumbent, often in lateral recumbency and some are unable to move their head. There is extension and crossing of the hind limbs with hypersensitivity to noise and touch. Often when animals are encouraged to stand there are myoclonic spasms with the body becoming rigid. At necropsy there is usually damage to the hip joints, probably secondary to myoclonic contractions. There is no oedema of the central nervous system. The main differential diagnosis is maple syrup urine disease. No treatment is possible and the same mating pattern should not be used again.

Maple syrup urine disease (branched-chain ketoacid decarboxylase deficiency, BCKAD)

This condition is possibly inherited as an autosomal recessive gene. It is very uncommon but may be seen in polled Hereford calves (see p. 893). There are higher than normal concentrations of branched-chain amino acids in plasma and/or serum, urine, cerebrospinal fluid and formalin-fixed cerebral tissue. It has been suggested that the condition is analogous to branched-chain ketoacid decarboxylase deficiency or maple syrup urine disease. There is dullness, opisthotonus and recumbency and a poor response to touch or auditory stimuli. At post mortem there is severe stratus spongiosus. The main differential diagnosis is inherited congenital myoclonus.

Congenital pastern paralysis

The defect is lethal due to prolonged recumbency and in Red Danish cattle at birth can take the form of opisthotonus–muscle tremor with spastic extension of the limbs and exaggerated tendon reflexes. There is neuronal degeneration in many parts of the brain and spinal cord. In the Norwegian Red Poll a similar condition is seen but only involving opisthotonus and muscle tremors.

Perosomus elumbis

This occurs very occasionally in ruminants. There is aplasia or hypoplasia of the spinal cord caudal to the thoracic area. This results in rigidity of the hind limbs, there is muscle atrophy and no joint movement. Most cases are born dead.

Ocular defects (see p. 914 onwards)

Reports of ocular defects in cattle are few. Anophthalmia and microphthalmia occur infrequently. Entropion is also very rare. Dermoids can occur on the

eyelids, conjunctiva and cornea, but they are commonest on the third eyelid.

Exophthalmus with strabismus (see p. 918)

This has been recorded in the Hereford and Holstein is combined with strabismus in Shorthorns and their crosses in Britain and Jerseys in America. The signs, particularly in the Shorthorn, are usually delayed until a year old, although occasionally young calves are affected. The condition is progressive and defective vision is observed first, followed by protrusion and deviation of both eyeballs medially with difficulty in focusing. The condition is considered to be inherited as a recessive gene, but some occur in cases of cerebellar hypoplasia or mucosal disease.

Colobomata (see pp. 923, 924)

These problems appear to have a high prevalence in the Charolais. There is an absence of part of one or more of the structures of the eye. The condition occurs during early gestation, when the eye is developing. Although always bilateral, it may not be symmetrical and it is usually found associated with the optic disc and the tapetum nigrum below the disc. The retina is involved and in some animals the choroid and sclera are also affected. The condition is present at birth and does not progress. The mode of inheritance has been debated, but a dominant gene with incomplete penetrance, autosomal recessive or polygenic inheritance have all been suggested. Signs are not usually apparent although an ophthalmoscopic examination will reveal the lesion. The very severely affected animal can be blind, and a few others are considered to be hyperexcitable due to the defective vision.

Congenital cataract (see p. 923)

Lens opacity is present from birth. The condition has been recorded in the Friesian, Hereford, Jersey and Shorthorn. Some cases in the Holstein and Jersey are considered to be due to an autosomal recessive gene or infections. A form of nuclear cataract in Friesian and Friesian-cross calves appears to be more common in calves born in the summer months and is considered to be of environmental origin. The condition is bilateral and not progressive. In most animals the degree of involvement of each eye is similar. In severe cases blindness is apparent. It is not always possible to examine the fundus of the eye, but in most affected calves there is no abnormality of the retina or optic disc (see p. 923).

Persistent hyaloid vessels

These are quite common and are the vestige of the earlier development of the eye. They have no practical significance.

Skin defects

Symmetrical alopecia

This is apparently inherited as a single autosomal recessive characteristic in Holstein cattle. It involves animals born with a normal hair coat but which is then lost in a symmetrical pattern over the body. It occurs between six weeks and six months of age and affects both pigmented and non-pigmented areas.

Congenital hypotrichosis

Several forms are recorded that vary both in inheritance and degree. There may be partial or complete loss of hair and the condition is present at birth. In some instances the animals will grow satisfactorily provided there is sufficient shelter.

Epitheliogenesis imperfecta

This condition can occur in either sex and reports include Holstein, Ayrshire and Jersey calves. Most animals die within a few days of birth. It is considered to be caused by an autosomal recessive gene. There are normally areas of varying size devoid of skin or mucous membrane. The defects are often distal to the tarsal and carpal joints. Lesions may also occur on the muzzle, tongue, hard palate, cheeks and nostrils.

Keratogenesis imperfecta (baldy calves)

The condition appears a few months after birth and is lethal. It has been observed in the Friesian and is due to an autosomal recessive gene. The skin tends to develop alopecia, there is a loss of body condition and the horns do not grow. The skin then becomes scaly, thickened and folded, particularly on the neck and shoulders. There is alopecia and raw areas may develop, particularly on the knees, hocks, elbows, axillae and flanks. The joints tend to be stiff and there is overgrowth of the hooves.

Inherited parakeratosis (lethal trait A46)

This is possibly an autosomal recessive condition. It is seen in Friesian cattle and is thought to be due to an increased zinc requirement. The signs are usually seen about four to eight months after birth with alopecia and

parakeratosis of the limbs, muzzle and under the jaw. The animal becomes stunted and, if untreated, it dies in about four months. At necropsy there is thickened skin with thick crusts over the skin lesions. The spleen shows hypoplasia. Diagnosis depends on low serum zinc levels (normal 12–27 µmol/l; 80–120 mg/100 ml) and history of parakeratosis. Therapy must continue for the rest of the animal's life and as a calf about 0.5 g zinc oxide or 1 g zinc sulphate daily is required. The dose should be increased as the animal grows older (see p. 260).

Interdigital hyperplasia (see p. 429)

This condition is particularly seen in the Hereford and it is considered to have a genetic predisposition. The condition tends to be present in the older animal and can be surgically removed, but has a tendency to recur.

Albinism

Varying types occur. In partial albinism the coat colour is normal for the breed or a dilute colour, but the iris is blue and white centrally, with a brown border. Incomplete albinism is characterized by a white or mainly white coat and the iris may be blue, grey or white. The condition is inherited by an autosomal dominant gene. In complete albinism the coat is pure white and the iris white or pink. The condition is inherited as a simple autosomal recessive trait.

Familial acantholysis

This has been recorded in Aberdeen Angus calves. There is a loss of skin at the carpal and metacarpal joints and coronet, where there is horn separation. The defect is one of defective collagen in the basal and prickle layers.

Congenital ichthyosis

This is also known as fish scale disease in that there is alopecia and the presence of a horny epidermis.

Body cavity defects

Umbilical herniae (navel ruptures)

These are found with a low frequency in several breeds, but especially the Friesian and Holstein. It would appear in some cases to be due to the environment, following infection, to a dominant gene with incomplete penetrance, or autosomal recessive genes. In one study of the progeny of Holstein bulls, more cases occurred in the female than the male offspring. In the male many

umbilical herniae are missed unless a conscious effort is made to look for the defect. This is due to the hernia occurring just anterior to the prepuce orifice. If the hernia is small it may not need to be treated. Larger hernias may need surgical repair (see p. 1122) by suturing across the hole or surgical webbing may need to be introduced. Many cases are inherited and the animal should be recorded as often the hernia is hard to detect in the adult. Do not breed from affected cattle.

Inguinal herniae

These occur far less commonly than umbilical herniae. Little is known about aetiology.

Scrotal herniae

Like inguinal herniae, these are rarely seen but can occur in the Sussex and Friesian breeds. Little is known about the aetiology, but there is a familial trait.

Schistosoma reflexus

This is a group of conditions in which there is longitudinal fissure in the body wall. The cause is unknown, but it may be due to the failure of the somatopleure of the blastodermic vesicle to close. At birth the vertebral column is angulated with the head and tail showing approximation dorsally. The abdominal and thoracic organs lie free in the dam's uterine cavity.

Diaphragm defects

These occur occasionally and, depending on size and position, they may or may not involve abdominal organ herniation.

Reproductive system defects

Testicular hypoplasia (see p. 618)

This occurs sporadically in all breeds of bull. The problem can be bilateral or unilateral as well as being partial or complete. The left side is more commonly affected. Work on gonadal hypoplasia in Swedish Highland cattle showed an inherited origin and this is probably also the case in British breeds.

Cryptorchidism (see p. 482)

There is incomplete descent of the testicles into the scrotum and this may be unilateral or bilateral, although the former is more common. Bilateral cryptorchidism usually produces a sterile animal. The

condition occurs in most breeds including the Friesian and Hereford. Although studies of aetiology are few, it is considered to have an inherited basis.

Wolffian duct aplasia

This is normally seen in the area of the epididymal head.

Ovarian aplasia

This occurs occasionally with or without other reproductive abnormalities.

Ovarian hypoplasia

As with testicular hypoplasia, this has mainly been recorded in the Swedish Highland breed where it is inherited.

Müllerian duct aplasia

Various forms can occur and all are uncommon, but the main form is uterus unicorni.

Duplication of the reproductive tracts

This can occur as a deficient union or exaggerated union of the Müllerian ducts. They can result in a partial or complete duplication of the cervix or uterine body or vaginal septa.

White heifer disease

The condition used to be common in the white Short-horn with up to 10 per cent of them being affected. It is now rare, but can be found in other breeds. There are varying degrees of involvement. In all cases there is partial or complete persistence of the hymen. This may be the only abnormality, but in other animals there are abnormalities cranial to the hymen. These defects may include the absence of the cranial vaginal cervix, uterine body or horns. The ovaries are functional and in most cases there is a distension of the normal organs due to the accumulation of the products of secretion.

Prolonged gestation

This has been recorded in most dairy breeds and in some cases it has an inherited origin. There are two main forms of the condition.

(1) Prolonged gestation with fetal giantism. In these animals the fetus continues to grow *in utero* before parturition 21 to 100 days late. The cow usually calves with no udder development or ligament relaxation and

usually first stage labour is minimal, necessitating a Caesarean section. The calves tend to be heavy, have well-erupted teeth and a good coat growth. The adrenals of the calves are hypoplastic and following delivery most are weak and die in hypoglycaemic crisis. The condition is the result of an autosomal recessive gene.

(2) Prolonged gestation with adrenohypophyseal hypoplasia. This is due to a recessive gene and it is mainly recorded in the Channel Island breeds. The gestation length is increased by weeks or months and parturition occurs about seven to fourteen days after the calf's death. There is again no udder development and few signs of parturition. The calf in this case is small and ceases to grow after the seventh month of gestation, so it can often be delivered by manual traction. It may show disproportionate dwarfism, craniofacial defects that may cause hydrocephalus, alopecia and abdominal distension. There is no or only partial development of the adenohypophysis.

It should be remembered that the gestation period of some of the larger beef breeds such as the Charolais, Simmental and Limousin is longer than for the Friesian or most British beef breeds.

Hermaphroditism

Both true and pseudohermaphrodites occur. In the true form there are gonads of both sexes, although they may be combined into an ovo-testis. In the pseudohermaphrodite, cattle are genetically female with female gonads but they have partial masculinization of the external genitalia. The animals usually exhibit normal oestrous behaviour and on investigation have normal ovaries. However, the vulvar orifice is usually small and displaced ventrally.

Freemartinism

This is seen in twins where a female is developing with a male and this affects about 11 out of 12 such twins. The calf contains both normal 60 XX chromosomes and a few 60 XY (male) chromosomes. Occasionally, a female calf will be born singly with this abnormality and this is due to the death of the other twin. Freemartins are usually sterile.

The external genitalia resemble a female, but the vulva is smaller than normal. Later a tuft of hair develops at the vulva and in many cases an over-sized clitoris is found. Internally, there is a varying amount of agenesis or hypoplasia of the Müllerian system and stimulation of the Wolffian system. The ovaries tend to be hypoplastic and the vagina is usually non-patent, which allows diagnosis of the condition in the calf by the passage of a probe. However, occasionally the vagina is tubular and terminates at the normal position

of the cervix, which is absent. The uterus tends to be two thick cords and there are two thin ducts that extend from the gonads to the intrapelvic urethra. There are often seminal vesicles present and sometimes testicles.

Urinary system defects

Pervious urachus

The defect occurs occasionally in calves. However, it may go undetected for weeks or even months, particularly in the male. Urine is discharged in a dribble from the urachus. All urine may be passed via the urachus although in some cases passage is also via the urethra. The condition may lead to cystitis and, as the umbilicus does not heal, there is often omphalophlebitis, septicaemia and polyarthritis. Surgical correction of the condition is possible and can be successful.

Other defects

Congenital porphyria

This is very rare. It is mainly seen in the Friesian and Holstein. It is caused by a simple recessive gene and occurs more frequently in the female than the male. There is increased porphyria in the blood and urine leading to the accumulation of the product in the tissues. The teeth tend to be pink or brown in colour and this can be seen in the newborn. The urine is red or purple and animals will develop cutaneous photosensitization and anaemia. There are high levels of uroporphyrins and coproporphyrins in the blood.

Familial polycythaemia

The condition is seen in the Jersey and is inherited as a simple autosomal recessive trait. There are early deaths. Those alive have poor growth, congestion of the mucosae and dyspnoea. There is a reduced erythrocyte count, packed cell volume and haemoglobin concentration.

Congenital goitre

This is an inherited condition but animals can be kept alive although mortality is high. Goitre also occurs when iodine deficiency affects the gestating dam (see pp. 257, 301)

Anomalous twins

There is faulty division in monozygotic twinning and this results in various abnormalities. There are varying degrees of conjunction, but double-headed monsters are most often seen. Others have a single head and the posterior part of the body is divided. In some cases the separation of the vertebral column may be almost complete, resulting in Siamese twins. Occasionally, small amorphous monsters called amorphous globosus or acardiac twins occur. They are related to double monsters and identical twins. They are found attached to the fetal membranes of the other calves and comprise an outer skin enclosing adipose tissue.

Chromosomal translocations

There are always 60 chromosomes present in the normal bovine. Translocation is the fusion of two morphologically distinct chromosomes. The most common is 1/29 translocation where there is fusion between number 1 and 29 pairs; it is also referred to as the Robertsonian translocation. It has been recorded in the Swedish Red and White breed, Charolais, Red Poll, British White and other breeds. The condition appears to be of importance in that there is reduced fertility in such animals due to early embryonic death.

Introduction

Diarrhoea in the neonatal calf is a serious welfare problem and a cause of economic loss due to mortality, treatment costs and poor growth. Calf diarrhoea is an example of a complex or multifactorial disease, resulting as it does from an interaction between the calf, its environment and nutrition and infectious agents (Fig. 14.1). Successful control of an outbreak will depend on recognition of the important factors in that outbreak and correction of the problems. Identification of the infectious agents involved is important because it

permits a logical approach to disease control. Appropriate advice on nutrition, colostrum feeding, vaccination, hygiene and the use of antibiotics can only be given if it is clear which infectious agents are present and what their contribution to the disease process might be.

Causative mechanisms in diarrhoea

The digestive tract may be regarded as a high fluid flow system in which 80 per cent of the fluid contained within it is secreted into it and 20 per cent is ingested. Secreted fluid originates from salivary glands, gastric mucosa, pancreas, liver and small and large intestinal mucosa. Of the water that enters the digestive tract, 95 per cent is absorbed. Diarrhoea may be defined as an increase in faecal water loss due to increased faecal water content or to increased volume of faeces excreted or to a combination of both. The occurrence of diarrhoea indicates an imbalance between absorption and secretion of water and electrolytes. Only a slight imbalance in the equilibrium between secretion and absorption, in favour of secretion, may lead to severe diarrhoea because very large volumes of fluid are fluxing in both directions. There are several possible causes of imbalance.

Altered ion transport

Diarrhoea due to altered ion transport is caused by reduced absorption of sodium ions by villous enterocytes (Fig. 14.2), by increased secretion of chloride ions by crypt cells (Fig. 14.3) or by both mechanisms acting together. These changes are stimulated in calf diarrhoea by bacterial enterotoxins produced by enterotoxigenic *Escherichia coli* (Fig. 14.4). These bacteria, held on the gut surface by fimbrial adhesins, release enterotoxins. The subunit A of the heat-labile toxin activates adenylate cyclase located on the basolateral membrane which, in turn, raises the production of intracellular cyclic adenosine monophosphate (cyclic-AMP). Increased production of cyclic-AMP reduces sodium ion absorption by villous cells (Fig. 14.5) and

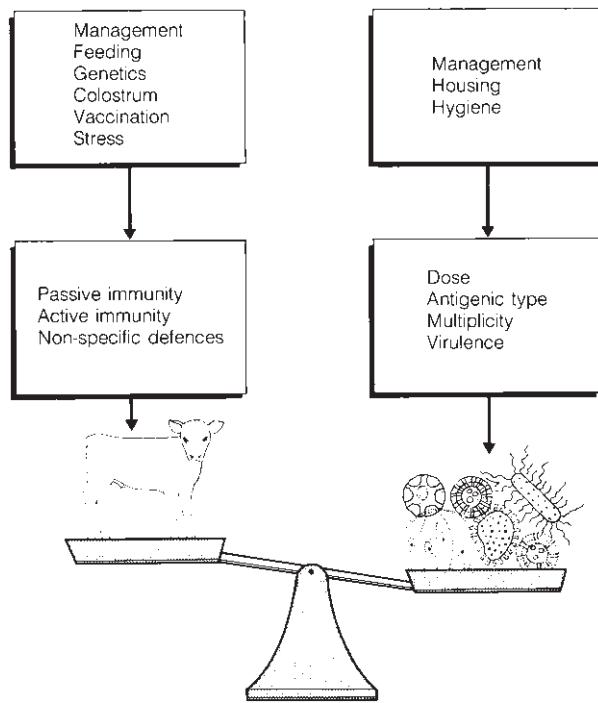

Fig. 14.1 Interactions between management, the calf and enteric agents. Reproduced from Morgan (1990).

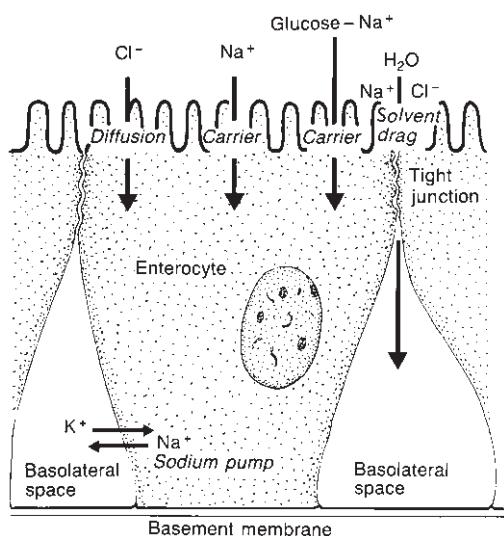

Fig. 14.2 Line drawing illustrating some mechanisms of movement of sodium and chloride ions and water from the intestinal lumen into basolateral spaces. The sodium pump expels sodium ions from the villous enterocyte into the basolateral space. Sodium ions diffuse along the electrochemical gradient created by the sodium pump, through the enterocyte luminal surface membrane, where passage is assisted by glucose-dependent and glucose-independent carrier systems. Chloride ions and water follow the movement of sodium ions.

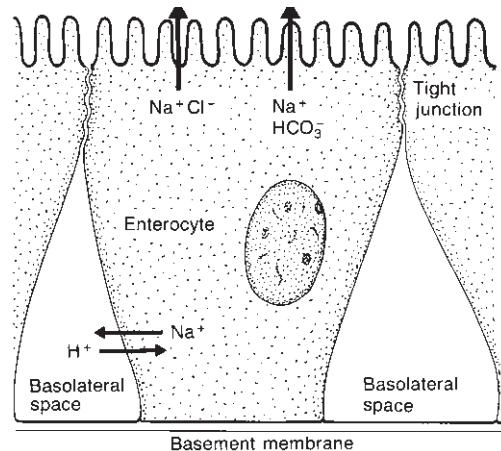

Fig. 14.3 Line drawing illustrating some mechanisms of sodium secretion by crypt enterocytes. Sodium ions are secreted through the luminal surface and chloride and bicarbonate ions and water are transported within sodium ions.

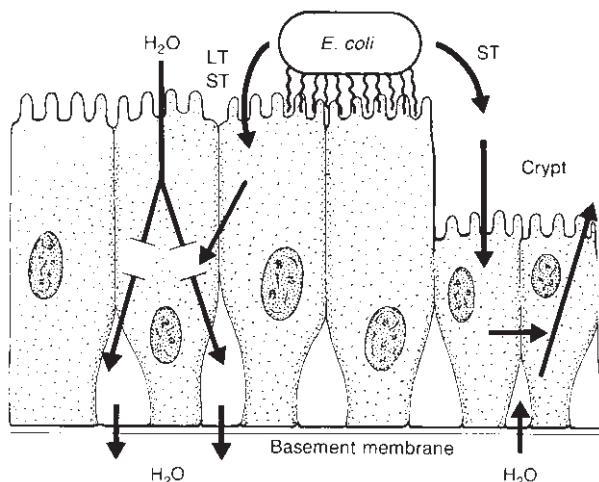

Fig. 14.4 Line drawing illustrating the mechanisms by which enterotoxigenic *E. coli* cause diarrhoea. Bacteria are attached to the enterocyte surface by fimbriae and secrete heat-labile enterotoxin (LT) or heat-stable toxin (ST), which act on metabolic pathways in villous enterocytes to block water absorption and on metabolic pathways in crypt enterocytes to stimulate water secretion.

consequently water absorption is reduced. At the same time secretion of chloride ions, and therefore water, is stimulated in crypt cells (Fig. 14.6). The heat-stable enterotoxin activates guanylate cyclase, stimulating intracellular synthesis of cyclic guanosine monophosphate (cyclic-GMP), which probably stimulates secretion and reduces absorption, although the precise mechanisms are not known (Fig. 14.5).

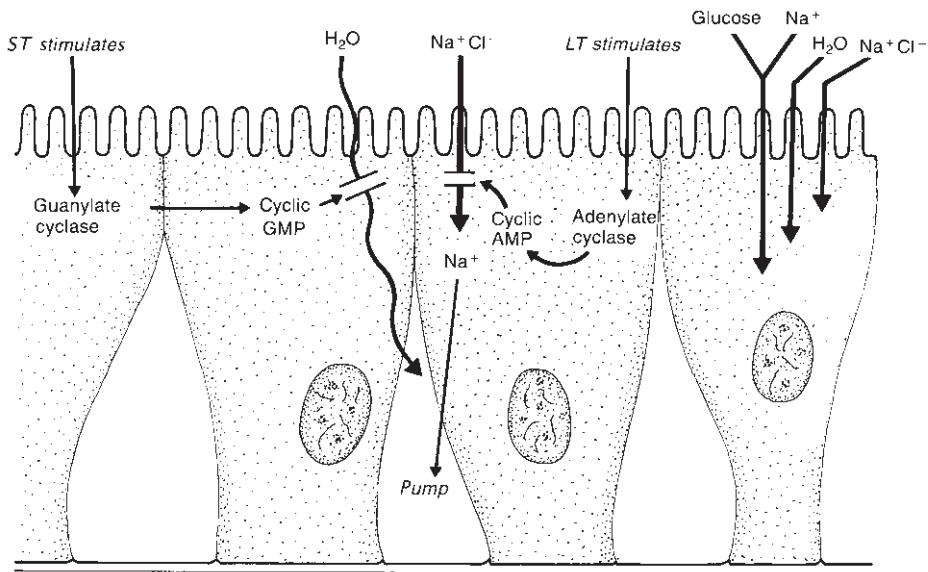

Fig. 14.5 Line drawing illustrating the effects of heat-stable enterotoxin (ST) and heat-labile enterotoxin (LT) on movement of water through villous enterocytes into basolateral spaces. ST inhibits water absorption via cyclic-GMP and LT, acting via cyclic-AMP, blocks absorption of sodium ions and water along the glucose-independent carrier system. The glucose-dependent carrier system is not affected by either toxin.

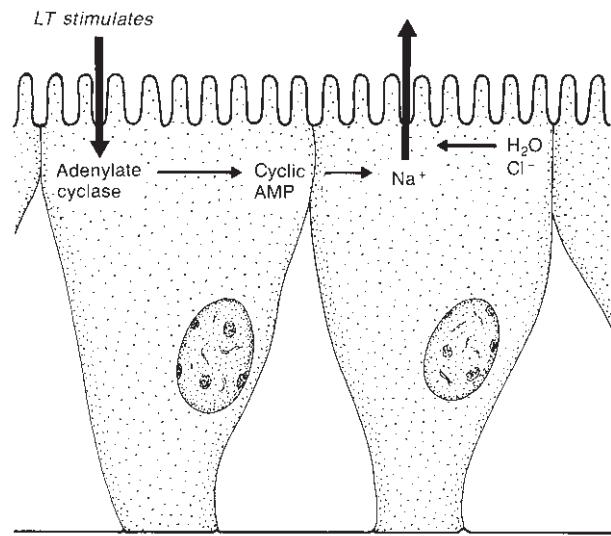

Fig. 14.6 Line drawing illustrating the effects of heat-labile enterotoxin (LT) on the secretion of sodium ions by crypt enterocytes. LT increases production of intracellular cyclic-AMP and this stimulates secretion of sodium ions, which carry with them chloride ions and water.

Passive malabsorption

Diarrhoea may be the consequence of water malabsorption (Fig. 14.7). If malabsorption occurs then normal secretory processes and fluid loss due to tissue hydrostatic pressure will continue and will cause diarrhoea. Water malabsorption will follow a direct reduction of active uptake of sodium ions from the intestinal

lumen. Malabsorption also occurs when morphological changes reduce the absorbing surface area. The best example of such morphological change is villus stunting produced by viral enteritis. The mature villous enterocytes can be regarded as the functional compartment of the small intestine, with absorption as one of the principal functions. A substantial reduction in the number of villous enterocytes causes a corresponding loss of function. Furthermore, crypt hyperplasia occurs in viral infections and immature secretory cells migrate onto the villus, increasing secretory capacity. In addition to loss of absorptive capacity there is also loss of digestive capacity, therefore maldigestion occurs, which can lead to an osmotically induced diarrhoea.

Intestinal motility

Increased intestinal motility may contribute to the development of diarrhoea, resulting in decreased transit time and insufficient time for normal absorption. The role of motility is now considered to be less important than was thought previously.

Osmotic effects

Lactose, the major sugar in cows' milk, is split into glucose and galactose by the enzyme galactosidase (lactase), which is located on microvilli of jejunal enterocytes. These monosaccharides are rapidly absorbed and therefore have little osmotic effect. Viral enteropathogens destroy mature enterocytes, thus creating a transient deficiency of galactosidase. Consequently, lactose passes undigested to the colon together

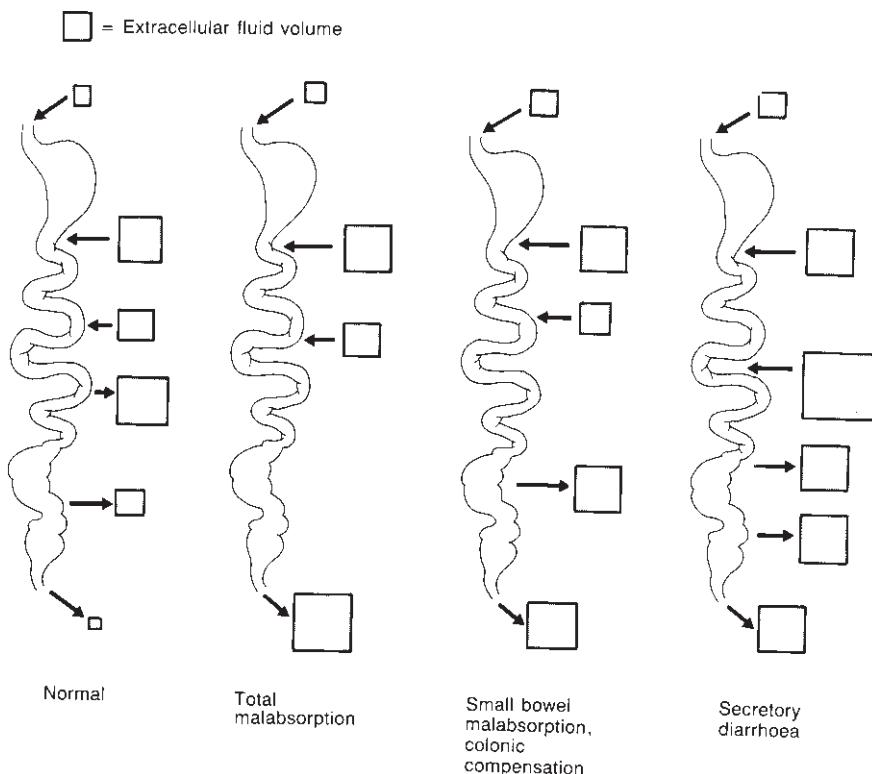

Fig. 14.7 Fluid fluxes in normal growing pigs (40 kg) and pigs with diarrhoea. Volumes of fluid entering and leaving the intestines are drawn in proportional size to the extracellular fluid volume shown at the top. Most water is absorbed by the distal small intestine and colon in pigs of this age and colonic compensation is likely to be much less in neonatal pigs.
Source: Argenzi (1984).

with an osmotic equivalent of water. It may be inferred from studies of pigs, goats and horses that the consequence of increased lactose in the colon depends on the balance between input of lactose and the fermentative capacity of the colonic microbial flora. If the calf possesses a well-developed colon and colonic microbial flora and the amount of lactose entering is not excessive because of restricted dietary intake and/or slight intestinal damage, then the lactose will be fermented to short-chain fatty acids. These will be absorbed through the colonic mucosa, a process that facilitates the absorption of sodium ions and water by the colonic mucosa. These processes are 'anti-diarrhoeal' (Fig. 14.8). In a young animal, with a poorly developed colon and colonic microflora, there may be little fermentation of lactose that remains in the lumen, holding water and contributing to the diarrhoea (Fig. 14.8). In an animal with a well-developed colonic microflora, dumping of large amounts of lactose into the colon as a result of *ad libitum* feeding and severe intestinal damage results in hyperfermentation and the production of lactic acid rather than short-chain fatty acids. Lactate is poorly absorbed and draws water into the colon by osmosis, exacerbating the diarrhoea. These mechanisms explain why withholding milk from calves with rotavirus scour reduces the severity of the diarrhoea (Fig. 14.8).

Tissue hydrostatic pressure and increased permeability

Tissue hydrostatic pressure results in a continual seepage of water from the mucosa into the lumen and this can contribute to the pathogenesis of diarrhoea if malabsorption is present. Seepage may be increased by inflammation of the mucosa, which allows greater leakage of fluid between enterocytes. In very severe inflammatory conditions, for example acute salmonellosis, the epithelium may be so extensively damaged as to allow erythrocytes to leak from capillaries, through the epithelium into the lumen; clearly other blood constituents will be lost also.

Types of diarrhoea

Having examined the various pathophysiological processes that can give rise to diarrhoea, two general types of diarrhoea can be recognized.

Secretory diarrhoea

A diarrhoea resulting from net movement of fluid into the gut lumen despite fasting. Faeces are

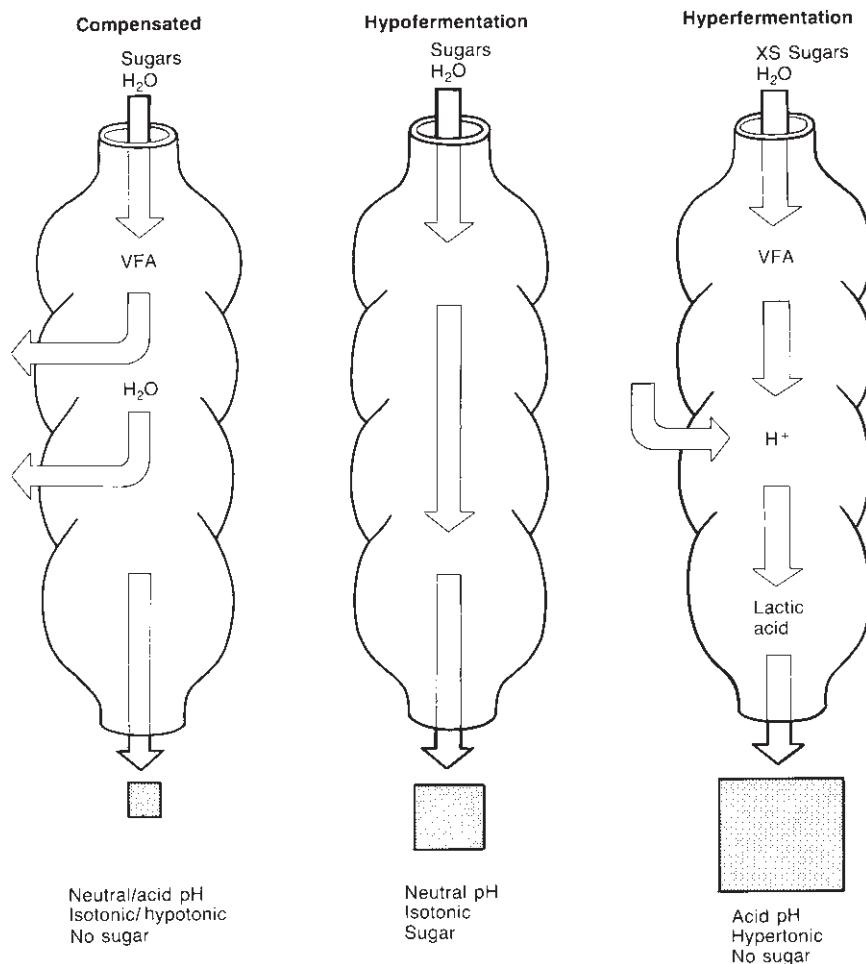

Fig. 14.8 Three alternative consequences of a small intestinal maldigestion and malabsorption, as seen in rotavirus infection. In the 'compensated' situation, the colonic flora is well developed and microbial fermentation of the moderate amounts of malabsorbed carbohydrate yields volatile fatty acids (VFA). These are rapidly absorbed, stimulating water absorption and promoting colonic compensation so that diarrhoea does not occur. If the colon and colonic flora are poorly developed there is hypofermentation and consequently no compensation, and diarrhoea occurs. If the colonic flora is well developed and is overloaded with sugar, hyperfermentation occurs and lactic acid is produced that promotes osmotic diarrhoea. Source: Argenzio (1984).

characteristically isotonic with plasma, watery and alkaline, and the volumes produced are usually large. The faeces are alkaline because sodium and bicarbonate ions are secreted by the ileum. In compensation, the colon may be exchanging potassium ions for sodium ions. Acute secretory diarrhoea is always caused by a bacterial infection.

Osmotic diarrhoea

A diarrhoea where the faeces may have high osmolality due to unabsorbed molecules with osmotic activity, usually of dietary origin. Faeces may contain undigested lactose and faecal pH will vary, depending on the amount of lactose fermented to short-chain fatty acids or lactic acid. Osmotic diarrhoea may also be thought of as a diarrhoea caused by malabsorption and maldigestion. Faecal volume is smaller than in secretory diarrhoea and the diarrhoea is reduced or abolished by fasting. Viruses are one cause of this.

Role of the large intestine

Most diarrhoea in the calf originates in the small intestine and as a result small intestinal function has received most study. It is evident that the large intestine, particularly the colon, is a very important site of water absorption and consequently may contribute to the development of diarrhoea if its functional capacity is overwhelmed or impaired by the fermentative mechanisms described above. Similarly, its function may be impaired by infection with *Cryptosporidium*, coronaviruses or enterohaemorrhagic *E. coli*. Ingesta entering the colon from the small intestine may be damaging.

Effects of diarrhoea and their clinical signs

The systemic effects of diarrhoea, which eventually culminate in death, are precipitated by a single event, the

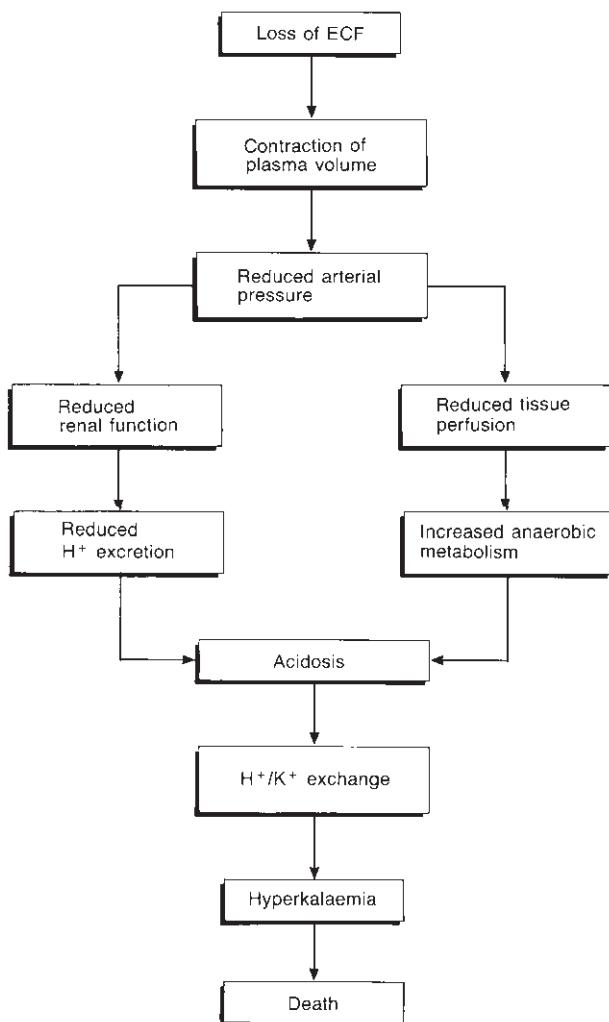

Fig. 14.9 The systemic consequences of diarrhoea. Reduction of extracellular fluid volume leads to acidosis, an exchange of extracellular H^+ for intracellular K^+ leading to hyperkalaemia causing cardiac failure. Source: Argenzi (1984).

loss of extracellular fluid. Endogenous secretion into the gastrointestinal tract in 24 hours may equal the extracellular fluid volume. Loss of 7 per cent of the extracellular fluid volume leads to clinical signs and loss of 30 per cent results in death.

Diarrhoea causes changes in plasma constituents that are similar regardless of the cause of the diarrhoea (Fig. 14.9). When neonatal colostrum-fed calves were experimentally inoculated with coronavirus, the water and electrolyte losses were severe (Lewis & Philips, 1978). Faecal water loss increased 28-fold, faecal volume increased 22-fold and faecal water content increased from 73 to 94 per cent. Renal water loss was reduced to 30 per cent of normal and there were severe losses of

sodium and chloride ions and considerable losses of bicarbonate and potassium ions. There was loss of body weight, 12.7 per cent between onset of diarrhoea and death. Plasma volume decreased by 40 per cent leading to a 39 per cent increase in haematocrit and a 33 per cent increase in plasma protein concentration. The increase in plasma protein concentration was lower, possibly because of protein loss by catabolism or by leakage into the intestinal lumen. Both these values vary widely between individuals and are of little value in assessing severity of fluid loss.

Contraction of plasma volume gives rise to the clinical signs of sunken eyes and ‘tenting’ of skin folds; it leads to a fall in arterial blood pressure, which stimulates peripheral vasoconstriction. Peripheral vasoconstriction, in its turn, leads to poor tissue perfusion with blood, localized ischaemia and lower metabolic activity so that the temperature of peripheral tissues falls, approaching ambient temperature prior to death; the extremities, the ears and mouth, feel cold. Rectal temperature increases until near to death when it falls rapidly to below normal.

Acidosis is an important consequence of diarrhoea and a number of factors contribute to its development. A major factor is loss of bicarbonate ions in faeces and, additionally, there may be absorption of acids produced by microbial fermentation of lactose in the large intestine. Loss of extracellular fluid (dehydration) causes decreased perfusion of the kidney with blood, causing reduced renal function, which leads to decreased excretion of hydrogen ions by the kidney. Finally, lactic acidosis may develop because of increased production of lactate following peripheral hypoxia, and decreased utilization of lactate due to decreased delivery of lactate to the liver. The ability of the liver to use lactate for gluconeogenesis may be impaired because of increased intracellular concentration of hydrogen ions. Indeed, the liver may become a lactate producer rather than a lactate utilizer. The calf attempts to reduce metabolic acidosis by panting to increase exhalation of carbon dioxide. Intracellular acidosis occurs in parallel with the fall in the blood pH. Intracellular production of hydrogen ions increases and hydrogen ions move into cells. This movement of hydrogen ions into cells forces potassium and sodium ions to be lost and hyperkalaemia develops. However, potassium is also lost in the faeces, so that the plasma concentration may, theoretically, be increased, normal or decreased depending on the rate of loss from plasma into faeces, and from cells into plasma. In general it is increased. The loss of potassium ions from cells into the interstitial fluid causes levels of intracellular potassium to fall and levels in interstitial fluid and plasma to rise and, consequently, adjacent to cells, the ratio of extracellular potassium:intracellular potassium is reduced. This redistribution of potassium

causes a reduction in the resting potential of cell membranes, which has serious and eventually lethal effects on cardiac muscle function. As the concentration of potassium ions in plasma rises, heart rate falls and there is a decreased amplitude, or loss of the P wave. The activity in plasma of the myocardial enzymes lactate dehydrogenase isoenzyme 1, creatinine phosphokinase 1 and aldolase is raised indicating cardiac damage. Thus death from acute severe diarrhoea in the calf appears to be due to potassium cardiotoxicosis.

Metabolic and hormonal changes

Hypoglycaemia frequently occurs in acute severe diarrhoea of calves, especially young calves near death. Anorexia, decreased absorption of nutrients, minimal glycogen reserves, inhibited gluconeogenesis, increased glycolysis due to reduced tissue perfusion and anoxia and insulin-like effect of bacterial endotoxins on liver may contribute to the hypoglycaemia. Signs of hypoglycaemia are weakness, lethargy, convulsions and coma. Hypoglycaemia stimulates corticoid secretion; plasma concentration of corticosterone and hydrocortisone are elevated in calves with diarrhoea and are higher in calves that die. Theoretically, corticosteroids help counter hypoglycaemia by stimulating gluconeogenesis but their effects may be blocked. Plasma aldosterone concentrations are increased in calves with diarrhoea probably due to acidosis, hypovolaemia, hyperkalaemia and hyponatraemia. The actions of aldosterone are helpful in that sodium and water retention is increased as is excretion of potassium and hydrogen ions. There is, however, decreased renal function, which limits the helpful actions of aldosterone.

Infectious agents

The elucidation of the infectious causes of calf diarrhoea has been a major area of progress over the last 30 years. For many years, salmonellas were the only known cause, but in 1967 it became clear that a small number of strains of *E. coli* caused a watery diarrhoea and subsequently these came to be known as enterotoxigenic *E. coli* (ETEC). Rotavirus was the first viral enteropathogen to be recognized, followed by coronaviruses, and more recently Breda virus. Approximately 20 years ago, *Cryptosporidium parvum* was found to cause diarrhoea in calves. Most recently, *E. coli* have been identified that cause diarrhoea without producing enterotoxins; these include strains that infect the large intestine and cause mild dysentery, the enterohaemorrhagic *E. coli* (EHEC), and strains comparable to human enteropathogenic *E. coli* (EPEC).

Bovine rotavirus

The agent

Rotavirus is a new genus within the family Reoviridae. The virus contains double-stranded RNA in 11 segments. Particles have a wheel-like appearance; a wide hub formed by the core, spokes formed by 20 outer capsomeres and an often ill-defined outer rim (Fig. 14.10). Incomplete particles lacking the outer capsid layer are frequently seen in faeces. Almost all bovine rotaviruses share a common antigen and have been classified as group A rotaviruses.

Epidemiology

Bovine rotavirus is universally present in all cattle herds but is a more significant problem in single-suckled beef calves than dairy calves because of the much greater risk from cross-contamination between calves, the seasonal nature of the calving pattern and financial restrictions leading to lower nutritional inputs during late gestation.

The incubation period varies from 15 hours to five days and is followed by virus excretion which commences in the second week of life. Many infections are subclinical but a proportion results in severe diarrhoea and even death if not treated promptly. The peak incidence of diarrhoea occurs at about 10 to 14 days of age. Initially, calves are dull and reluctant to suck. The dam's udder becomes distended with milk and may be the first indication to the diligent stockperson that the calf is unwell. Diarrhoea develops which is pale yellow or white and may contain mucus; dehydration and metabolic acidosis develop in more severely affected calves

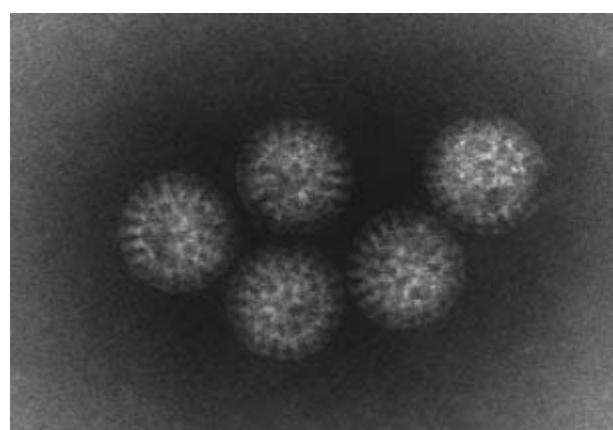

Fig. 14.10 Transmission electron micrograph of a cluster of five bovine rotavirus particles. Visible are the wide hub, spokes formed by the capsomeres, and the outer rim. (Courtesy of Dr J.C. Bridger, Royal Veterinary College, University of London.)

and may be fatal. At this stage the calf may have abdominal distension due to fluid sequestration in the small intestine. Excretion of copious amounts of yoghurt-like faeces is typical of rotavirus infections that are uncomplicated by other enteropathogens and the faeces are thought to have this appearance because they represent the passage of partially digested or undigested milk.

Occurrence of pyrexia is variable, but when it occurs it is usually mild ($<39.5^{\circ}\text{C}$) and may be more suggestive of a focal bacterial infection such as omphalophlebitis or polyarthritis.

Pathogenesis

Rotaviruses infect mature enterocytes, located on the surface of villi. Particles are detected in the cytoplasm, usually in dilated cisternae of the endoplasmic reticulum. Masses of granular or finely fibrillar virus precursor (viroplasm) containing virus cores are present outside the cisternae. Particles released from viroplasm pass into the cisternae; some bud through the membrane of the endoplasmic reticulum and acquire an envelope. Viral multiplication within the cells initiates degenerative changes, the cell exfoliates and the rapid loss of large numbers of cells leads to fusion and stunting of villi. The columnar epithelium is replaced by enterocytes that are cuboidal or squamous and the epithelium contains increased numbers of immature cells from the crypts (Fig. 14.11). In very severe cases the villi may be obliterated leading to a totally flat epithelium. The pathogenic process may commence in the upper jejunum and progress along the small intestine to the ileum, producing a wave of damage (Mebus

et al., 1971). There is variation in pathogenicity between strains; whilst some strains may only damage a limited length of upper jejunum, others may damage the entire length of the small intestine. Some poorly virulent strains are able to infect enterocytes, replicate within them and cause enterocyte loss, but not at a sufficiently rapid rate to outpace repair mechanisms and cause lesions and diarrhoea. The existence of strains of low virulence has implications for accurate diagnosis of rotavirus diarrhoea because it may be assumed that such strains could be excreted by calves with diarrhoea caused by other enteropathogens. To be confident in a diagnosis of rotavirus diarrhoea, it is necessary to identify rotavirus in the faeces of significantly more diarrhoeic calves than in age-matched, clinically normal calves on the same farm. On the basis of present knowledge, groups of four affected and four normal calves are adequate.

The changes in intestinal structure affect its function. Loss of mature enterocytes with their lactase, and their replacement with immature enterocytes containing less lactase, results in a reduced capacity of the mucosa to digest lactose, especially in the jejunum. Because the surface area of the small intestine is reduced, there is reduced ability to absorb the glucose and galactose that is produced from the digestion of lactose. Thus lactose accumulates in the large intestine, where by virtue of its hypertonicity it prevents absorption of water from faeces and contributes to the development of water loss and dehydration. Bacterial fermentation of the lactose may increase the osmotic effects. As a result of enterocyte loss, the population of enterocytes on the villi changes from mature cells with digestive and absorptive function to predominantly immature cells with

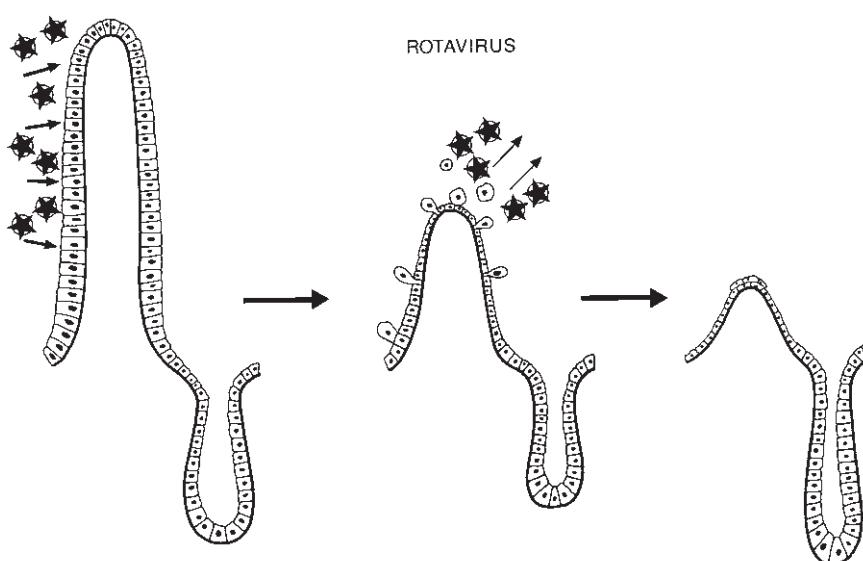

Fig. 14.11 Line drawing illustrating the development of the small intestinal lesion in rotavirus infection. Mature enterocytes are infected and virus replication causes enterocyte death and sloughing. Villi stunt and the surviving enterocytes are cuboidal or squamous. Mitosis increases in the crypts, which elongate. The star within a circle represents a virus particle.

secretory function. The number of cells in the crypts (secretory cells) also increases. Thus the functional balance may change from absorption to secretion.

Prevention

Virtually all calves that have sucked colostrum will have serum antibody to rotavirus, which can be detected by a number of tests. These antibodies, however, do not protect against infection and disease because for protective purposes neutralizing antibody is required in the gut lumen. This is because the entire disease process occurs on the mucosal surface and if antibodies are to interfere with the pathogenic process they must be present in the gut contents that bathe the mucosal surface; luminal antibodies neutralize virus and prevent initial infection and spread of infection from enterocyte to enterocyte. There is recent evidence, however, suggesting that serum antibodies, which originated from the colostrum of hyperimmune cows, can be transferred to the gut where they are protective.

Following natural infection, calves are immune to disease; this is thought to be the result of an active mucosal immunity provided by IgA and cell-mediated mechanisms. Repeated episodes of reinfection without signs occur throughout life, maintaining herd immunity and the virus in the population and environment.

Colostrum contains antibodies to rotavirus that help protect the calf against infection and disease. The concentration of antibody in colostrum and early milk from unvaccinated cows declines rapidly, reaching levels that are thought to be non-protective three to four days after parturition (Fig. 14.12).

Under farm conditions where rotavirus is always present, feeding colostrum only immediately after birth delays, rather than prevents, rotavirus excretion and calves are susceptible to infection and disease in the second week of life. Protection of the calf has been achieved by providing enhanced passive protection to

calves by vaccinating dams with commercial combined inactivated vaccines containing rotavirus, coronavirus and *E. coli* K99 one to three months before the anticipated calving date. Because rotavirus is endemic in herds, cows have antibodies to rotavirus in their serum and parenteral administration of a single dose of inactivated virus absorbed onto aluminium hydroxide gel, and the whole emulsified in a light mineral oil, boosts these pre-existing serum antibodies. Consequently, the concentration of antibody in colostrum and milk is increased and antibody is present in milk for longer than in unvaccinated animals. Thus, dam vaccination is essential on those farms which have experienced losses due to viral diarrhoea in young calves. This system is suitable for both suckled calves, and for artificially reared calves where hyperimmune colostrum is saved from the first six to eight milkings and stored in a cool place and ideally fed at a rate of 2.5 to 3.5 litres per day for the first two weeks of life.

It is essential that all calves ingest sufficient good quality colostrum within the first six hours after birth with values equivalent to between 7 and 10 per cent of bodyweight commonly quoted. Factors that may reduce the level of specific antibody accumulation in the colostrum differ between beef and dairy cows because of the lower nutritional and management inputs in beef herds and the higher prevalence of metabolic disease in high-yielding dairy cows.

Problems with sufficient colostrum accumulation in the udder of beef cows include debility of the dam, poor nutritional status during late gestation, intercurrent disease such as fascioliasis and chronic mastitis caused by *Arcanobacterium pyogenes* (summer mastitis) (Chapter 24). Dystokia is more common in beef calves leading to extended intervals to standing and sucking. As a general rule, those calves born following an assisted calving should receive 2 litres of colostrum within the first two hours of life and be closely supervised to ensure normal sucking behaviour.

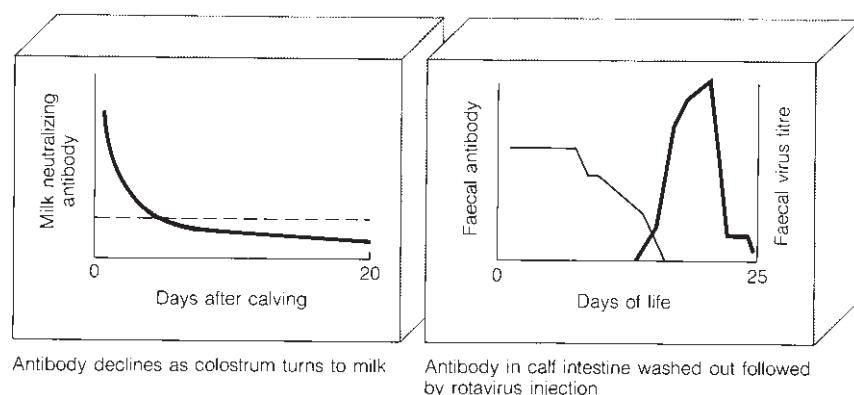

Fig. 14.12 Graphical illustration of changes that occur in neutralizing antibody to rotavirus in cows' milk after calving and faecal antibody to rotavirus and faecal virus in the early days of a calf's life. Reproduced from Morgan (1990).

Recumbency resulting from hypocalcaemia, overcrowding of the calving accommodation, slippery underfoot conditions and poor mothering ability, especially in dairy heifers, may delay the ingestion of sufficient colostrum by the newborn dairy calf.

Dam vaccination may not prevent all episodes and rotavirus diarrhoea may follow stressful events such as housing and disbudding if undertaken before the calves are six weeks old.

Diagnosis

Rotavirus infection produces the complete range of clinical signs from no observed abnormality through to severe diarrhoea and dehydration with high mortality even in treated calves. The incubation period is one to three days depending upon the level of viral challenge. Isolation of rotavirus from faecal samples does not necessarily indicate a diagnosis of rotavirus diarrhoea because rotavirus can be isolated from a high proportion of normal healthy calves without signs of diarrhoea. Comparison of faeces samples collected from healthy and diarrhoeic populations of calves may be necessary to determine the precise aetiology but such sampling will prove cost-prohibitive in most farm situations. Determination of the age of affected calves, and vaccination status of their dams against infectious causes of neonatal diarrhoea, will assist in determining the aetiology of the disease outbreak, noting that mixed infections are common. For example, *Cryptosporidium* spp. often exacerbate the severity of diarrhoea caused by rotavirus infection.

Calves with rotavirus infection during the early stages of disease typically show signs of mild depression and salivation, reluctance to stand and suck and profuse diarrhoea when eight to fourteen days old. Disease rapidly spreads among young calves present on the farm when clinical signs may be seen from six days of age. There is extensive faecal staining of the perineum and tail. The faeces are yellow and fluid but without blood or mucosal casts. The rectal temperature is usually within normal limits during the early stages unless there is evidence of focal bacterial infection. Without oral rehydration therapy the affected calf becomes dehydrated, hypothermic and weak, and remains in sternal recumbency. The eyes are sunken and the skin becomes tight and inelastic, consistent with 8 to 10 per cent dehydration within 48 hours, unless treated appropriately. As hypovolaemic shock develops, peripheral vasoconstriction causes the calf's extremities to feel cold. At this stage the calf is often hypothermic ($<38.0^{\circ}\text{C}$). Without treatment, death may ensue within 72 hours of the onset of diarrhoea.

In most situations diarrhoeic calves have been treated by farm staff with oral rehydration solutions

which alter the clinical presentation, whereby profound acidosis is the main presenting feature rather than severe dehydration. The abdomen appears distended and the abomasum and intestines are distended with fluid and 'slosh' when succussed.

Calves treated with oral rehydration solutions by the farmer using an oesophageal feeder often have normal hydration status but become severely acidotic, causing profound weakness and depression extending to stupor. There is no relationship between the degree of dehydration and the severity of the acidosis. The eyes are not sunken and the skin tent duration is normal. Fluid distension of the abdomen is obvious. The respiratory rate is increased above 40 breaths per minute with increased depth of expiration. The heart rate is often less than 90 beats per minute.

A thorough clinical examination is essential in all young calves with diarrhoea because of the likelihood of other focal infections such as early bacterial meningoencephalitis, respiratory disease, omphalophlebitis and possible associated peritonitis, hypopyon and polyarthritis. Indeed, the diarrhoea reported by the client may be the agonal stage of a septicaemia, although such peracute infections usually occur in calves less than six days old.

In normal calves more than two days old the umbilical remnant is dry and shrivelled, hastened by its immersion in strong veterinary iodine solution immediately after birth and again six to 12 hours later. Omphalophlebitis manifests as a swollen ($>3\text{ cm}$ diameter), wet and painful umbilicus which may discharge pus under digital pressure (see p. 249). Localized peritonitis associated with omphalophlebitis may result in the formation of fibrinous adhesions and associated ileus which proves difficult to detect on clinical examination alone. Abdominocentesis is difficult to perform on such recumbent calves because of the fluid-distended intestines and the scant fibrinous nature of the adhesions. Similarly, abdominal ultrasonography fails to identify such early adhesions. Calves with peritonitis fail to respond to standard fluid therapy and antibiotic therapy regimens, with the adhesions identified at post-mortem examination.

Polyarthritis manifests as hot, distended and painful joints, typically the fetlock, hock and carpal joints, resulting in the tendency for calves to adopt lateral recumbency rather than sternal recumbency associated with weakness (see pp. 249, 455).

Laboratory diagnosis of rotavirus

Enzyme-linked immunosorbent assays (ELISA) have been developed for rotavirus and a plate ELISA is used by many diagnostic laboratories. Some diagnostic laboratories use the polyacrylamide gel electrophoresis

method, which has proved to be equally satisfactory. The diagnostic kits available to practice laboratories in the UK are a dot ELISA, a latex method and a plate ELISA system. The plate ELISA system requires a minimum of equipment and also tests for bovine coronaviruses and K99⁺ *Escherichia coli*; a modification to the system has permitted the detection of *Cryptosporidium* spp.

The identification of rotavirus particles or antigen in the faeces of calves with diarrhoea does not automatically lead to a diagnosis of rotavirus disease in the outbreak. Rotavirus antigen was detected in 50 per cent of faeces from healthy calves aged one to two weeks in a study in which an ELISA test was used. Thus, in order to reach a sound diagnosis, and using that test to identify excretors, it was necessary to show that significantly more than 50 per cent of diarrhoeic calves were excreting rotavirus. This was achieved by examining faeces from four calves with diarrhoea and four matching normal calves on the farm. The number of calf faeces that will need to be examined in an investigation of an outbreak will depend on the ability of the diagnostic test in use to detect excretion by normal calves.

Treatment (see p. 209)

Veterinary treatment of calf diarrhoea is generally limited to collapsed animals which have failed to respond to oral rehydration solutions. Administration of oral rehydration solutions is frequently made by the farmer using an oesophageal feeder. While this procedure has considerable time savings, it is frequently used for weak recumbent calves without a strong suck reflex which serves to further delay veterinary involvement to the stage where calves are profoundly acidotic when presented. In veterinary practice therefore, treatment of calf diarrhoea involves the correction of acidosis rather than simple correction of hydration status, although both problems may have to be tackled at the same time.

Basic animal husbandry is frequently overlooked in many modern beef production systems. The diarrhoeic calf should be isolated in a warm, dry and well-bedded pen. In beef herds, the dam should be separated from the calf by a gate which allows visual contact. Hypothermic calves should be warmed and this is best achieved with convector heaters rather than heat lamps.

Intravenous fluids are essential because most severely affected diarrhoeic calves are profoundly acidotic (see example below), with variable degrees of dehydration depending upon previous oral rehydration therapy.

Example: treatment of diarrhoeic calf under field situations

The objectives of intravenous fluid therapy include the correction of extracellular fluid volume, plasma pH, blood glucose concentration and plasma concentrations of sodium and potassium, restoration of cellular potassium and the provision of nutrients.

A 10 day-old, 45kg single suckled beef calf is presented with profuse diarrhoea with faecal staining of the tail, perineum and hind legs. The calf is weak, unable to rise or remain standing when lifted. It is markedly depressed with cold extremities. The skin tent is about three seconds. The eyes do not appear sunken but the scleral vascularity is pale. The heart rate is 85 beats/minute and the respiratory rate is 45 breaths/minute. Two litres of an oral rehydration solution have been administered by oesophageal feeder twice daily for the past two days.

Typical laboratory values: Typical laboratory values are listed below for this calf but such analyses are rarely possible under field situations. Excellent clinical recovery rates for such cases are achieved in general practice using estimations of the base deficit based upon the clinical examination

| | |
|---------------------------------|------------------------------|
| Packed cell volume = 31% | Arterial blood gas analysis: |
| Total plasma protein = 68.0 g/l | pH = 6.9 |
| Sodium = 128 mmol/l | pCO ₂ = 46 mmHg |
| Potassium = 7.2 mmol/l | HCO ₃ = 7 mmol/l |
| Chloride = 105 mmol/l | Base deficit = 20 mmol/l |

The calf is estimated to be only 5 per cent dehydrated. The serum potassium concentration is elevated because intracellular K⁺ ions exchange with H⁺ and pass into the extracellular fluid. However, the intracellular (and total body) K⁺ ion concentrations will be lowered, but this deficit is more safely replaced by the oral rehydration solution rather than the intravenous fluid. Diarrhoeic calves are not markedly hypoglycaemic and nutrients are better supplied in the oral rehydration solution, and then milk, than in the intravenous fluids.

Intravenous fluid therapy: The fluid requirements are calculated as:

$$45\text{ kg} \times 0.05 = 2 \text{ litres}$$

The daily requirement of 75–150 ml/kg should be added to this deficit. The fluids should be warmed to body temperature before administration and insulated if left suspended in a cold environment.

Base deficit: The base deficit is estimated from the clinical findings whereby profoundly weak and

depressed/stuporous calves, in the absence of septicaemia or bacterial meningoencephalitis, have a base deficit in the region of 20mmol/l. As an alternative practical guideline, calves able to maintain sternal recumbency are reported to have a base deficit of 15mmol/l, whilst those in lateral recumbency have a deficit of 20mmol/l (Naylor, 1996). However, such distinction is not necessary to achieve excellent results, even under less than ideal practice situations.

The total base deficit (or negative base excess) can be calculated as:

$$\text{base deficit} \times \text{bicarbonate space} \times \text{dehydrated calf weight} = 20 \times (0.3 \text{ to } 0.6) \times 45 = 270 \text{ to } 540 \text{ mmol bicarbonate}$$

There is considerable debate as to which value should be employed for the bicarbonate space because this value is higher in neonates than adults. In practice situations, where blood gas analysis is rarely available, an estimate of 20mmol/l for base deficit in recumbent stuporous calves is commonly used in conjunction with an estimate of 0.5 to 0.6 for the bicarbonate space. While it is accepted that there will be errors in such a simplified approach, this regimen has proved very reliable in general practice where the rapid response to intravenous fluid therapy spiked with bicarbonate is the most valuable indicator of success of the fluid therapy regimen.

Typically, stuporous calves should be much improved after three to four hours, and be able to stand six to eight hours after the start of intravenous fluid therapy. A thorough initial clinical examination will eliminate focal and septicaemic infections from the list of differential diagnoses. Re-evaluation of the diagnosis and/or treatment is necessary if the calf's condition has not markedly improved within six hours of commencing intravenous fluid therapy. The two most common reasons why the calf's condition has not improved are: the extent of the base deficit has been underestimated and insufficient bicarbonate has been infused or, less commonly, that the calf has bacterial meningoencephalitis (see pp. 251, 901).

Some practice laboratories use a Harleco apparatus to determine total CO₂, which is a useful index of the severity of the metabolic acidosis. However, determination of metabolic acidosis using either the Harleco or blood gas analysis necessitates hospitalization of the calf with the attendant risks of contaminating the facilities with a range of enteropathogens, some of which are serious zoonoses. While blood samples can be transported to the practice laboratory for blood gas analysis, such retrospective information may not be so helpful because financial considerations frequently preclude a second veterinary visit to correct any estimations based upon clinical findings. Alternatively, with accu-

rate information on the precise severity of the acidosis, the farmer can be instructed to spike the intravenous fluid with materials left on the farm.

Treatment regimen: Under practical conditions on farm a 14 gauge (or 16 gauge) catheter should be stitched into a jugular vein as this makes fluid administration much easier because the calf can be left unattended. A 5cm by 5cm area of skin overlying a jugular vein is shaved and aseptically prepared. A stab incision through the skin overlying the jugular vein using a 15T blade greatly facilitates catheter placement. If the calf is severely dehydrated and cannot be catheterized easily, either the first litre of fluid can be administered through a 16 gauge hypodermic needle or the calf is suspended by its hind legs to distend the jugular veins, thereby facilitating catheterization.

A typical treatment regime for a recumbent acidotic calf would commence with 1 litre of isotonic saline spiked with 200mmol bicarbonate (16g sodium bicarbonate) administered intravenously over 20 to 30 minutes. This solution can be administered while the veterinary surgeon remains on the farm suturing the catheter in position, securing the fluid administration set, and possibly attending further calves with diarrhoea or collecting faecal samples as appropriate.

A further 3 litres of isotonic saline solution containing the balance of the estimated bicarbonate deficit (approximately 400mmol) should then be administered over the next four to six hours, by which time the calf's demeanour will be much improved. The calf should be able to stand and suck a teat enthusiastically at this stage. An oesophageal feeder should be used only as a last resort to administer oral fluids because the calf's demeanour and willingness to suck are valuable indicators of the calf's recovery. Indeed, early cases of bacterial meningoencephalitis may be difficult to differentiate from profound acidosis, but acidotic calves should respond well within six hours to spiked intravenous fluid therapy and suck, whereas those with meningoencephalitis will not and may progress to opisthotonus with spontaneous nystagmus. Alternatively, in cases where meningoencephalitis is suspected during the veterinary examination, lumbar CSF can be collected under local anaesthesia and inspected visually for turbidity caused by white cell infiltration.

This approach to fluid therapy of collapsed acidotic calves described above has been employed in many farm animal practices because the calf remains on the farm and is visited by the veterinary surgeon, thereby removing the risk of introducing enteropathogens, including *Salmonella* spp., into the practice hospital facilities with the potential for disastrous consequences. Often only one veterinary visit is possible for each diarrhoeic calf because of cost limitations, but this system

of intravenous fluid administration works well in practice.

Most diarrhoeic calves are not profoundly hypoglycaemic and the addition of glucose to the intravenous solutions is generally not undertaken. Energy supply is better given as a component of the oral rehydration solution therapy (high energy rehydration solution), which often commences within six to eight hours of the start of intravenous fluid administration. Recently-introduced oral rehydration solutions have a high energy content designed to counter the energy deficit state caused by withholding milk from the calf's diet. As soon as the suck reflex returns, the calf should be offered either one litre of oral rehydration solution or milk at alternate feeds every two hours.

Other intravenous fluids: Clinical evaluation of the alkalinizing effect of various bases in diarrhoeic calves suffering from severe dehydration and acidosis (Kasari & Naylor, 1986) clearly demonstrated the advantages in both speed and extent of administering isotonic saline solutions containing bicarbonate compared to those solutions containing either lactate or acetate.

Lactated Ringer's solution should not be used to treat severe acidosis because it contains only 30 mmol/l of lactate, which would necessitate in excess of 15 litres to counter severe acidosis in a calf. Furthermore, lactate must be metabolized to yield bicarbonate but the young calf cannot fully utilize D-lactate in the racemic mixture. Hypertonic (7.2%) saline solutions are not indicated in the treatment of acidotic calves because of their lack of alkalinizing effect, although successful treatment of mild acidosis in experimental calves has been reported using a hypertonic saline solution containing sodium bicarbonate (Dupe *et al.*, 1993).

The administration of sterile isotonic saline solutions spiked with bicarbonate described above has obvious advantages over non-sterile fluids made using tap water; however, solutions prepared using small water purification plants are reported to work well under practice conditions. A typical mixture of salts available in the UK (Electrolyte ED; Vetoquinol Ltd) added to 5 litres of water yields 141 mmol/l sodium, 4 mmol/l potassium, and 35 mmol/l bicarbonate, which can then be spiked with additional sodium bicarbonate. Extra bicarbonate can be administered either as a 1.3 per cent isotonic solution (65 g sodium bicarbonate to 5 litres, yielding 150 mmol/l bicarbonate) or by adding 35 g sodium bicarbonate to yield 400 mmol in addition to the 175 mmol already present in the 5 litre solution (Grove-White, 2000).

Oral rehydration solutions: There are a large number of oral rehydration solutions available but all utilize the active glucose/sodium-linked gut transport system

whereby sodium is transported across the gut wall into the extracellular fluid and water follows along the osmotic gradient. Other molecules, including acetate, propionate, glycine and glutamine, also play an important role in sodium transport.

The original World Health Organization (WHO) oral rehydration solution was an equimolar solution containing approximately 100 mmol/l sodium and glucose and was the basis of the first generation oral rehydration solutions introduced into veterinary practice during the 1970s. Potassium was present to assist in restoring any deficits. These solutions contain no bicarbonate or precursor and are therefore unable to correct a significant acidosis, but are effective in many cases of calf diarrhoea associated with dehydration. Viral causes of neonatal diarrhoea were not reported in the United Kingdom until the mid-1980s (Snodgrass *et al.*, 1986), and these oral rehydration solutions proved effective in the treatment of bacterial and nutritional causes of calf diarrhoea which were not usually associated with severe metabolic acidosis.

The widespread occurrence of rotavirus-induced diarrhoea and associated metabolic acidosis led to the development of oral rehydration solutions containing 80 to 120 mmol/l bicarbonate as a precursor, whether lactate, propionate or citrate. These solutions have been referred to as 'second generation' oral rehydration solutions. While these solutions are very effective in meeting the primary objectives of correcting hypovolaemia, moderate metabolic acidosis (and associated hyperkalaemia) and hyponatraemia, they fail to provide sufficient calorific support and treated calves lose considerable body condition during treatment when milk is withheld from the diet.

'Third generation' oral rehydration solutions contain much higher concentrations of glucose (up to 375 mmol/l) and sodium (up to 133 mmol/l) to counter the energy deficit which results when milk is withheld from the calf's diet. Such hypertonic solutions do not worsen diarrhoea due to osmosis or produce hypernatraemia and, when compared to standard oral rehydration solutions, these 'third generation' solutions have reduced the liveweight loss which results from calf diarrhoea.

Further developments in oral fluid therapy ('fourth generation') include the addition of the amino acid glutamine to promote enteric sodium uptake and sustain villus form and function. A high-calorie oral rehydration solution with glutamine was more effective in correcting plasma, extracellular fluid and blood volume than solutions without (one WHO-type solution and two high-glucose but glutamine-free solutions) using an *Escherichia coli* model (Brooks *et al.*, 1997).

In summary, an oral rehydration solution should be judged on the composition of the solution in mmol/l and not on a dry matter percentage basis. The sodium

concentration should not exceed 130 mmol/l. The bicarbonate concentration (usually as a precursor such as citrate, acetate or propionate) should be in the region of 80 to 120 mmol/l. The role of glycine may be overstated with respect to sodium transport but it aids palatability. High-energy-containing oral rehydration solutions, with glucose concentrations up to 375 mmol/l, limit liveweight loss during diarrhoea and should be considered if milk is withheld for more than two days. The addition of glutamine to the oral rehydration solution appears to offer numerous advantages over other solutions (Brooks *et al.*, 1997).

Treatment with oral rehydration solutions: As detailed above, there is an almost bewildering list of oral rehydration solutions which can be used to treat diarrhoeic calves, each supported by its own experimental and clinical database. For veterinary practitioners presented with a recumbent calf with severe metabolic acidosis, the most critical treatment is appropriate intravenous fluid therapy. No oral rehydration solution will correct the moderate to severe base deficit in these profoundly weak and recumbent calves. Within six to eight hours of the start of intravenous fluid therapy the calf should be much improved, with return of the suck reflex. This clinical improvement indicates that the acidosis has been largely corrected, but to counter ongoing losses 1 litre of a high-calorie oral rehydration solution with a high alkalinizing ability should be offered eight times daily (note: this may be twice the recommended rate detailed in the product data sheets). The presence of a vigorous suck reflex is the best indicator that the calf is recovering and is a more important factor than the continued production of fluid faeces.

The calf should be returned to a milk diet as soon as possible, and this should be a complete change. The milk must not be diluted with an oral rehydration solution. Typically, when milk is added to the diet, the calf will continue to have profuse diarrhoea for a few days but it will possess a strong suck reflex, be bright and alert with no signs of weakness. Assessment of the calf's recovery based upon demeanour, activity and appetite is more important than the negative aspect of the continued production of fluid faeces.

Traditionally, milk was withheld from diarrhoeic calves until solid faeces were passed, which often did not occur until after four or more days of administration of only oral rehydration solutions. This calorific deprivation led to considerable body condition loss and a protracted convalescence. Some clinicians recommend that milk and an oral rehydration solution are alternated every two to four hours during the early convalescent phase, thereby largely overcoming the calorie deficit but still retaining the benefits of the oral rehydration solution. Oral rehydration solutions with an

increased glucose content as energy source should be chosen if the calf is fed only oral rehydration solution for more than 24 hours (third or fourth generation oral rehydration solutions).

Antibiotics: Antibiotics are frequently employed in the treatment of diarrhoeic calves despite the fact that significant bacterial causes are limited to age-specific periods within the first four days (*enterotoxigenic E. coli*) and at over three weeks old (*Salmonella* spp.). Unsupervised widespread use of antibiotics prescribed by veterinary surgeons for the treatment of calf diarrhoea has been claimed to result in an increased prevalence of multiple resistant enteropathogens in humans, which cautions against their use except for specific bacterial causes (see also p. 210).

Enterotoxigenic E. coli do not display a high degree of antibiotic resistance and the commonly used antibiotics such as trimethoprim-sulpha are effective. Such calves do not develop a bacteraemia and oral antibiotic administration is preferable. Many *Salmonella* spp. infections result in bacteraemia with localization in the lungs, joints and growth plates. Antibiotic selection should be guided by bacterial isolation and antibiotic sensitivity testing. Improved biosecurity and hygiene, and possibly dam vaccination, should all be considered to control salmonellosis in neonatal calves, thereby reducing the need for antibiotic therapy. The use of fluoroquinolone antibiotics to treat salmonellosis in calves should be carefully considered and employed only where there is no alternative antibiotic.

The use of antibiotics in rotavirus diarrhoea is not indicated, but care must be taken not to overlook focal bacterial infections. Indeed, it is possible to overlook early cases of bacterial polyarthritis and meningoencephalitis, but such infections generally appear in calves less than six days old whereas rotavirus infection causing recumbency and stupor occurs in calves more than eight days old with a history of diarrhoea for the past two days or more.

Following intravenous fluid therapy it is important that the catheter is removed within 24 hours to reduce the risk of thrombophlebitis; parenteral antibiotics should not be necessary simply because the jugular vein has been catheterized.

Non-steroidal anti-inflammatory drugs: Non-steroidal anti-inflammatory drugs (NSAIDs) such as flunixin meglumine and ketoprofen have been recommended for diarrhoeic calves but have not been fully evaluated as a supportive treatment. Some reports refer to reduced severity of scouring following flunixin injection while other clinicians comment that dehydrated calves must not be given NSAIDs.

Protectants: Protectants, e.g. kaolin and pectin mixtures, are used as an adjunct to treatment but their value in serious cases is doubtful.

Convalescence

Convalescence from rotavirus-induced diarrhoea is often protracted because of physical loss of absorptive capacity of the small intestine. The villus epithelial cells are lost, resulting in stunted villi (Fig. 14.11). These lining cells are initially replaced with undifferentiated squamous and cuboidal cells, and only later replaced by specialized absorptive columnar cells. Extended oral administration of certain antimicrobials may prolong this delay to normal absorptive capacity.

Management

The management of an outbreak of rotavirus diarrhoea, once it has been diagnosed, should be based on the twin concepts of reducing exposure to infection and enhancing resistance to infection by ensuring passive transfer of specific antibody induced by timely vaccination of the dam (see p. 1006). Good hygiene will not be successful in controlling spread of infection because rotavirus is endemic and highly infectious, but it will help to reduce the build-up of infection throughout the calving period and thus reduce the infectious challenge to which calves are exposed; several studies have recorded beneficial results from good hygiene.

Unlike dairy herds, most beef cattle have a seasonal calving pattern with over 90 per cent of the cows calving during a nine week period, which presents problems with stocking levels in farm buildings and calving accommodation. Beef cattle should calve outdoors wherever possible. Newly-calved cows and their calves should be moved to clean pastures as soon as possible after birth. The stocking density on these pastures should be kept as low as practicable to prevent environmental contamination and build-up of infection. Problems with rotavirus diarrhoea usually appear during the second half of the calving period and are often associated with adverse weather conditions during early spring or late autumn, when young calves are crowded in sheltered areas of the field facilitating build-up of infection. Infection builds up rapidly in housed beef herds where poor building design and lack of sufficient straw bedding material aggravate overstocked conditions. The provision of a dry, well-bedded creep area for calves may reduce the level of challenge but is not sufficient to prevent disease.

To assist good hygiene, calving accommodation and calf pens on dairy farms should be designed for ease of cleaning and with adequate drainage. An 'all-in, all-out' policy should be adopted where possible, especially in

units rearing purchased calves. Pens should be cleaned between batches, steamed, disinfected and allowed to dry.

Disinfectants that have been reported to be effective against rotavirus are 0.25 per cent formaldehyde, 2 per cent phenol, 1 per cent sodium hypochlorite, 0.25 per cent propiolactone, quaternary ammonium compounds and iodophores. Mixing calves of different ages should be avoided and stress should be limited by staggering management interference such as castration, disbudding and changing of accommodation.

Bovine coronavirus

The agent

Bovine coronavirus (BCV) is a member of a group of viruses with a characteristic morphology seen in the electron microscope (Fig. 14.13). The virions, which contain single-stranded polyadenylated RNA, are pleomorphic spherical particles 70 to 220 nm in diameter with a corona of widely spaced club-shaped surface projections (peplomers), which are 20 nm long. Bovine coronavirus has two types of peplomer of different length. There is only one serotype of bovine coronavirus.

Signs

Calves usually become infected with coronavirus when they are between one and three weeks old, although disease may occur in calves up to three months of age. Transmission of infection is by the faecal-oral route. Calves develop diarrhoea in a manner virtually

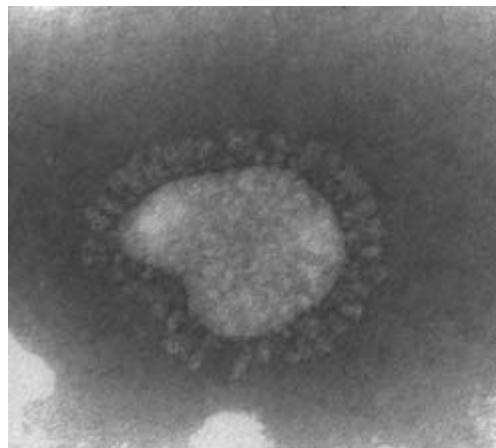

Fig. 14.13 Transmission electron micrograph of a single particle of bovine coronavirus. The particle has an irregular shape and is covered by a corona of peplomers. (Courtesy of Dr J.C. Bridger, Royal Veterinary College, University of London.)

identical to rotavirus; studies of experimental inoculations suggest that the incubation period is 20 to 30 hours. Generally, coronavirus diarrhoea is more watery and of greater severity than rotavirus diarrhoea, leading more rapidly to dehydration and acidosis. The severe diarrhoea also leads to substantial losses of sodium, potassium, chloride and bicarbonate ions. Fluid yellow faeces are passed at first and these turn to a yellow liquid containing milk clots and mucus.

Pathogenesis

Bovine coronavirus infects mature enterocytes located on the surface of villi and epithelial cells of the upper respiratory tract. The small intestine is severely damaged due to sloughing of infected cells, especially the ileum, and cells on the surface and in the crypts of the large intestine are also killed. Infection of the upper respiratory tract does not appear to cause lesions. Virus particles are assembled in the cytoplasm by a budding process through the rough endoplasmic reticulum. They are subsequently transported through and accumulate in the Golgi complex and are released from the cell by lysis. The range of lesions seen in the small intestine is identical to those produced by rotavirus and repair can occur rapidly because small intestinal crypt cells are largely unaffected. Virus damage to colonic crypt cells results in atrophy of the mucosal ridges and dilated crypts containing dead exfoliated cells. The mechanisms by which the intestinal damage caused by bovine coronavirus results in diarrhoea are thought to be the same as described for rotavirus. The presence of severe lesions in the ileum, caecum and colon, areas of the small and large intestine that absorb water, may account for the more watery nature of the diarrhoea seen in BCV infections. It is not clear whether or not strains of BCV vary in virulence, as is seen in bovine rotaviruses.

Prevention

There are two inactivated vaccines available in the UK which combines coronavirus, rotavirus and *E. coli* K99 to provide protective antibody in colostrum and early milk. The vaccines are administered 12 to 13 weeks before the anticipated calving date.

Diagnosis

Bovine coronavirus is universally present on all cattle farms, as indicated by the presence of antibodies in all adults. Diagnosis of coronavirus disease, like that of rotavirus disease, is based on the detection of virus or virus antigen in intestinal tissue or faeces. Assays using ELISA have been developed for detection of bovine

coronavirus and are used by diagnostic laboratories. The existence of bovine coronavirus excretion by clinically normal calves is recorded, although it is not seen as commonly as is rotavirus.

Management

An outbreak of BCV diarrhoea should be managed in the same way as an outbreak of rotavirus diarrhoea; that is, aim to reduce exposure to infection and enhance resistance to infection by vaccination of the dam and ensuring adequate passive antibody transfer (see p. 1006).

Sick calves should be moved to isolation facilities to help prevent a build-up of infection and to facilitate the provision of rehydration therapy. Diarrhoea induced by BCV is often more watery than that caused by rotavirus, possibly because the colon is less able to absorb water because it is damaged by the infection. The watery diarrhoea is likely to lead to severe dehydration and rehydration therapy as outlined for rotavirus is indicated (see pp. 195–6).

Calici-like virus (Newbury agent)

Particles of calf calici-like virus measure approximately 33 nm in diameter and have an indefinite feathery outline with dark hollows on the surface. Some particles have a 10-spiked sphere morphology. The virus was first detected in faeces of calves with diarrhoea and the pathogenic process has been studied in gnotobiotic calves. As far as is known, the disease is confined to the unweaned calf, although a gnotobiotic calf aged 60 days was susceptible to infection and disease. In gnotobiotic calves, clinical signs of enteric disease are identical to those seen in rotavirus infections and the lesions are comparable to those produced by rotavirus and BCV.

Two antigenically distinct isolates of Newbury agent have been identified and infection with either virus did not protect against clinical illness following infection with the other virus three weeks later. There are no specific diagnostic tests for the calf calici-like viruses, other than electron microscopic examination of faeces concentrated and purified by ultracentrifugation. They might be suspected as the aetiological agent in cases that appeared clinically similar to rotavirus, but are negative for rotavirus and other enteropathogens. Calves with diarrhoea caused by a calici-like virus may be managed as though they were infected with rotavirus.

Astrovirus

Astrovirus is a descriptive name for viruses with a star-like pattern on their surface in the electron microscope. They have a diameter of 28–30 nm and contain single-stranded RNA. Astroviruses have also been detected in

faeces of lambs with diarrhoea where the virus infected enterocytes causing mild villus stunting in the mid small intestine. Astroviruses have been detected in calf faeces in association with diarrhoea but experimental infection of gnotobiotic calves with astrovirus did not cause diarrhoea. Nevertheless, antibodies to astrovirus are widespread in cattle sera, having been found in 11 out of 22 herds in the UK and in 30 per cent of cattle sera examined in the USA. Recently, astroviruses were shown to infect and damage the specialized epithelium of the dome villi (Fig. 14.14) in the Peyer's patches of calves. These calves did not develop diarrhoea, but severe diarrhoea occurred in mixed infections of astrovirus and rotavirus or astrovirus and Breda agent. It is probable that astrovirus are not pathogenic on their own, but may increase the severity of the disease produced by other enteropathogenic viruses. There are no routine tests to detect astroviruses in faeces, but in the research laboratory they can be identified by electron microscopic examination of faeces concentrated by centrifugation.

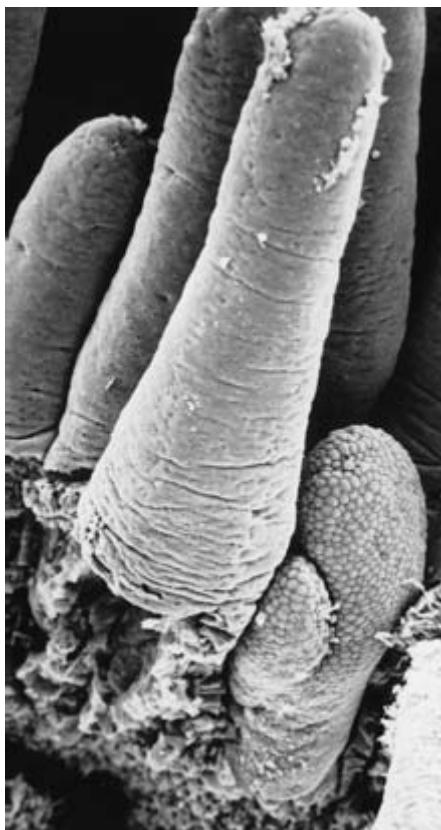

Fig. 14.14 Scanning electron micrograph of calf small intestine illustrating absorptive villi and a dome villus covered by a characteristic epithelium, which is thought to be specialized for antigen uptake and which has been shown to be susceptible to infection and damage by bovine astroviruses.

Breda virus

This virus was first described as causing calf diarrhoea in the USA in 1982. Lesions were similar to those produced by coronavirus. Jejunal and ileal villi were stunted and there were crypt abscesses in the small intestine and particularly in the colon. There were areas of necrosis of the surface epithelium of the colon.

There are no tests available commercially which detect Breda virus in faeces. Electron microscopy of faeces and thin sections through ultracentrifuge pellets may be used in the research laboratory and, because all isolates of Breda virus possess common antigens, antibodies to these can be used in an immunofluorescent test of intestinal sections and in an ELISA test. Examination by ELISA of over 200 faeces from UK calves with diarrhoea failed to detect Breda virus. However, in a separate study, antibodies to Breda virus were detected in 55 per cent of cattle sera.

Escherichia coli

Three groups of *E. coli* have been identified that appear to cause diarrhoea in calves. Strains that elaborate a heat-labile enterotoxin or a heat-stable enterotoxin are called the enterotoxigenic *E. coli* (ETEC). A second collection of strains exists that colonize the small intestinal mucosa and cause diarrhoea, but do not elaborate enterotoxins. Characteristically, these strains attach closely to the luminal surface of enterocytes, often in cup-shaped depressions or on cytoplasmic protrusions, described as 'pedestals'. This attachment of bacteria to the enterocyte surface usually results in the microvilli being effaced and the lesion has been named the 'attaching and effacing' (AE) lesion (Fig. 14.15). Comparable strains cause diarrhoea in children and are called enteropathogenic *E. coli* (EPEC). It is appropriate to use this term for equivalent calf strains, but care is required because the term enteropathogenic *E. coli* has been used in the veterinary literature for many years to describe strains associated with diarrhoea, regardless of their pathogenic mechanism.

A third group of strains colonizes the surface of the large intestine and causes a mild dysentery. These strains also cause AE lesions but because they cause blood to be lost into the lumen of the large intestine, they are called enterohaemorrhagic *E. coli* (EHEC); once again comparable strains cause a similar disease in children. Some EPEC and EHEC, but not all, produce a toxin that kills Vero cells *in vitro* and is called Verocytotoxin (VT) or Shiga-like toxin (SLT). This toxin does not cause AE lesions, but is probably involved in the pathogenic process. *Escherichia coli* that produce VT are referred to as VT+ *E. coli* or VTEC. VTEC have been isolated from calves with diarrhoea,

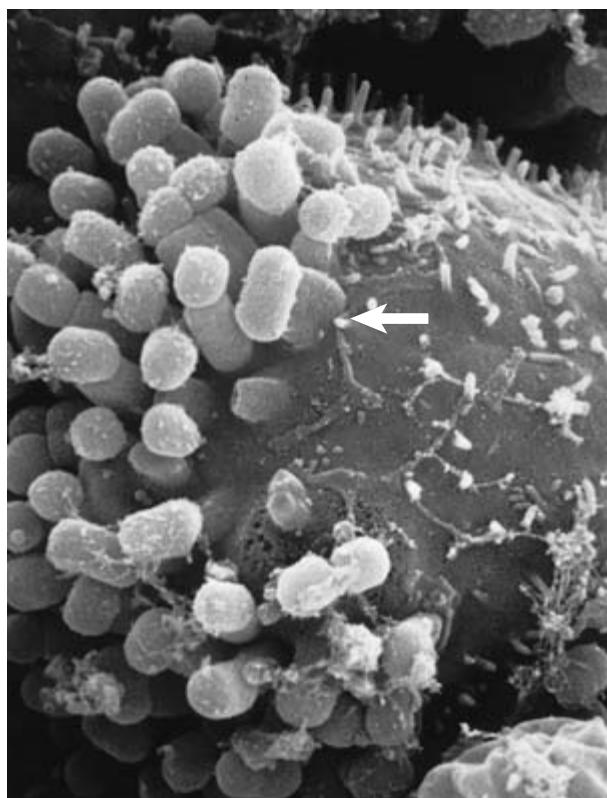

Fig. 14.15 Scanning electron micrograph of an enterocyte in the colonic mucosa of a gnotobiotic calf inoculated experimentally with an enterohaemorrhagic *E. coli* (strain S102–9). Bacteria are attached closely to the surface of the enterocyte, often on 'pedestals' (arrow) and the microvilli have been effaced.

but they may also be present in the faeces of healthy calves. In an epidemiological study, they were found to be as common in the faeces of healthy calves as in the faeces of calves with diarrhoea. Therefore, designation of an *E. coli* as a VTEC may not necessarily define it as an isolate capable of causing diarrhoea and demonstration of a VTEC in the faeces of a calf or calves with diarrhoea does not constitute a diagnosis of the cause of the diarrhoea.

Enterotoxigenic E. coli

Enterotoxigenic *E. coli* most commonly cause diarrhoea in calves under four days old. In experimentally infected newborn calves the incubation period is 12 to 18 hours. Calves are depressed and anorexic and rapidly dehydrate and die. In calves ETEC diarrhoea can be diagnosed clinically because it causes disease in very young calves and because it produces a very profuse and much more watery diarrhoea than any other of the calf enteropathogens.

Enterotoxigenic *E. coli* possess two virulence attributes (determinants) that distinguish them from non-pathogenic strains: ability to adhere to the mucosal surface of enterocytes and, as mentioned previously, ability to produce enterotoxins (see Fig. 14.4).

Adhesion is mediated by filamentous protein structures called fimbriae, sometimes called pili or adhesins, which bind to specific receptors on the enterocyte cell membrane. Adhesion mediated by fimbriae does not bring the bacterium in close contact with the enterocyte luminal surface as is the case of EPEC and EHEC. The microvilli are unaltered and 'cups' and 'pedestals' are not seen. The presence of receptors is affected by age, and susceptibility to infection is greatest in the newborn calf when expression of receptors is greatest. These fimbriae are antigenic and so many of them are known by their antigenic name (e.g. K99, F41). Their adhesive ability allows ETEC to overcome the peristalsis of the small intestine by sticking to the mucosal surface. The adhesion antigens commonly found in ETEC of calves are K99 and F41; they often occur together but may be present independently. K99⁺ strains are also capable of inducing diarrhoea in pigs, foals, lambs, goats and possibly other ruminants. Adhesion of the bacterium to the enterocyte surface confers another advantage to the bacterium because enterotoxins are released close to their receptor sites. The ability of ETEC to produce fimbriae and enterotoxins is determined by genes that are usually carried on a single plasmid and thus occur together. It is adequate, therefore, to diagnose ETEC infection by detecting either the enterotoxin or the adhesin.

Detection of adhesins forms the basis of the diagnostic tests for ETEC because they are easier to detect than enterotoxins. Special culture media may be required to encourage ETEC to express adhesins because, in general, K99 and F41 are poorly produced by bacteria *in vitro*, although they are readily produced by bacteria growing in the gut. Once expressed they can be detected using specific antisera in agglutination, haemagglutination or ELISA tests.

It is helpful to understand the mechanisms of absorption and secretion in the small intestine before considering how the enterotoxins produced by ETEC cause diarrhoea. Absorption occurs through the activity of the mature villus enterocyte. Sodium ions are transported out of enterocytes through the basolateral cell membranes into the basolateral spaces by an energy-dependent mechanism, the sodium pump. This creates a concentration gradient extending from the lumen into the enterocyte. Sodium ions, followed by chloride ions, diffuse along the concentration gradient from the lumen through the microvillous surface, assisted by a brush border carrier system. The osmolality in the basolateral spaces increases and water passes from the

lumen along the osmotic gradient (see Fig. 14.2). There are several carrier systems that assist the entry of sodium ions; one system does not utilize the products of digestion, another utilizes glucose, which is specifically absorbed through the luminal surface of enterocytes and each molecule of glucose carries with it a molecule of sodium. Chloride ions and water follow and this flow of water traps additional sodium and chloride ions by solvent drag (Fig. 14.2). Carrier systems for amino acids and citrate also transport sodium ions and water through the intestinal mucosa. These carrier systems, particularly the glucose carrier system, are particularly important in oral rehydration therapy. Secretion occurs from crypt cells; sodium passes into the intestinal lumen taking chloride and bicarbonate ions and water with it (Fig. 14.3). Cyclic-AMP stimulates this secretory activity.

The heat-stable enterotoxin (ST) is the enterotoxin usually produced by ETEC strains from calves. Two forms of ST occur (ST_A , and ST_B), but only ST_A occurs in calves. Both forms stimulate guanylate cyclase activity within enterocytes, causing increased levels of intracellular cyclic-GMP, which inhibits absorption by villous enterocytes but has no effect on secretion.

The heat-labile enterotoxin (LT), rarely produced by calf ETEC strains, is made up of two subunits. Subunit A stimulates adenylate cyclase activity within enterocytes. Subunit B assists entry of subunit A into enterocytes. Adenylate cyclase raises the levels of cyclic-AMP in mature villous enterocytes and crypt cells. In mature villous enterocytes, cyclic-AMP inhibits the independent pathway for the absorption of sodium ions and therefore of chloride and water (see Fig. 14.5). In crypt cells, it stimulates sodium secretion, which takes with it chloride and water (see Fig. 14.6).

Although the main mechanism for the pathogenesis of diarrhoea is attributed to enterotoxins, which do not cause visible damage to the gut, experimental infections of gnotobiotic and conventional calves, both colostrum fed and colostrum deprived, have revealed a pathology associated with ETEC infections that probably contributes to the development of diarrhoea. Villi become stunted and fused together and the enterocytes change shape from columnar to cuboidal. These cells are probably immature enterocytes and these changes indicate an increased rate of enterocyte loss.

Immunoprophylaxis against ETEC-induced diarrhoea is based on the use of immune colostrum. Dam vaccination is used to stimulate high levels of antibody in the colostrum and this approach is particularly successful because calves are susceptible to this disease for only the first few days of life when colostrum is fed. Vaccines containing the K99 fimbriae, or dead bacteria with the K99 antigen expressed on the surface, are used

because adhesion is an important component of the pathogenic process.

It is possible to recognize clinically an outbreak of calf diarrhoea caused by ETEC because of the severity and age group of calves affected. An outbreak characterized by the rapid onset of severe, very watery diarrhoea, which quickly causes dehydration and collapse and which is frequently fatal and occurs in calves that are less than 96 hours old, is likely to be caused by ETEC. In some circumstances, calves may die before there is evidence of profuse diarrhoea. There is rapid and severe dehydration. The calf quickly becomes recumbent. Sequestration of fluid in the abomasum and intestines gives the abdomen a bloated appearance which 'sloshes' on succussion. The rectal temperature may be elevated in the early stages but rapidly falls to subnormal. Affected calves are rarely acidotic. Faecal bacteriology will confirm the diagnosis. ETEC diarrhoea is not common in the UK (less than one per cent of calf diarrhoea outbreaks), but outbreaks have been associated with poor housing and management at calving.

There are a number of possible causes of recency in neonatal calves which must be excluded from the differential diagnosis list, including congenital heart defects, rupture of liver/spleen following dystokia and bilateral femoral nerve paralysis. Atresia coli/ani cases present with increasing abdominal distension, progressive weakness and dehydration leading to recency. Septicaemia and bacterial meningoencephalitis are also commonly encountered in calves less than four days old. Congenital neosporosis has also recently been reported as a cause of recency in neonatal calves.

The immediate response must be rapid isolation and treatment of sick calves by rehydration with an electrolyte solution. Acidosis is not a feature of diarrhoea in calves less than six days old and spiking intravenous fluids with bicarbonate is not indicated in calves with enterotoxicogenic *E. coli* infections. Rehydration may be given by intravenous infusion if the calf is unable to feed; intravenous infusions may be changed to oral administration as the calf recovers strength. Less severely dehydrated calves may be treated only by oral rehydration. The biochemistry of oral rehydration has been discussed earlier (pp. 197–8). Oral antibiotics should be administered to all calves at birth in the face of an outbreak until the vaccine administered to all remaining pregnant cattle can provide protective immunoglobulins in the colostrum. Antibiotic resistance is not a problem in such outbreaks thus antibiotic selection is not critical to a successful outcome. Fluid therapy is the first priority because calves may die of dehydration before any beneficial effects are obtained from antibiotic therapy.

Following immediate management of an outbreak with fluid therapy and antibiotics, it is essential to

introduce dam vaccination (see p. 1006). It should be possible to eliminate the infection from the herd with the use of antibiotics, dam vaccination and good hygiene. ETEC with the K99 antigen are absent from most farms and disease prevention should concentrate on exclusion of the infection by good herd biosecurity.

Enteropathogenic E. coli, enterohaemorrhagic E. coli and verocytotoxin-producing E. coli

There are no specific clinical signs of diarrhoea caused by EPEC and VTEC although a yellow watery diarrhoea has been reported. The mean age of calves with diarrhoea caused by EHEC was 15 days. Calves maintained a normal appetite and did not develop pyrexia, but a mild diarrhoea containing blood was seen. In prolonged cases there was dullness, signs of abdominal pain, dehydration and weight loss.

Although the EPEC, EHEC and VTEC are capable of causing diarrhoea in calves and have been associated with outbreaks of disease, it is difficult to diagnose their specific involvement. Presence of frank blood in the faeces is suggestive of EHEC, especially if salmonellas and cryptosporidia are not isolated from faeces. The presence of these enteropathogens will be suggested by the failure to find other agents and possibly by the finding of *E. coli* in association with the mucosa of the small or large intestine.

Clinical signs of septicaemia

In many situations it can prove difficult to differentiate the cause of the calf's depression, lethargy and weakness between profound acidosis or early septicaemia/bacterial meningoencephalitis. Most septicaemic calves are less than six days old and this age prevalence differs from the typical occurrence of viral-induced diarrhoea and acidosis (more than eight days old). Septicaemic calves usually present with episcleral injection, toxic mucous membranes and evidence of multi-organ system involvement such as joints, respiratory tract and eyes. Pyrexia above 39.5°C is not a consistent finding in septicaemic calves while diarrhoea is often only present during the terminal stage of illness.

Lumbar cerebrospinal fluid (CSF) collection and visual inspection of the turbid sample on farm enables immediate diagnosis of bacterial meningoencephalitis and appropriate aggressive antimicrobial therapy (Scott & Penny, 1993). This sampling procedure is recommended in those cases where the clinician is unsure of the diagnosis. On-farm collection of lumbar CSF in depressed calves is a simple procedure which only requires a knowledge of the bony landmarks and an appropriate length hypodermic needle without stylette (see p. 896). With appropriate aseptic precautions, there

is little risk of spinal meningitis. Selection of a narrow gauge hypodermic needle, and removal of only 1 to 2 ml of CSF, will greatly reduce any risks associated with sudden release of CSF pressure.

***Campylobacter spp.* (see p. 852)**

The related campylobacters, *Campylobacter jejuni* and *C. coli*, have been recognized recently as important enteric pathogens in humans. They are the most common cause of diarrhoea in developed countries and they are one of the three most common causes of human diarrhoea in developing countries; *E. coli* and rotavirus are the other two enteropathogens of major importance. Recognition of the importance of campylobacters followed marked improvements in culture techniques that improved isolation and identification from faeces. They have been isolated from healthy and diseased domestic animals and poultry for many years and, not unexpectedly, the most common sources of infection in human outbreaks are fresh poultry, minced meat and unpasteurized milk.

The recognition of animal products as the source of human infection has prompted a reassessment of the importance of *C. jejuni* and *C. coli* in causing enteric disease of farm animals. Since the 1930s, campylobacters have been thought of as the cause of an enteric disease of housed adult cattle in the winter-syndromes referred to as 'winter dysentery', 'winter scours', 'vibrionic enteritis'. The above association has, however, been questioned and more recently a coronavirus has been implicated as the cause of winter dysentery (see p. 852). The association of campylobacters with calf diarrhoea has been examined in experimental infections and in case-control studies of field outbreaks. The results have shown that *C. jejuni* is present on all farms and most case-control studies have failed to demonstrate an association between excretion of this organism and calf diarrhoea. In the majority of experimental studies, inoculation of calves with *C. jejuni*, even using high doses, resulted in colonization without diarrhoea. *Campylobacter jejuni* may be detected in up to 80 per cent of weaned calves, indicating that isolation of this organism from calves with diarrhoea does not constitute a diagnosis. *Campylobacter coli* is less commonly isolated from cattle and experimental inoculations and case-control studies indicate clearly that it is non-pathogenic. *Campylobacter fetus* subsp. *fetus* and *C. hyoilectinalis* are also commonly isolated from cattle of all ages, but most evidence suggests that they are not a cause of intestinal disease.

***Cryptosporidium parvum* (see p. 286)**

Cryptosporidium parvum is an enteric coccidia recognized commonly in calves and lambs and is a zoonosis.

The organisms are spherical or ovoid parasites that adhere to the microvilli of enterocytes, particularly in the ileum, but also in the large intestine. Cryptosporidia exhibit three important differences from other enteric coccidia: excreted oocysts are directly infective to new hosts, cryptosporidia are not host specific so that infection can spread between mammalian species, including man, and finally they are unaffected by most existing anticoccidial drugs (see pp. 206, 1029).

The life cycle commences with the ingestion of oocysts containing sporozoites, which become trophozoites. In the asexual phase of the life cycle the trophozoites mature to schizonts containing eight merozoites, which are liberated and infect new enterocytes to form a second generation of merozoites. In the sexual phase, macrogametes fuse with microgametes and give rise to zygotes, which form oocysts. Sporozoites form within oocysts in the intestinal lumen or whilst they are still attached to the surface of enterocytes so that oocysts excreted in the faeces are directly infective to new hosts without an obligatory period of maturation outside the host body. Consequently, infection can spread rapidly within a group of calves and the pattern of spread is

similar to that seen with rotavirus and not similar to that seen in *Eimeria* spp.

Cryptosporidiosis is seen in neonatal calves, usually when they are aged one to two weeks (peak 11 days old), at about the same time as they develop rotavirus diarrhoea. Most calves appear to become infected, but not all develop diarrhoea. Subclinical infections are not thought to be the result of passive protection by colostral antibodies because experiments have shown that antibodies that are fed are not protective; subclinical infections remain unexplained. Experimental infections indicate an incubation period of two to five days and close association between occurrence of diarrhoea and excretion of oocysts. Depression and anorexia accompany the profuse watery green diarrhoea, which contains mucus and occasionally blood. Diarrhoea may be intermittent and lasts two to 14 days (usually about seven) and causes dehydration which often requires treatment with oral rehydration solutions. Morbidity is usually high and mortality low, although some outbreaks have been associated with high mortality.

Infected mucosae (Fig. 14.16) are congested and villi are stunted in the ileum. Enterocytes in the small and

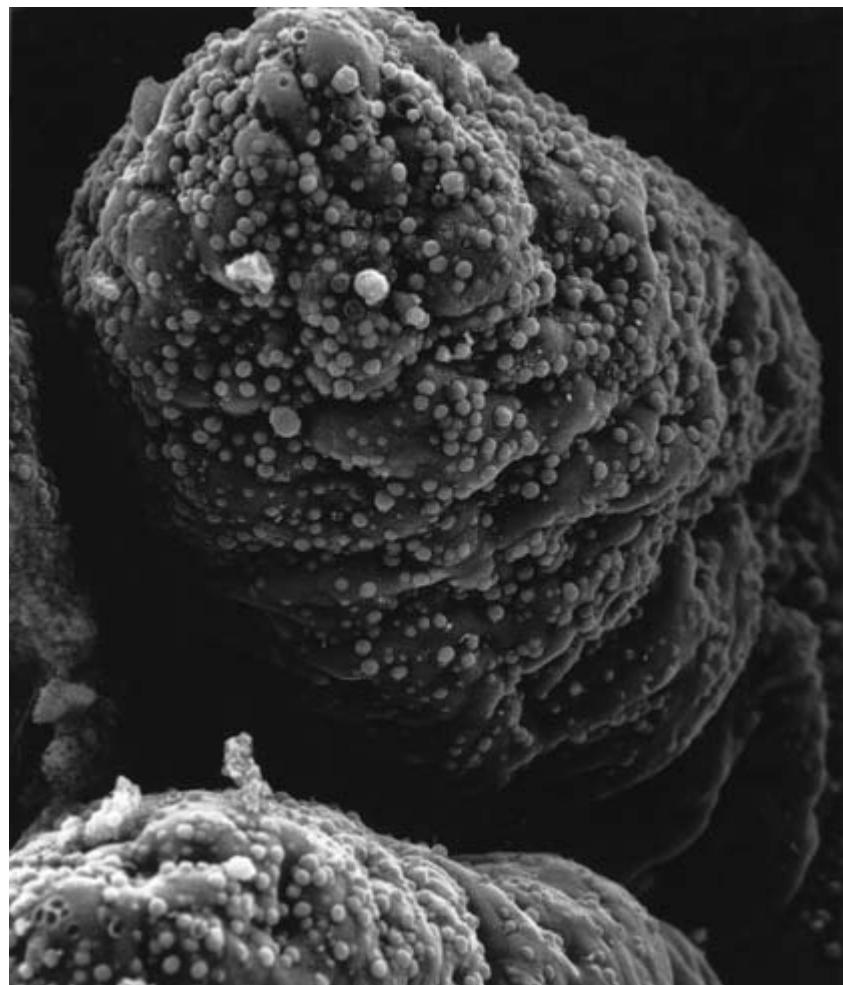

Fig. 14.16 Scanning electron micrograph of the ileal mucosa of a calf naturally infected with *Cryptosporidium parvum*. The surface of the villi is heavily infected and partially exfoliated enterocytes are present at the tip of the villus.

large intestines become cuboidal or squamous and crypts may become dilated and filled with exfoliated cells and neutrophils. The lamina may become infiltrated with mononuclear inflammatory cells, neutrophils and eosinophils. Cryptosporidia appear to cause diarrhoea by destroying mature enterocytes, but by an unknown mechanism. The population of mature enterocytes is reduced in size and numbers of immature cells are increased. Mucosal lactase activity is markedly depressed and there is reduced ability to digest and absorb food. Intestinal secretion may be enhanced due to the increased numbers of secretory cells in the mucosa. The self-limiting nature of natural and experimental infections and the widespread detection of antibodies indicate that immune responses occur that are protective. No further information is available on immunity.

Cryptosporidiosis can be diagnosed by detection of oocysts in faecal smears but more reliable results are obtained from stained gut sections. However, such material is rarely available due to the low mortality. Several staining methods are available, of which the Giemsa stain, the modified acid fast method and auramine are the most widely used. Alternatively, mucosal smears of ileum may be stained with Giemsa or histological sections of ileum stained by haematoxylin and eosin. The histological method is of little value if autolysis is advanced because the enterocytes will have sloughed from the mucosal surface. The most reliable method is to make and stain smears of oocysts concentrated from faeces using flotation techniques.

Management of an outbreak presents problems; although a large number of chemotherapeutic agents have been tested for efficacy against *Cryptosporidium*, only halufuginone has been found to be effective. Most workers recommend high levels of hygiene as the best approach to control, but oocysts are extremely resistant to a variety of disinfectants, including iodophor, cresylic acid, sodium hypochlorite, benzylkonium chloride, sodium hydroxide and aldehyde-based disinfectants. Ammonia and formalin are effective disinfectants. The organism is susceptible to freezing and thawing and to temperatures over 50°C. Steam cleaning is strongly recommended.

Investigating an outbreak of calf diarrhoea

The investigation should start with a farm visit to examine the calves clinically and establish a picture of calf husbandry and of the outbreak. Enterotoxigenic *E. coli* diarrhoea can be suspected on the basis of age of affected calves. Faeces, not rectal swabs, should be collected as soon as possible after the onset of diarrhoea

and before treatment commences and should be examined for rotavirus, coronavirus, *Cryptosporidium* and *Salmonella* spp. Samples from very young calves with watery diarrhoea should be tested for K99⁺ *E. coli*. Faeces should be collected from affected calves and age-matched healthy calves on the farm, a minimum of four calves in each category. Faecal collection should continue if the outbreak persists to monitor for changes in enteropathogens being excreted.

Where a problem persists, or no diagnosis has been reached, samples may be sent to a research laboratory for examination by electron microscopy or for the detection of EPEC, EHEC and VTEC. A post-mortem examination of a calf submitted alive to a laboratory may help to elucidate the significance of results of faecal examination and indicate the presence of other agents not detected by faecal examination. Laboratories are frequently asked to assist in the diagnosis of the aetiology of calf diarrhoea outbreaks on the basis of samples submitted from one or two calves only. Clearly this is pointless, because diagnosis of disease caused by an endemic agent is based on the detection of the agent in a higher percentage of the faeces of calves with diarrhoea than in healthy calves on the same farm. Where data are not available from healthy calves on the same farm, results from other studies may be considered. Rotavirus and cryptosporidia have rarely been found in more than 50 per cent of randomly selected healthy calves and coronavirus is usually detected in less than 25 per cent. Figures above these values may be taken as a tentative diagnosis.

Salmonellas, which may be suspected clinically, are often only detected qualitatively. Merely isolating these bacteria is relatively meaningless; quantitative bacteriological techniques should be used to demonstrate excretion of large numbers of bacteria from calves with diarrhoea. It is only worth looking for K99 adhesins where the outbreak is suggestive of ETEC, i.e. if calves under four days of age are affected and there is severe watery diarrhoea.

Epidemiology

On a farm basis, the infectious agents that have been associated with neonatal calf diarrhoea can be divided into three groups: those infections that are usually absent but may be introduced and cause an outbreak of disease (ETEC, *Salmonella* spp.); the ubiquitous agents (rotavirus, coronavirus, and cryptosporidium) that are invariably present on every farm; and those agents for which inadequate epidemiological data are available (Breda virus and VTEC). Although there is evidence to support the view that all the above infectious agents are able to cause diarrhoea in calves, it is clear that their

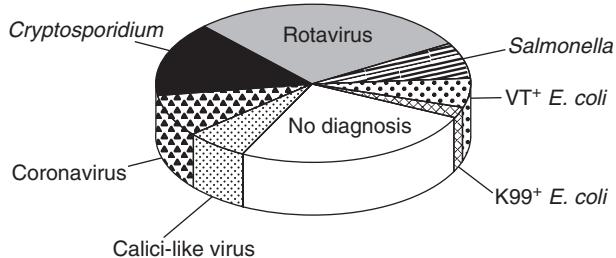

Fig. 14.17 Prevalence of pathogenic agents in calf diarrhoea.

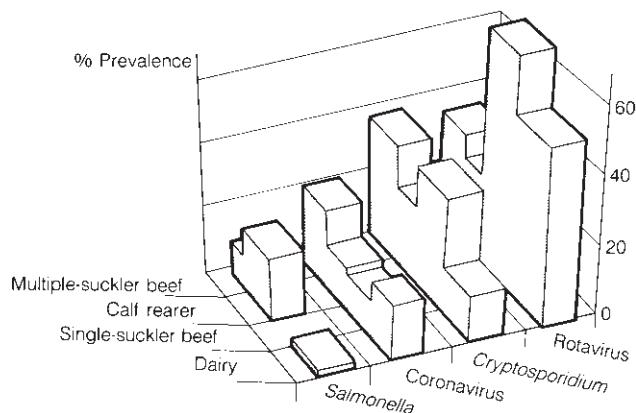

Fig. 14.18 Correlation of farm type with prevalence of pathogens in calf diarrhoea. Reproduced from Morgan (1990).

presence in the intestinal tract does not inevitably lead to disease and they are not all equally important in the aetiology of calf diarrhoea.

The prevalence of these agents in calves with diarrhoea in southern Britain, as determined from 45 outbreaks of calf diarrhoea, is shown in Fig. 14.17 (Reynolds *et al.*, 1986); another survey examined outbreaks in northern England and southern Scotland (Snodgrass *et al.*, 1986). Rotavirus was associated most frequently with calf diarrhoea and was most common on dairy farms and single-suckler beef units (Fig. 14.18). Cryptosporidia oocysts were associated with calf diarrhoea slightly less often than rotavirus and were more common in beef suckler units than in dairy farms. In southern England, salmonellas occurred in 25 per cent of outbreaks and were most often a problem for rearers of calves bought in from markets. Enteropathogens were not detected in 31 per cent of faeces of calves with diarrhoea. Rotavirus and cryptosporidia were excreted by up to 50 per cent of normal calves, and on the basis of this evidence an outbreak of rotavirus-induced or cryptosporidia-induced diarrhoea should only be diagnosed if more than 50 per cent of calves with diarrhoea are excreting either enteropathogen. Coronavirus was

detected rarely in clinically normal calves and it was invariably associated with disease, usually in outbreaks with high mortality. Results of two surveys show that diarrhoea caused by ETEC was uncommon in the UK at that time; this may still be the situation. Intermittent excretion of ETEC may occur throughout life, often unassociated with diarrhoea, making interpretation of diagnostic findings difficult and emphasizing the need for quantitative bacteriology.

These survey data have been reproduced by numerous monitoring organizations over the past 15 years which clearly indicates the important role of rotavirus and coronavirus in neonatal enteritis. Vaccination is highly effective against these viral causes of diarrhoea but the need for annual vaccination and perceived high cost have resulted in many beef calves remaining unprotected.

Mixed infections

With the recognition of enteropathogenic agents and the development of diagnostic tests, it has been possible to look at outbreaks of diarrhoea and at individual animals to assess the importance of mixed infections. Results of surveys of faeces of calves with diarrhoea indicate that although single infections may result in diarrhoea, the likelihood of diarrhoea occurring increases with the number of enteropathogens present. When 21 moribund calves with diarrhoea were examined in detail by necropsy, two or more enteropathogens were detected in 19 calves (Hall *et al.*, 1988). The most common combination of enteropathogens revealed by these studies has been rotavirus and cryptosporidia and the way in which these infections can overlap in rearing pens is illustrated in Figs 14.19 and 14.20. Studies of distribution of infection of the gut mucosa with these two agents and the severity of the lesions have shown that either agent, as a single infection, might not cause sufficient intestinal damage to cause diarrhoea, but together they could. A study of the intestinal pathology of normal calves that were excreting rotavirus showed that there were severe lesions in the anterior small intestine and mild lesions in the mid small intestine, but the lower small intestine and large intestine were normal (Reynolds *et al.*, 1985).

Cryptosporidia, however, infect and damage the lower small intestine and the large intestine, so that in a combined infection the cumulative damage would be sufficient to cause diarrhoea (Fig. 14.21). Similarly, if simultaneous infection with coronavirus and either rotavirus or calici-like virus occurred there would be cumulative damage because the former infects and damages the lower small intestine and large intestine, whilst the latter infects and damages the upper small

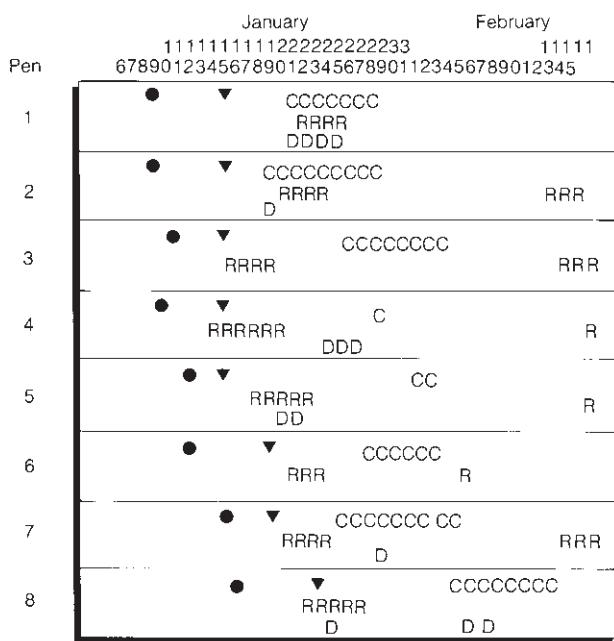

Fig. 14.19 The spread of rotavirus and *Cryptosporidium* between calves in adjacent pens. (●) Day of birth, (▼) day of move to rearing pens. C, *Cryptosporidium* excretion; R, rotavirus excretion; D, day of diarrhoea. Reproduced from Morgan (1990).

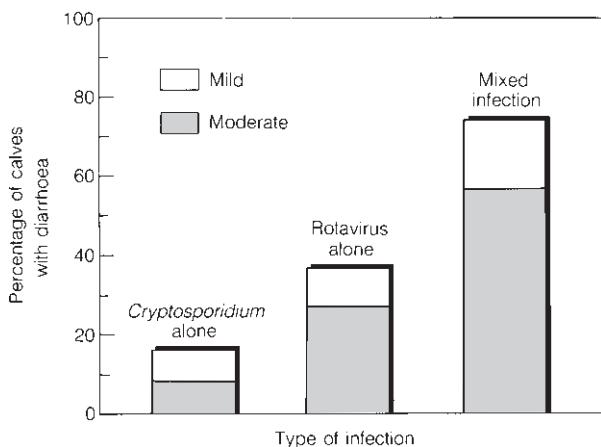

Fig. 14.20 Occurrence of diarrhoea in farm calves infected with either rotavirus or *Cryptosporidium* and in mixed infections.

intestine. The concept that mixed infections involving rotavirus, cryptosporidia, and coronavirus cause cumulative damage in the small and large intestines is based on information presently available concerning the predilection sites of these pathogens. There is, however, evidence that different strains of rotavirus and coronavirus may have different predilection sites within the small intestine and this could affect the development of cumulative damage.

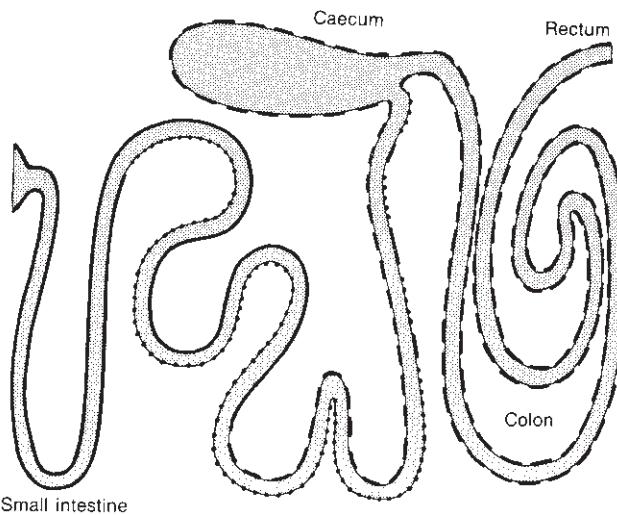

Fig. 14.21 Line drawing illustrating the small and large intestines of the calf and indication of those parts susceptible to infection by rotavirus (---) and those susceptible to infection by *Cryptosporidium* spp. (—). Reproduced from Hall (1989).

Many of the recognized enteropathogens infect and damage the small intestine and coronavirus, Breda virus, EHEC and cryptosporidia also damage the large intestine. However, assuming that diarrhoea is more likely to occur when both the small and large intestines are damaged, there is a need to study the infectious agents that damage the large intestine. Diarrhoea was often associated with infections and lesions throughout the small and large intestines in a study of the pathology of 21 calves with diarrhoea in southern Britain (Hall *et al.*, 1988); coronavirus and bacteria adherent to the mucosal surface were associated with the lesions in the large intestine. The results indicate that these bacteria, some of which were EHEC, were contributing to the development of diarrhoea. Evidence from field studies also suggests that mixed infections are important in the development of diarrhoea. In a longitudinal study of calves, from birth to weaning, only 15 per cent of calves that excreted *Cryptosporidium* sp. and 37 per cent of calves that excreted rotavirus experienced diarrhoea, but in calves in which the two infections occurred together, 75 per cent developed diarrhoea (Fig. 14.20).

Rotavirus and ETEC were the infectious agents first identified as able to cause diarrhoea in calves and, as a result, combined inoculations with these agents were studied by several groups. The interaction between these two agents was studied despite the fact that ETEC cause diarrhoea in calves that are less than 48 hours old, whereas the mean age of calves with rotavirus diarrhoea is ten days. The conclusions reached from these studies were that combined infections were more severe, although it was unclear whether this was due to additive effects or synergism.

Management of diarrhoea

The first priority is to treat fluid depletion, i.e. restore extracellular fluid volume so as to counter shock and acidosis.

Rehydration (see also p. 195)

Oral fluids are very satisfactory in the less severely affected animals. They are usually isotonic with plasma and contain sufficient K^+ and HCO_3^- to replace faecal losses and Na^+ and glucose in equimolar amounts. Such preparations are formulated to utilize the pathways of absorption of glucose, amino acids and citrate, which carry water with them. These formulations have been improved by inclusion of 80 to 100 mmol/l bicarbonate as a precursor, usually citrate, which is catabolized to give bicarbonate ions which helps to counter metabolic acidosis. Energy is supplied as glucose and citrate. More recently, oral rehydration solutions have been introduced which contain up to 375 mmol/l glucose in an attempt to counteract the energy deficit when milk is removed from the calf's diet. An oral rehydration solu-

tion containing glutamine, a simple amino acid and high levels of glucose has also recently been introduced with the claim that this combination will have a beneficial effect on mucosal architecture by reducing the severity of villous atrophy and promoting repair. Commercially prepared oral rehydration solutions are sophisticated formulations and should always be used.

As a rule of thumb, if the calf is weak and presents in lateral recumbency, use intravenous therapy; if it can lift its head but has no suck reflex, use intravenous therapy. If the calf can drink, offer electrolyte solution by teat and bottle as reluctance to suck may be the first indicator of septicaemia/bacterial meningoencephalitis. The calf should be fed every two to four hours and carefully monitored; loss of an active suck reflex indicates deterioration of the calf's condition and veterinary attendance is necessary without further delay.

The efficacy of oral rehydration varies with the type of diarrhoea. In secretory diarrhoea, the sodium glucose absorption system is unaffected by bacterial enterotoxins and glucose/electrolyte solutions are very effective in rehydrating the animal. Nevertheless, the diarrhoea continues and this should be stressed to the client (Fig. 14.22). The small intestine may be so

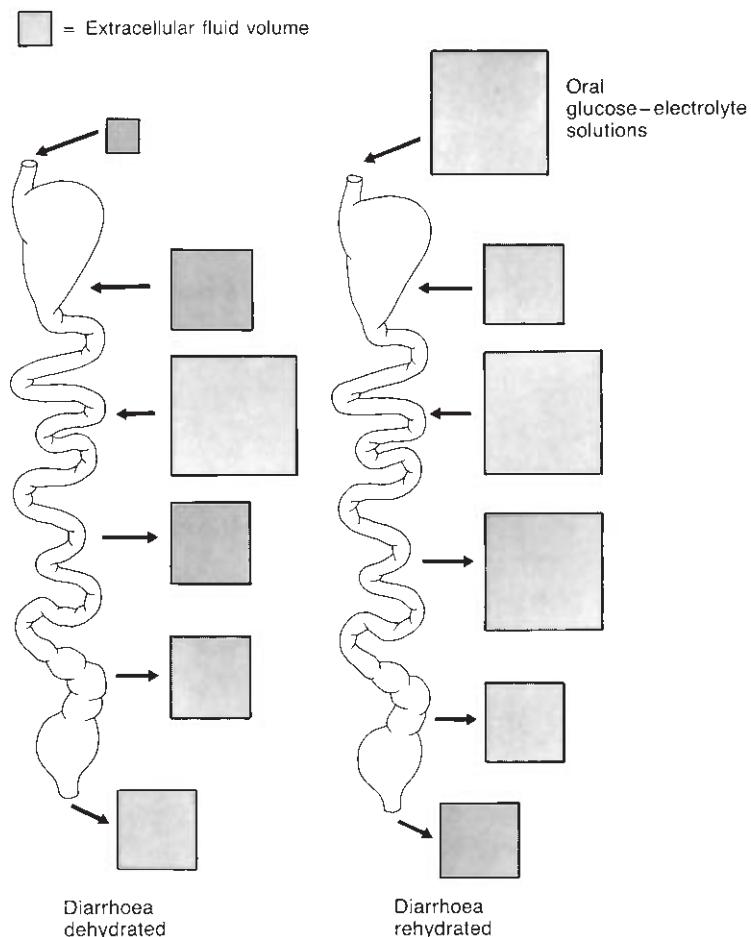

Fig. 14.22 Effect of orally administered glucose/electrolyte solution of fluid fluxes in secretory diarrhoea in the pig. Where glucose/electrolyte solution is not given, there is a net loss of water and dehydration develops. Where glucose/electrolyte solution is given, the diarrhoea continues but there is a net gain of fluid by intestinal absorption and rehydration occurs. Source: Argenzio (1984).

severely damaged in very severe viral infections that oral electrolyte solutions are ineffective. In less severe viral infections, for example many rotavirus infections of calves, sufficient functional surface may remain for oral electrolytes to be effective.

Nutrition

The energy requirements of a newborn calf are approximately 2500kcal/day, equivalent to 600g of glucose. The glucose content of 10 litres of an oral glucose/electrolyte solution containing 80mmol glucose is 144g, which does not supply sufficient energy but this can be largely overcome by feeding an oral rehydration solution containing 375mmol/l. A rational approach is to feed electrolyte solution alone for one to two days and subsequently alternate feeds of milk and electrolyte solution. While mixing electrolyte solution and milk does not appear to interfere with clotting of milk in the abomasum, this method is to be avoided if possible. With suckled calves, separate the calf and the cow, feed electrolyte and then allow the calf to suck the cow for approximately five minutes.

Drugs (pp. 189, 229)

In severe dehydration, rehydration must be the first priority. There are two situations where the use of antibiotics is indicated: infections with *Salmonella* spp. or with pathogenic *E. coli* (ETEC, EHEC and VTEC). Broad-spectrum antibiotics and antimicrobials have been used widely as a primary form of treatment of calves with neonatal diarrhoea, without sound reason in many cases. Most therapeutic trials for treatment of diarrhoeal calves with antibiotics have been uncontrolled or used small numbers of animals and have not, therefore, been convincing.

The disadvantages of using antibiotics are that some directly damage the intestinal mucosa, delaying repair, and may contribute to the development of diarrhoea. Antibiotics add significantly to production costs, they may contribute to the problem of resistance factors in the enterobacteria, they may result in residues in meat and antibiotic use may result in the carrier state in *Salmonella* infections.

Environment

The impact of environment on the pathogenesis of calf diarrhoea may be discussed under the following headings: microbial environment, immunological environment, nutritional environment and physical environment.

Microbial environment

The enteropathogens that have been discussed are all excreted in faeces in very large numbers by clinically sick calves. It is clear, therefore, that once an outbreak is established the major source of infection is faecal contamination of the environment by clinically affected calves. Other animal sources or reservoirs of infection have been described; rotavirus and coronavirus are excreted by calves and cows with subclinical infections and similar situations could be expected for the other enteropathogens, which have been investigated less well. Studies of dairy systems (Greene, 1983; McNulty & Logan, 1983) have shown the value of cleansing, disinfection and use of the 'all-in all-out' system in the control of diagnosed and undiagnosed calf diarrhoea. Calving accommodation and calf pens should be designed for ease of cleaning, steaming and disinfection and with adequate drainage. Pens should be well ventilated, but draught free. Pens and utensils should be kept clean, and pens kept dry with adequate straw.

The same principles apply in beef systems (Radostits & Acres, 1980). Firstly, it is important to remove the source of infection from the calves' environment, or minimize it. Measures that can be adopted include the following.

- Avoid confining the herd, especially at calving. Avoid using calving paddocks in which mud and faeces soon predominate and where animal density is high.
- Regularly change the pastures that the herd grazes.
- Do not calve cows and heifers on the pasture on which they have been held during winter; move them to clean areas just before calving.
- Do not calve on the same area year after year. Avoid calving in barns and sheds where infection builds up rapidly, and ventilation and sunlight are restricted, encouraging survival of infection.
- Choose a calving ground that is sheltered and well drained. Avoid creating local areas within calving grounds where animals congregate and infection builds up, i.e. restricted feeding or watering areas.
- Calving areas should be cleaned up and left vacant during summer.
- Isolate calves, as far as is possible, from the contaminated environment by removing calves from areas contaminated by diarrhoeic calves. Reduce crowding of calves by dividing the calving herd into small subgroups and dispersing newborn calves with their mothers soon after birth.

Immunological environment

Neonatal calves are more resistant to enteric infections when suckled than when fed artificial feeds,

regardless of whether or not there is absorption of colostral immunoglobulins. This suggests that components of colostrum and milk that are not absorbed have an intestinal role in protecting the neonate. The other quite distinct protective function provided by the immune components of mammary secretions is their absorption to provide passive circulating antibody, which prevents invasion of micro-organisms.

Specific protective systems in colostrum and milk
(see p. 1002)

Immunoglobulins are concentrated from the cow's serum into colostrum from five weeks prepartum. The classes of immunoglobulins that are present in colostrum and milk are IgA, IgG₁, IgG₂ and IgM. IgA and IgG₂ each comprises 5 per cent of colostral immunoglobulins and IgM comprises approximately 7 per cent. The majority of colostral immunoglobulins (80 to 90 per cent) are IgG₁ and the concentration of IgG₁ in colostrum is three to twelve times that of maternal serum, because of selective secretion by the acinar epithelial cells of the mammary gland.

Colostral proteins are absorbed very rapidly and efficiently by the small intestine of the newborn calf. The small intestinal villi are covered by highly vacuolated enterocytes, which are specialized in the uptake of macromolecules by pinocytosis. The ability to absorb macromolecules may persist for up to 24 hours after birth and its disappearance is known as 'closure of the gut'. Although the gut may remain 'open' for up to 24 hours, closure occurs rapidly after ingestion of the first feed. If the first feed is colostrum, all is well, but if the first feed is milk, the gut will 'close' and colostrum fed subsequently will not be absorbed. Thus, IgG₁ is absorbed into the blood of the calf in large amounts during the first 24 hours of life. All macromolecules presented are absorbed but IgG₁ is predominant and therefore it is absorbed in greatest amounts. IgA in milk provides a passive intestinal humoral immunity in other species. In ruminants the predominance of IgG₁ in milk suggests that it has a similar function. Determination of passive antibody transfer can be easily achieved by measuring total plasma protein concentration using a refractometer where values greater than 65 g/l are considered optimum and concentration below 50 g/l inadequate.

The immune components of mammary secretions have two functions. Firstly, colostral antibodies absorbed into the circulation of the neonate provide passive circulating antibody, which prevents invasion of micro-organisms (e.g. septicaemic *E. coli*). Secondly, colostral antibodies that are not absorbed due to gut closure, and milk antibodies, act within the gut lumen, providing passive local immunity. Milk antibody has

been shown to protect calves from ETEC, probably by anti-adhesive activity. Absorbed colostral antibody may also influence enteric infections because IgA is absorbed along with IgG₁ and some is resecreted onto mucosal surfaces.

Studies of the concentration of immunoglobulins in the blood of diseased calves showed that calves with the lowest levels of immunoglobulin had highest mortality; colisepticaemia was the major killer, either rapidly or via abscesses in the umbilicus, liver and joints. Calves with low levels of immunoglobulins may also show a greater incidence of diarrhoea.

Colostral antibodies, if they are to be absorbed effectively or if they are to have a protective function in the gut lumen, must resist rapid degradation. The mechanisms that protect colostrum from degradation in the gastrointestinal tract are the low activity of pancreatic protease in the neonatal calf, the presence of a trypsin inhibitor in colostrum, the high buffering capacity of colostrum, the reduced secretion of acid in the abomasum in the first three days of life and the resistance of IgG₁ to proteolysis by chymotrypsin. The enterocytes of the newborn calf are specialized for non-selective macromolecule absorption by pinocytosis and vesicle transport. This process results in rapid and effective uptake of antibodies (IgG₁) because these are the major macromolecules in colostrum.

There are, in addition to protective immunoglobulins, non-specific protective systems in colostrum and milk (Reiter, 1978; see also Chapter 58). Lactoferrin, an iron-binding protein present in colostrum and milk, inhibits bacterial growth, possibly by reducing availability of iron to bacteria. There are appreciable amounts in bovine colostrum but little in bovine milk. Citrate, also present in colostrum, competes for iron, making it available for bacteria. Therefore, normal colostrum is not bacteriostatic for *E. coli*, but once the citrate is removed colostrum is bacteriostatic. Conditions in the calf small intestine apparently favour the action of lactoferrin because citrate is rapidly absorbed from the calf small intestine and bicarbonate, which assists binding of iron and lactoferrin, is secreted into the small intestine. The antibacterial action of lactoferrin is enhanced by specific antibodies in colostrum. The lactoperoxidase/thiocyanate/hydrogen peroxidase system is inhibitory or lethal to bacteria via the production of an oxidation product. Lactoperoxidase is synthesized by the mammary gland, thiocyanate ions are present in milk and are secreted into the calf stomach and cow's milk contains glucose and glucose oxidase, which provide hydrogen peroxide; hydrogen peroxide is also produced by lactobacilli, which are the predominant bacteria in the flora of the stomach and small intestines of newborn calves. Thus, all the components of this protective system are present in the calf *in vivo*.

The absorption of colostral immunoglobulins is influenced by several factors and 20 to 50 per cent of calves attain inadequate serum IgG levels. The time of the first colostrum meal is an important determinant of serum immunoglobulin concentration; late feeding leads to lower levels. Also, first-milk colostrum has the highest concentration of immunoglobulins, therefore parturient leaking or milking leads to poorer quality post-parturient colostrum. Colostrum is secreted prepartum and once removed is not replaced. The amount of immunoglobulin absorbed varies with its concentration in the colostrum and this is more important than the quantity of colostrum consumed.

Maternal nutrition may affect colostrum production. Poor nutrition does not, apparently, influence the concentration of immunoglobulin in colostrum but decreases the amount of colostrum produced, therefore sucking calves achieve lower levels of serum immunoglobulin; heifers produce less colostrum than cows. A second feed of colostrum increases the absorption of immunoglobulin from the first feed, presumably because the second feed displaces colostrum from the upper gastrointestinal tract into the jejunum.

The presence of the dam improves the efficiency of absorption of immunoglobulins by the calf by up to 80 per cent. Lower serum levels are obtained if the calf and dam are separated at birth and colostrum is fed by bucket. The dam licks and cleans the newborn calf in the order: thorax, back, abdomen, head, neck and perineum. The placenta is then eaten. Suckling does not occur unless the licking process occurs. An easy parturition leads to early licking. Beef cows mother better than dairy cows; they lick longer and stand better to be suckled. The speed at which calves stand is important because they then start to seek the teats. If cows have calved standing then sucking is likely to start earlier. Field-born calves have higher levels of serum immunoglobulins than box-born calves. The cow is likely to be the primary object of teat-seeking attention but in a box the walls may confuse the calf. Low pendulous udders delay successful sucking.

Farmers should be encouraged to ensure that all calves receive a minimum of 2 litres of colostrum soon after birth, certainly within 4 to 6 hours. Practical recommendations to enhance colostrum uptake include the following:

- Do not separate dam and calf until 24 hours postpartum.
- Provide bedding to allow the calf to stand easily.
- Encourage early feeding, which is very beneficial. The calf may need assistance to ensure this.
- Keep a supply of frozen colostrum for use after prepartum leakage.

- Encourage outdoor calving in warm weather; it is more likely to lead to higher levels of serum immunoglobulins.

Methods of measuring the concentration of immunoglobulins in calf serum include the following:

- Single radial immunodiffusion: convenient, accurate and capable of measuring IgG₁, IgG₂ and IgA.
- Zinc sulphate turbidity test: depends on the selective precipitation of immunoglobulin by zinc sulphate; there is good correlation between zinc sulphate turbidity and total immunoglobulin content of serum.
- Sodium sulphite precipitation method.
- Refractometry: measures total protein.

The immunoglobulin content of colostrum can be assessed simply and accurately with a hydrometer (Fleenor & Stott, 1980) and one designed specifically for the purpose is available in the UK.

Nutritional environment

Skim milk powders, which have been severely heat treated, and some non-milk proteins (e.g. soya) do not coagulate well in the abomasum. This may result in gastric stasis and reduced secretion of gastric acid and enzymes, which causes increased escape of undigested protein into the duodenum and reduced secretion of pancreatic enzymes. These events result in diarrhoea. Soya initiates immune-mediated intestinal damage in some calves and heated soya may contain substances that are directly damaging to the intestinal mucosa. Some feeding methods may upset the balance between the calf and the infectious agents to which it is exposed, thus precipitating diarrhoea. These include feeding cold milk, bucket feeding, high-fat diets and skim milk. Alternatively, feeding methods that are said to alleviate diarrhoea include use of acidified milk and fermented colostrum, even though it is less well absorbed than fresh colostrum.

Physical environment

Hypogammaglobinaemia is more common in single-suckled beef herds where the stocking density is high, presumably due to poor mothering and supervision. Calf mortality is less if the person who looks after the calves is the farmer, or a member of his or her family.

Single penning helps reduce the spread of infection, as do solid walls between pens. Aspects of the physical environment that contribute to the development of diarrhoea by stressing calves are inclement weather,

particularly snow and rain, cold wet bedding and overcrowding.

Necrotic enteritis (See p. 238)

Necrotic or necrotizing enteritis is the term used to describe a distinct clinicopathological syndrome characterized by severe diarrhoea, pyrexia and neutropaenia in two to three month-old beef calves (Penny *et al.*, 1994). The disease has been reported to occur in the same beef herd for four consecutive years, affecting approximately 5 per cent of calves when seven to 12 weeks-old (Penny *et al.*, 1994). Despite intensive supportive and antibiotic therapy approximately 25 per cent of affected calves died after five to 10 days of illness. The clinical presentation of necrotic enteritis is not dissimilar to coccidiosis but the morbidity is much lower and the findings more severe in nature.

Affected calves are dull and depressed and do not suck. These calves are moderately (5 to 7 per cent) to severely (8 to 10 per cent) dehydrated, and pyrexic (39.5 to 42.0°C) with pale mucous and oral membranes. Sudden onset profuse dark green diarrhoea containing fresh blood is a consistent feature. Tenesmus is also a common feature and becomes more prominent during the latter stages of the disease and may cause temporary rectal prolapse. There is rapid loss of body condition and affected calves have a gaunt appearance with a tucked-up abdomen. This syndrome has many clinical features of mucosal disease but oral erosions and ulceration are observed in less than 50 per cent of calves, and there are no interdigital lesions.

Muco-purulent ocular and nasal discharges, commonly seen in mucosal disease, are not observed in necrotic enteritis. The age-specific occurrence of necrotic enteritis differs from mucosal disease which more commonly affects yearling cattle although BVD/MD persistently affected cattle may die of intercurrent disease, especially bacterial pneumonia, from two months old. BVD antigen has not been detected in blood samples from affected calves nor from fresh tissue samples. No recognized enteropathogen has been isolated from faecal examinations. There is mild to severe anaemia and profound leucopaenia caused predominantly by a severe non-regenerative neutropaenia.

The administration of oral and/or systemic antibiotics has no effect on the outcome of necrotic enteritis. Supportive therapy comprising oral and intravenous fluids, and flunixin meglumine, may effect a temporary improvement but does not alter the prognosis.

Erosion or ulceration of the hard palate is common but no oesophageal ulceration has been recorded. Consistent findings are necrotizing lesions in the abomasum and small and large intestine, particularly involving the ter-

minal ileum and colon. Abomasal lesions range from discrete 1 to 3 cm diameter oval ulcers to large confluent areas of ulceration and necrosis in the pyloric region. Haemorrhagic or necrotic lesions overlying gut-associated lymphoid tissue (Peyer's patches) are common.

Introduction

Salmonellosis is a collective description of a group of diseases caused by bacteria of the genus *Salmonella* with signs that vary from severe enteric fever to mild food poisoning. One of the characteristics of *Salmonella* is that different serotypes vary in the range of animals that they can infect and cause disease. For example, *S. typhimurium* and *S. enteritidis* have a very broad host range and infections with these serotypes have been associated with virtually all warm-blooded animals. In contrast, other serotypes have a more limited host range and this has been interchangeably referred to as host specificity, restriction or adaptation. The highly host-specific serotypes infect only phylogenetically closely-related host species; for example *S. typhi* infects only human beings, *S. abortusovis* infects only sheep and goats and *S. gallinarum* infects only poultry. Other serotypes are predominately associated with disease in one species but may also infect a limited number of other host species. For example, *S. dublin* is usually associated with cattle, but natural infection by this serotype may occur in other animals, including human beings and sheep.

Salmonellosis as a disease of human beings, cattle, sheep, pigs and poultry is manifested clinically by one

of three major syndromes: a peracute systemic infection, an acute enteritis or a chronic enteritis. In humans, this ranges from the generalized typhoid infection, through the less severe paratyphoid infections to a mild gastroenteritis. The majority of serotypes produce a mild to severe gastroenteritis that only rarely becomes generalized and severe infections are most often encountered in very young, old or immunologically-compromised patients. It is generally accepted that *Salmonella* gastroenteritis is a zoonotic disease, mainly contracted by consuming large numbers of salmonellas in food of animal origin or foods contaminated with animal products in which the salmonellas have proliferated. There is, however, convincing evidence not only that infection can be a sequel to the consumption of small doses but that direct person-to-person contact is involved in many outbreaks.

The disease in cattle differs from the disease in humans, where the majority of cases in the developed world represent self-limiting intestinal infections, but which occasionally have a high mortality even when treated.

Until recently salmonellosis in animals in the UK was characterized by the large proportion of infections caused by the 'host-specific' and 'host-restricted' serotypes: *S. choleraesuis* in pigs, *S. abortusovis* in sheep, *S. pullorum* and *S. gallinarum* in poultry, and *S. dublin* in cattle. Recently, apart from the latter, these serotypes have virtually disappeared in the UK although they remain important in other parts of the world. Salmonellas may be carried by animals in the absence of clinical signs and this is probably the normal situation in pigs and poultry, although *S. enteritidis* (phagetype 4) became associated with clinical disease in the latter.

The cycle of infection between man and farm animals is often called the '*Salmonella* cycle', which is shown in Fig. 15.1. Some of the links in the cycle are tentative and the main source of infection for humans is animal products and the principal sources of infection for domestic animals are other animals of the same species and contaminated feed.

Whilst it is accepted that infections in the human population are usually associated with the consumption of animal products such as eggs, meats and milk, it is

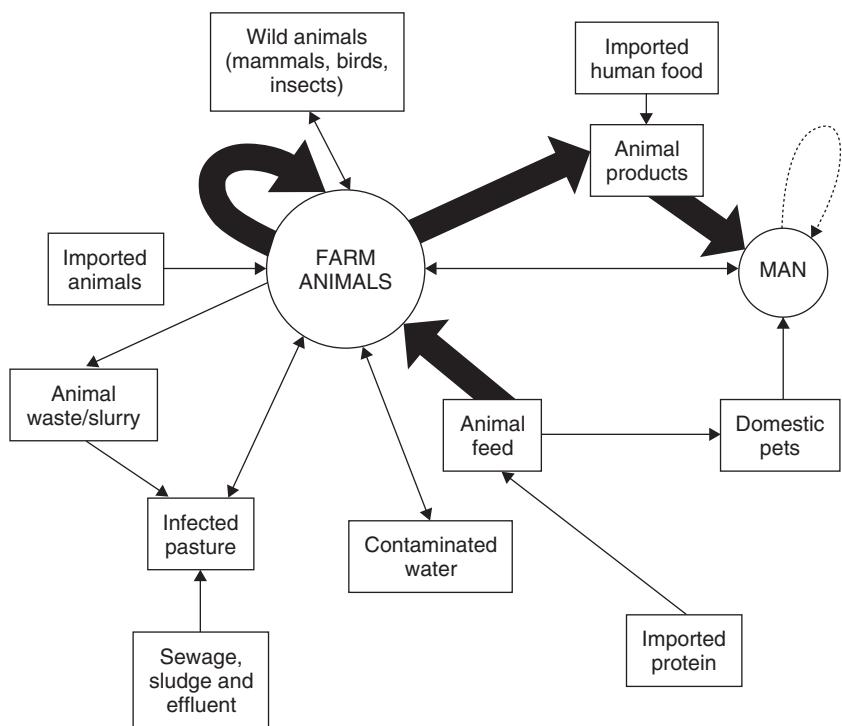

Fig. 15.1 The '*Salmonella* cycle'.

not always realized that it is possible for the farm animal population to become infected by direct contact with man or the waste products of man such as sewage and sewage-polluted waters. It is further complicated by the possibility of the spread of disease by wild animals such as rodents, birds and insects and by the recycling of animal products and wastes from one animal species to another. Thus an understanding of salmonellosis and the eventual solution of the current disease problems may only arise from an interrelated study of the disease in all groups of animals and of the manner in which the bacteria responsible contaminate the environment and pass from one animal to another.

Classification

Strains of the genus *Salmonella* obey the definition of the family *Enterobacteriaceae*: they are straight rods, usually motile with peritrichous flagella (*S. pullorum/gallinarum* which cause disease in poultry are the non-motile exceptions), facultatively anaerobic, ferment glucose usually with the production of gas (*S. typhi* and some strains of *S. dublin* are the exceptions) and reduce nitrate to nitrite. Most are prototrophic (grow in artificial media with glucose as the sole source of carbon and energy and ammonium ions as a nitrogen source). Most host-specific and host-restricted

strains are auxotrophic, e.g. *S. typhi* requires tryptophan for growth, *S. dublin* requires nicotinic acid and *S. choleraesuis* requires cysteine.

The genus is subdivided into serotypes (or serovars), which in some classifications are grouped into subgenera on the basis of their biochemical reactions. Subgenus I contains the 'typical' salmonellas isolated mainly from warm-blooded animals, and these are the bacteria which normally cause disease in cattle. The serotypes (or serovars) within a subgenus cannot, with rare exceptions, be distinguished biochemically and differentiation is on the basis of the possession of somatic (O) antigens and diphasic flagellar (H) antigens in the Kauffmann-White scheme. The antigenic formula consists of three parts delimiting the O antigens and the H antigens which may occur in two phases. O antigens have arabic numbers and H antigens have letters in phase 1 and letters and numerals in phase 2, since the same antigens may occasionally occur as phase 1 or phase 2 in different serotypes. Thus the common cattle pathogen *S. dublin* has the antigenic formula 1,9,12:gp:-; this denotes that it is distinguished by the presence of O antigens 1, 9 and 12 and H antigens g and p. It does not have a second phase. The other common cattle pathogen *S. typhimurium*, which is diphasic, has the formula 1,4,5,12:i:1,2. When initiated the scheme comprised 44 serotypes and varieties organized in five O groups (A-E), but it has since expanded to include

Table 15.1 The antigenic formulae (Kauffmann–White scheme) of *Salmonella* serotypes commonly isolated from cattle in the UK.

over 2400 serotypes organized in 48 O groups. The antigenic formulae of serotypes commonly involved in disease in cattle are shown in Table 15.1.

The names given to the serotypes do not follow the usual rules of nomenclature. The first serotypes to be identified, such as *S. typhi*, *S. choleraesuis*, *S. abortusovis* and *S. typhimurium*, were given names that indicated the disease with which they were associated or their common animal host, and these names, which have become accepted by clinical microbiologists, continue in common use. Serotypes isolated subsequently are named after the town or region in which they were first isolated, such as *S. dublin*, *S. liverpool*, *S. crossness* and *S. bareilly*, or are designated solely by their antigenic formulae. As an aid to epidemiological studies many of the commonest serotypes have been further subdivided into phageotypes, biotypes, plasmid types, etc.

In alternative classifications which are increasingly being used *Salmonella* is considered as one or two species (with subspecies *S. enterica* subsp. *enterica*, *S. enterica* subsp. *salamae*, *S. enterica* subsp. *arizona*, *S. enterica* subsp. *diarizoneae*, *S. enterica* subsp. *houtenae*

and *S. enterica* subsp. *indica*). The names of serotypes are not considered as species names and are not printed in italics. The species name is usually *S. enterica* and the serotypes are written, for example, as *S. enterica* (sometimes subsp. *enterica*) serovar *typhimurium* or *S. enterica* serovar *dublin*.

Resistance to antibiotics (see p. 1038)

A feature of salmonellosis in cattle during the last four decades has been the development of strains resistant to one or more antibiotics. This has occurred most commonly in a relatively small number of phageotypes of *S. typhimurium* and has been the subject of considerable debate on the use of antibiotics prophylactically, therapeutically and as growth promoters in calves. It is, however, generally accepted that resistance is developing under the selective pressure of the indiscriminate use of antibiotics. This is thought to be particularly true both of the use of mixtures of antimicrobials for therapy without diagnosis and antimicrobials mixed into animal feeds. The problem was first recognized in the 1960s when the number of antibiotic-resistant strains isolated from cattle rose from less than 3% at the beginning of the decade to more than 60% by 1965 and most of the isolates belonged to one phageotype (DT29). This phageotype disappeared at the end of the decade and the proportion of antibiotic-resistant isolates declined, but by the end of the next decade the proportion had again risen to approximately 60%. This was due to the emergence of two closely related types (DT193 and DT204) and was associated with the development of chloramphenicol resistance. Although these two phageotypes also subsequently declined, they were replaced during the 1980s by the closely related phageotype DT204c. This phageotype became endemic, particularly amongst market-purchased calves and in the calf-rearing trade. It subsequently declined and was replaced by phageotype DT104. This multiply-resistant phageotype also became established in sheep and pigs.

Strains of *S. dublin* isolated in the UK, unlike *S. typhimurium*, have remained comparatively sensitive to antibiotics. In contrast, strains isolated in Holland, Belgium, Germany and the USA are usually resistant to a number of antibiotics. The reason for the difference between British isolates and those from North America and Europe has not been explained satisfactorily but is usually attributed to the selection pressure of antibiotics in animal feed. Presumably the same pressure is exerted in the UK as elsewhere and is equally applied on *S. dublin* as on *S. typhimurium*. Multiply-antibiotic-resistant strains of *S. dublin* resistant to chloramphenicol began to be reported in the UK from 1979 and the chloramphenicol resistance was transmissible, although

located on R plasmids distinct from those carrying the same resistance genes in *S. typhimurium*.

Epidemiology of salmonellosis in cattle

In cattle the disease, which has been recognized for two centuries, has a world-wide distribution and has been associated primarily with *S. dublin* and *S. typhimurium*. Other serotypes infect cattle more sporadically and these 'exotic' serotypes have become more common in the UK during the past 50 years, although during the last 20 years approximately 100 serotypes other than *S. dublin* and *S. typhimurium* have accounted for only about 10 per cent of incidents. The number of outbreaks caused by the 'exotic' serotypes has declined in the last few years. There was a dramatic rise in the incidence of salmonellosis in cattle between 1960 and 1969 due to an increase in isolations of *S. dublin*. This was followed by an equally dramatic decline in both *S. dublin* and total incidents and a slight rise in *S. typhimurium*. Over the last 20 years the incidence has remained about the same and at present *S. dublin* and *S. typhimurium* are isolated at about the same frequency, with the former being more common in adults and the latter more common in calves.

Recent estimates would suggest that approximately 20 per cent of UK cattle herds may be infected with salmonellas at any one time, although obvious disease is a much rarer event. Serological surveys have suggested a history of infection in up to 75 per cent of UK dairy herds. In the UK approximately 400 to 500 incidents (outbreaks in a single herd) of salmonellosis in cattle are reported annually. This is almost certainly an underestimate since disease outbreaks often are not reported and carriage in the absence of disease is common.

The distribution of salmonellas in cattle in other parts of the world is similar to the UK. *S. dublin* is endemic in northern Europe and western North America and *S. dublin* and *S. typhimurium* tend to be present in most advanced dairying areas and intensive cattle rearing regions. In the rest of the world occurrence is more sporadic and serotypes other than *S. dublin* and *S. typhimurium* are commonly involved.

A feature of *Salmonella* infections in all species, however, is a continual fluctuation in the proportions of the serotypes involved. It is common for a serotype to be introduced to the country and to establish in one or more species, possibly as the predominant serotype, and then to decline without any apparent reason or without the intervention of public health or veterinary authorities. The predominance of *S. hadar* in poultry and the human population in the 1970s to 1980s is a good example and it may possibly be predicted that the

epidemic of *S. enteritidis* phagetype 4, which replaced *S. typhimurium* as the predominant serotype in poultry and the human population in the 1980s and 1990s, will follow the same course. It is always possible, therefore, for the relative importance of *S. typhimurium* and *S. dublin* to change and the relative importance of these two serotypes in cattle should not be judged on the basis of isolations over only a few years.

Salmonellosis occurs in calves in all months of the year but there is a peak of disease associated with all serotypes between October and December, with a low incidence in June and July. This is associated with calving patterns rather than a true seasonal increase and reflects the distribution of calvings in dairy herds and may change. Similarly, since the source of calves sold through markets to fattening units is bull calves from dairy herds and surplus cross-bred heifer calves from dairy and beef units, there is also a seasonal incidence in fattening units since most outbreaks in calves occur within a few weeks of purchase from markets.

The importance of salmonellosis as a disease of calves was demonstrated by a survey carried out by researchers at the Institute for Animal Health, Compton, and is described in detail later in this chapter (p. 219). In this survey samples of faeces from diarrhoeic calves on 45 farms in the south of England were examined for the presence of a variety of putative enteropathogens including salmonellas, rotavirus, calicivirus, coronaviruses, *E. coli*, cryptosporidia and campylobacters. Salmonellas were isolated from 12 per cent of diarrhoeic calves in 24 per cent of diarrhoea outbreaks. In 37 of the outbreaks, samples were taken from normal calves of similar age to the calves with diarrhoea and a comparison between isolation rates from healthy and diarrhoeic calves was prepared. Salmonellas were isolated from 12 per cent of diarrhoeic calves compared with only 3 per cent of normal calves, thus showing a clear association of the organism with disease. Salmonellas were associated with an outbreak of severe dysentery on six farms while single cases of typical salmonellosis occurred in three outbreaks, and salmonellas were detected with other agents as part of a diarrhoea problem in two outbreaks where dysentery and pyrexia were not recorded. This highlighted the problem of arriving at a diagnosis in an outbreak of enteritis when several organisms may be involved as part of a disease syndrome. Since salmonellas may be carried by apparently healthy animals, isolation of the organism, unless it is present in large numbers ($>10^5$ per gramme of faeces), is not proof of the cause of disease. There was a correlation between the type of farm and the isolation of salmonellas from diarrhoeic calves. Diarrhoea was more likely to be associated with salmonellas in units (calf-rearer, multiple-suckler) where

large numbers of calves were purchased from markets, although a large number of isolations were also made from calves on dairy farms.

The source of most outbreaks is probably animal-to-animal contact, although there are distinct differences in the epidemiology of the disease in adults and calves, and between serotypes. The main sources of infection for cattle herds are probably bought-in cattle, contaminated feed, contaminated animal wastes spread on pasture, human sewage sludge spread on pasture, contaminated water courses, birds, particularly gulls, rodents, insects and human contact. Infected cattle may excrete up to 10^8 salmonella/g of faeces and contamination of the environment in the proximity of other cattle by excreting animals will obviously be a potent source of infection. In an outbreak of *S. saintpaul* infection in two large dairy herds, infection rapidly spread from cows to their calves, presumably by contact with the contaminated environment of calving barns, and all calves that eventually became infected were excreting salmonellas within 72 hours of birth. Dairy calves may thus become infected by contact with their dam, other calves or the contaminated environment. The collection of calves for intensive rearing, which involves transport to markets and dealers' premises, produces an ideal environment for dissemination. When salmonellosis gains a foothold in calves subjected to this treatment it spreads so rapidly that entire herds in rearing premises may become infected.

There have been several reports that demonstrate the importance of salmonellas in market-purchased calves and in rearing units. One of these was a survey of almost 600 market-purchased calves supplied to 11 rearing units. Frequent swabbing of the calves indicated that less than 1 per cent were infected when they arrived at the rearing units but within the next six weeks over half the calves became infected. The calf units examined in this survey were cleaned and disinfected between batches of calves and yet salmonellas could still be isolated from the environment after cleaning in over half of the units. In a similar study of a calf unit in Berkshire, UK, which bought calves from local markets, 250 calves were examined over a two-year period and 51 were shown to be infected with one of four different phagetypes of *S. typhimurium*. Phagetype DT204c, which was multiply-antibiotic-resistant, was isolated at the beginning of the survey. This was eventually removed by destocking and a rigid hygiene programme. The calf units were steam-cleaned, after which *S. typhimurium* DT204c was still isolated from environmental samples. Following further steam-cleaning and washing with disinfectant the organism was no longer detectable in the environment but was detectable from the next batch of calves introduced to the units. Although it is not certain that this was the result of envi-

ronmental contamination the organism was not isolated from the calves on arrival. Subsequent batches of calves (20 or 30 per batch) were examined on arrival and three further serotypes, *S. typhimurium*, *S. agama* and *S. binza*, were isolated. Salmonellas were subsequently isolated from 20 per cent of calves that developed diarrhoea on the farm.

Both of these surveys amply demonstrate that infection in a limited number of calves can spread rapidly in young, susceptible animals subjected to the stress of the marketing and rearing systems and once established it may be difficult to remove the organism from an infected environment. It may also be possible that salmonellas, which cannot be recovered on normal bacteriological media may, although non-recoverable, remain viable and infective for animals.

The manner in which animals in previously uninfected dairy herds become infected is more problematical, and the source of infection may vary from serotype to serotype. Most outbreaks are probably associated with the introduction of infected stock or contaminated feed but polluted water supplies, the spreading of contaminated animal manures and human sewage sludge on pasture, and contamination of pasture or feed by scavenging birds may also be involved. Outbreaks have also been described where the probable source of infection was direct human contact. Insects may also be involved in mechanical transmission since it is difficult to contain salmonellosis outbreaks when animals are kept in units that are not insect-proofed and similar difficulties have been described in rearing *Salmonella*-free pigs unless fattening units were rendered fly-proof.

The epidemiology of *S. dublin* in dairy herds differs from that of other serotypes. *Salmonella dublin* has a precise geographical distribution. The organism has remained established in adult cattle in Wales and in southwest and northwest England. It is thought that this distribution may, in part, be due to an association between *S. dublin* and *Fasciola hepatica*, although this may be fortuitous and merely indicate that both are influenced by similar climates and survive better in wet conditions. *Salmonella dublin* probably persists on farms in these areas because recovered animals remain infected and excrete the bacteria in their faeces, either continuously or intermittently. Elsewhere in the UK the disease is predominantly one of calves in calf-rearing units rather than adults and it is introduced to the units with the introduction of infected animals.

The carrier state

Animals which excrete salmonellas continuously ('active carriers'), usually in concentrations of greater than 10^5 /g of faeces, can be detected by bacteriological

examination which will also detect 'passive carriers', animals that ingest salmonellas in their feed and pass them in their faeces without actual infection of the intestine or the mesenteric lymph nodes. When removed from an infected environment these latter animals stop excreting. Active excretion is usually a sequel to clinical enteritis or septicaemia and infected animals may excrete for many years and perhaps for life. It may also develop in animals that have not shown clinical signs, although this probably occurs only in cases of concurrent fascioliasis. In such cattle, *S. dublin* is characteristically present in the gall-bladder and alimentary contents without necessarily colonizing the rest of the animal. However, although active (persistent) excretors are an obvious source of infection for other cattle, and although the source of calf infection is assumed to be adult cattle, field studies have shown that the majority of calves infected with *S. dublin* are home-bred on farms where there is no clinical evidence of adult salmonellosis. This is characteristic of the disease and has led to a search for other sources of infection.

Many of the infections occur in closed herds; other sources of infection such as feed are not appropriate to a 'host-restricted' serotype such as *S. dublin* and although contaminated streams may be implicated, this gap in the epidemiology is usually explained by the existence of 'latent carriers'. These are animals that have salmonellas somewhere in their tissues or alimentary tract but only rarely excrete the organisms in their faeces. It has been suggested that infection with *S. dublin* is mainly latent, but is activated by stress, particularly at parturition, and the birth of congenitally infected calves to latent carriers or to cows that excrete *S. dublin* would only intermittently explain the occurrence of disease in calves on farms where searches for active carriers are unsuccessful. It is possible to detect greater numbers of excretors by bacteriological examination of faeces taken at calving and surveys have revealed animals which, although found to be infected with *S. dublin* at necropsy, were not detected as carriers by previous faecal sampling. It has not proved possible, however, to create such animals experimentally and serological tests for their detection have been singularly unsuccessful.

Serum agglutination tests (SAT) may detect a proportion of actively infected animals but they do not detect latent carriers and so far other immunological tests are equally unsuccessful, although they may be useful in detecting active carriers and infected herds. Delayed hypersensitivity skin tests can distinguish systemically infected animals but they may, unfortunately, also detect convalescent and recovered animals. It is possible that many unexplained outbreaks may be the result of human contact or extended survival of the organism in the environment, although most evidence,

particularly from field studies, would favour the latent carrier hypothesis.

In contrast to *S. dublin*, infection with other serotypes does not appear to result in active or latent carriers. Adult cattle usually excrete for a maximum of a few weeks following infection and excretion that is detected for longer periods probably reflects recontamination from the environment, although the establishment of some 'exotic' serotypes such as *S. saintpaul* for up to a year has been reported. Similarly, *S. saintpaul* has been shown to be retained in the tissues of calves for up to eight weeks after excretion had apparently ceased.

Pathogenesis

An overview of the main stages involved in *Salmonella* pathogenesis is presented in Fig. 15.2.

Initiation of infection

Cattle are probably infected with salmonellas by the oral route, although respiratory and conjunctival infection may also occur. The dose required to initiate infection is thought to be high and will be dependent on the age, immunity and dietary status of the animal and virulence of the infecting strain. However, it is probable that animals are infected naturally by much smaller doses since factors such as concurrent parasitism (particularly fascioliosis), ketosis, metritis, mastitis, cystitis, pneumonia, viral infection, dietary changes, pregnancy, food and water deprivation and other stress factors such as freezing, wet weather or worming may lead to increased susceptibility. In calves, colostrum, whether normal or immune, is particularly important and animals that have either not received colostrum or have received insufficient amounts are particularly susceptible. Natural infections have been described where animals may have been infected with very small doses, particularly from infected feed. In one such outbreak dairy cattle were infected from a component of feed containing less than three *S. mbandaka*/g and the infection spread to their calves. The experimental infectious oral dose for calves has been variously estimated as between 10^5 and 10^{11} organisms, although doses in excess of 10^8 are normally required. The dose for adult cattle is approximately 10^{11} orally and greater than 10^8 intravenously.

Gastric acidity is responsible for eliminating a large proportion of ingested organisms in both monogastric animals and ruminants. In ruminants, survival of salmonellas is further reduced by the high concentration of short-chain fatty acids in rumen fluid and consequently salmonellas disappear rapidly from the rumen of regularly fed cattle. Factors which alter the acidity and composition of rumen fluid, such as starvation and

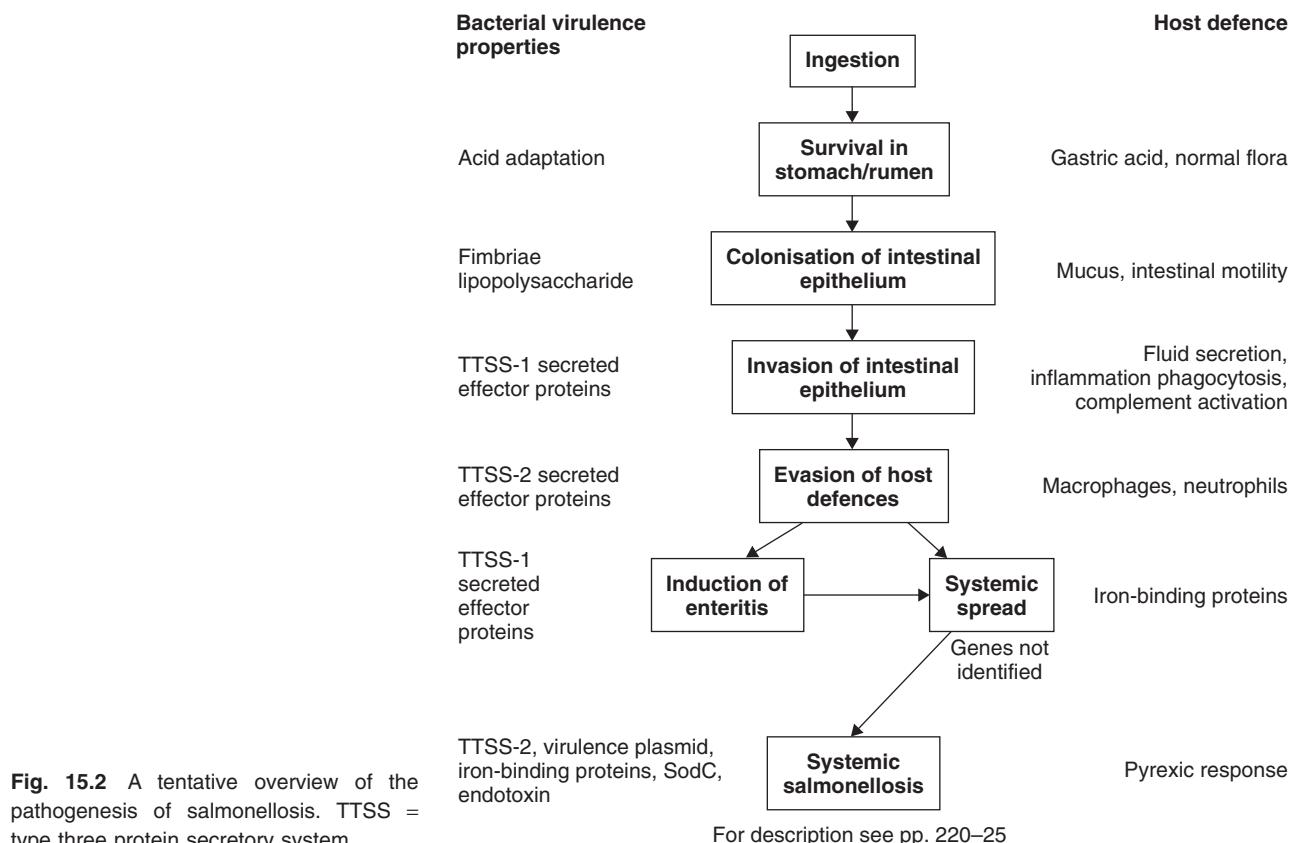

Fig. 15.2 A tentative overview of the pathogenesis of salmonellosis. TTSS = type three protein secretory system.

refeeding, achlorhydria or administration of antacid, increase susceptibility to infection. Salmonellas that survive passage through the stomach(s) will probably be phenotypically altered. Experiments *in vitro* have shown that exposure to low pH and/or short-chain fatty acids results in the induction of expression of up to 50 proteins. This correlates to increased bacterial resistance to further exposure to low pH. Several bacterial genetic loci have been shown to regulate this acid-adaptation response. Three of these genetic loci, *rpoS*, *fur* and *phoP/phoQ*, have previously been implicated in regulating virulence in the mouse model of systemic salmonellosis and mutation of several of the other genes has also suggested a link between acid adaptation, survival within murine macrophages and virulence in mice. To date, there have been no studies on the effect of acid adaptation on pathogenesis in bovine salmonellosis.

Interaction with the intestines

After passage through the stomach(s), surviving salmonellas must be able to resist several host innate defences, including lysozyme and lactoferrin, and to prevent their removal from the intestines in the normal movement of food by peristalsis. The bacterial flora of

the intestines may also be inhibitory to infection and the absence of a fully developed intestinal flora may in part account for the comparative lack of resistance of young animals to salmonellosis. Despite these host defences, salmonellas are able to associate rapidly with the intestinal epithelial monolayer. Bacterial motility and chemotaxis may aid this process by allowing the bacteria to move more freely within the intestinal lumen, to sense the presence of the epithelial monolayer and to penetrate the overlying mucus layer.

The interaction between salmonellas and the intestinal mucosa is highly dynamic. Salmonellas are rapidly able to mediate their own uptake into epithelial cells and this is associated with a dramatic, but temporary, ‘ruffling’ of the apical membrane of the epithelial cell at the site of bacterial entry (Figs 15.3 and 15.4). The main initial site of entry is probably the distal ileum. This may be because the intestinal contents are held within the distal ileum for some time before entry into the caecum and it may also be partly due to the relatively high number of M cells (specialized epithelial cells overlying the Peyer’s patches) in the distal ileum. In mice M cells are interspersed between enterocytes and salmonellas can clearly be seen preferentially interacting with the M cells. In calves, M cells form a

Fig. 15.3 Scanning electron micrograph of uninfected bovine ileum showing a group of typical M cells (M) on a domed villus. The cells have characteristic microfolds with a central area of short microvilli.

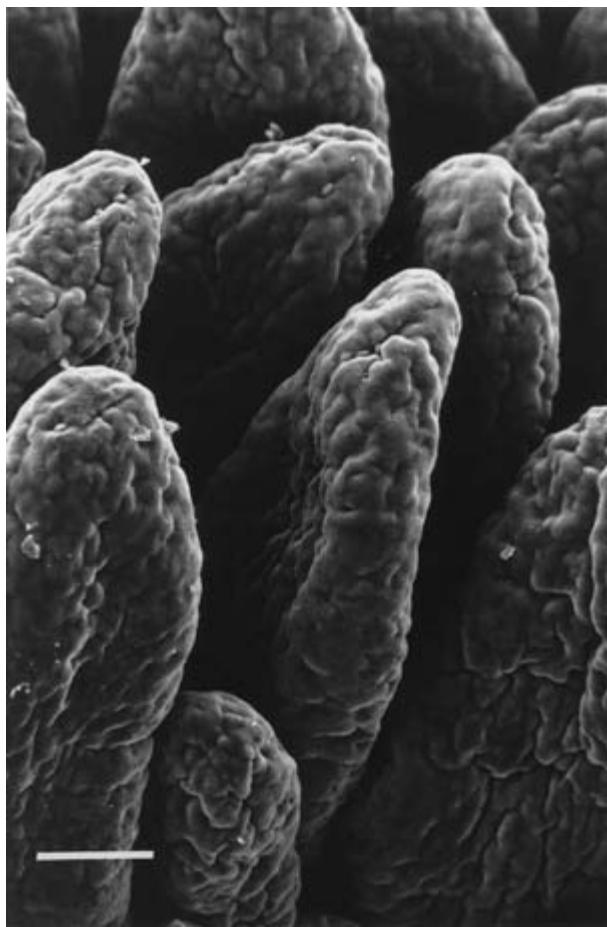

Fig. 15.5 Scanning electron micrograph of uninfected bovine ileum showing the normal morphology of villi.

Fig. 15.4 Scanning electron micrograph of bovine ileum after infection with *S. typhimurium*. The peripheral microfolds of the M cells are ruffled and bacteria (arrowheads) are being engulfed by the membrane ruffles.

homogeneous monolayer over the dome villi (villi associated with the Peyer's patches) and so the relative interaction of salmonellas with M cells and enterocytes is more difficult to assess. It appears, however, that salmonellas will initially interact with the M cells (within 10 minutes of direct inoculation into the distal ileum) and are not taken up by the enterocytes until slightly later (approximately 20 minutes after inoculation).

The mechanism of *Salmonella* invasion has been extensively studied. The bacterial genes involved in invasion are clustered together at one site on the chromosome, which has been named *Salmonella* pathogenicity island 1 (SPI-1). SPI-1 encodes a type 3 protein secretion system (TTSS-1; so called after comparison to two previously described secretion systems), regulatory genes and several effector proteins which are secreted by TTSS-1. TTSS-1 can be viewed as a proteinaceous microsyringe that spans the bacterial inner and outer membranes. The main function of TTSS-1 is the

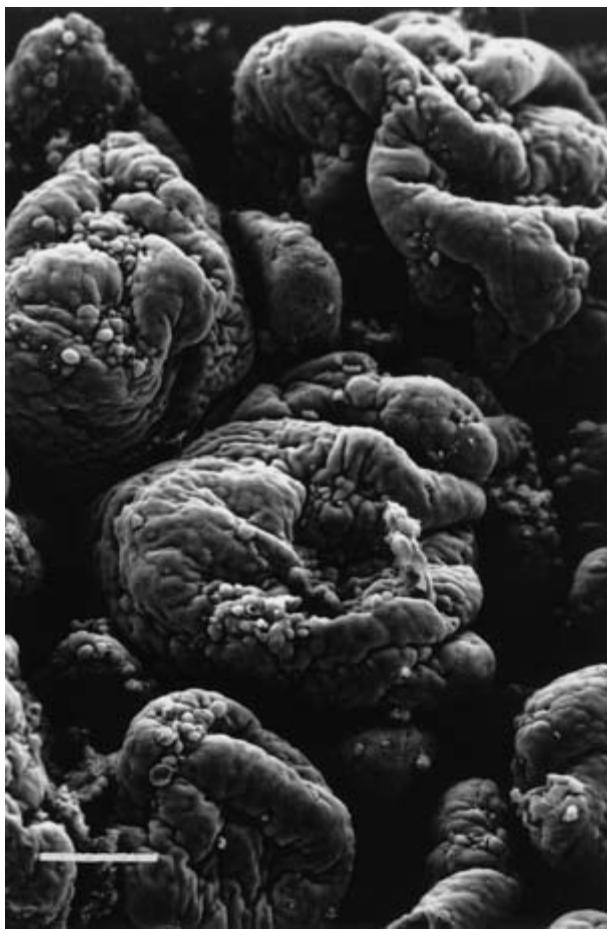

Fig. 15.6 Scanning electron micrograph of bovine ileum after infection with *S. typhimurium*. The villi are shortened and there is an abnormal extrusion of enterocytes.

co-ordinated secretion of specific bacterial proteins, not only out of the bacterial cell, but also directly into the target epithelial cell. The translocated proteins interfere with specific components of the host cell signalling pathways and cytoskeleton, resulting in bacterial uptake and potentially influencing the subsequent induction of enteropathogenic responses.

Infection of the intestines by *Salmonella* may result in several pathological changes (Figs 15.5–15.7). These can be studied using the calf ligated ileal loop model, which has been developed by researchers at the Institute for Animal Health, Compton. Results from this model correlate well with those from orally-inoculated animals. Short sections of the ileum are sealed *in situ* by surgical silk to form individual loops and each loop is directly inoculated with up to 10^9 salmonellas. This is an appropriate inoculum size, since faeces from infected calves may contain up to 10^8 salmonellas/g. The main advantage of this model is that pathological responses

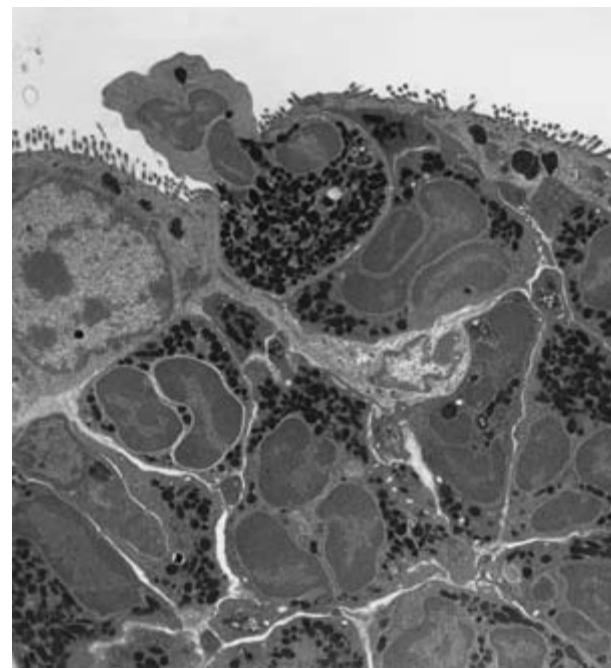

Fig. 15.7 Transmission electron micrograph of dome villus after infection with *S. typhimurium*. There are a large number of PMN leucocytes, one of which appears to be crossing the epithelial monolayer.

to several strains can be quantified in a single animal, thus dramatically reducing the number of animals required for such experiments. In infected ileal loops there is an increase in the rate of epithelial cell shedding, which could be viewed either as a bacterial cytotoxic activity, allowing further invasion, or as a host defence mechanism to eliminate infected cells rapidly.

An inflammatory response is initiated in the intestines by the production of cytokines and other pro-inflammatory mediators by infected host cells. It is unclear whether this is a generalized host response to invading bacteria, which will release pro-inflammatory molecules such as endotoxin, or if it is the result of the direct action of specific bacterial proteins acting on epithelial cells without necessarily requiring bacterial invasion. It results in a large influx of inflammatory cells, particularly polymorphonuclear (PMN) leucocytes, into the intestinal mucosa and lumen. However, salmonellas are relatively resistant to the bactericidal activity of PMN leucocytes and their influx may cause considerable damage to the mucosa by disrupting cellular junctions and releasing the contents of their granules extracellularly. The most striking pathological change is the increase in net fluid secretion by infected mucosa. By 12 hours after inoculation with either *S. typhimurium* or *S. dublin*, as much as 30 to 40 ml of fluid

may have accumulated in a 6 cm ligated ileal loop. This fluid secretion may initiate the physiological response of the infected host to eliminate infecting bacteria, but it will also be advantageous to the bacteria, because it mediates their dispersal into the environment.

This characteristic secretory response has led many investigators to look for enterotoxin activity associated with salmonellas. Despite numerous reports of enterotoxic activity in various extracts from salmonellas and using various enterotoxin assays, there is no conclusive evidence that *Salmonella* produce a classical enterotoxin. A *Salmonella* gene has been cloned on the basis of its homology to the cholera toxin gene from *Vibrio cholerae*. However, mutation of this gene in either *S. typhimurium* or *S. dublin* did not reduce fluid secretion into infected ligated ileal loops in calves. Despite the lack of evidence that *Salmonellae* produce a classical enterotoxin, there is growing evidence that they do produce proteins with enterotoxin activity, but which lack a receptor-binding domain and therefore require viable bacteria to translocate them into target host cells. The best characterized of these proteins is called SopB, and it is dependent on TTSS-1 for translocation into epithelial cells. SopB affects inositol phosphate eukaryotic cell signalling, which may lead to interference with chloride channel function and hence affect movement of electrolytes and water. Mutation of SopB in *S. dublin* significantly reduces fluid secretion and the influx of PMN leucocytes in calf ligated ileal loops. SopB is located within a small *Salmonella* pathogenicity island called SPI-5 and mutation of the other genes within SPI-5 also reduces enteropathogenic responses in bovine ligated ileal loops, although the biochemical basis of this is not known.

Elucidation of bacterial factors involved in the interaction of *Salmonella* with the intestines is advancing rapidly, but there is still a lack of knowledge as to how *Salmonella* induces enteritis. In addition to the intimate interaction with epithelial cells, bacteria also spread rapidly to the lamina propria and mesenteric lymph nodes, as well as being returned to the gut lumen by extrusion of infected epithelial cells. A significant proportion of luminal bacteria appear not to invade during the initial stages of infection. The presence of high numbers of luminal bacteria may extend the symptoms of enteritis by providing a continual source of bacteria to interact with epithelial cells. In addition, many of them will be expelled in the copious diarrhoea associated with disease, and are therefore vital to bacterial spread between animals. Salmonellas that have invaded the lamina propria and beyond may also contribute to enteritis. For example, *S. dublin* carrying mutations in TTSS-2, a second TTSS which is not required for invasion of bovine intestines but is required for subsequent intracellular persistence, are highly attenuated

in orally inoculated calves. The mechanisms of bacterial spread from the epithelial monolayer and the way in which intracellular persistence contributes to enteritis are not known. Several of the host responses to invasive bacteria may contribute to enteritis. For example, loss of epithelial cells will reduce the absorptive capacity of the intestines; the associated increase in crypt cell mitosis will alter electrolyte balance, and hence water movements, and the PMN leucocyte influx and associated vasodilation and mucosal damage may alter absorptive function, as well as allowing further bacterial spread. The relative importance of these host responses compared to the direct action of bacterial proteins, such as SopB, on epithelial cell function is not known.

Systemic spread and persistence

Salmonellas are able to spread rapidly to systemic sites, particularly the liver, lungs and spleen. In experimentally infected calves this may occur within 6 hours after oral inoculation. The most probable route of spread is via mesenteric lymph nodes, the efferent lymph draining these nodes, and subsequent entry into the general circulation via the thoracic duct. Cannulation of efferent lymphatic vessels draining bovine mesenteric lymph nodes has demonstrated that *S. dublin* leaves the nodes in efferent lymph. In general, the growth of *S. typhimurium* and *S. dublin* in the bovine liver and spleen appears to be relatively well controlled and in calves infected experimentally it is unusual to recover more than 10^5 bacteria/g of tissue, even at the peak of disease. However, the bovine infection model most commonly used (four-week-old Friesian calves) usually results in a predominantly enteric disease and may not be an appropriate model for the systemic disease occurring in some very young calves or adult cattle. The pathogenesis of systemic disease has been mainly studied in mice and the results extrapolated to other animal species. Natural resistance of mice to infection with *Salmonella* is controlled by a genetic locus called *Nramp1*, which affects the ability of macrophages to control intracellular bacterial growth in the reticuloendothelial organs during the early stages of infection. Resistance to salmonellosis in cattle may also be under genetic control and several researchers have commented on the variations in susceptibility to salmonellosis amongst breeds of cattle. For example, Friesian calves are thought to be less susceptible than Channel Island calves, although the genetic basis of this is not known. A homologue of *Nramp1* has been identified in cattle, but its contribution to susceptibility to salmonellosis is not yet clear.

Several bacterial factors involved in systemic spread and/or persistence have been identified. A variety of

Salmonella mutants that are unable to persist within murine macrophages *in vitro* have reduced virulence in mice and several bacterial genetic loci influencing persistence, including those encoding TTSS-2 and the two component transcription regulators PhoP/PhoQ have been identified. Mutation of one such gene, *slyA*, is highly attenuating in mice but only slightly attenuating in calves, which highlights the differences in pathogenesis between these infection models. In contrast, the *spv* (*Salmonella* plasmid virulence) genetic locus is required for systemic virulence in both mice and cattle. This locus is located on a high molecular weight plasmid, called the virulence plasmid, which is present in many *Salmonella* serotypes. The existence of large molecular weight plasmids in many of the more important serotypes of *Salmonella*, including *S. typhimurium*, *S. dublin*, *S. choleraesuis* and *S. enteritidis* (but interestingly not in *S. typhi* which causes the severe disease typhoid fever in humans), has been described for more than 20 years. The plasmid harboured is characteristic of the serotype and they were originally called 'serotype-specific plasmids'. Naturally-occurring plasmid-free strains and strains from which the plasmid has been removed are avirulent in the mouse model of salmonellosis. In calves infected experimentally, plasmid-containing strains cause enteritis and a generalized systemic infection while plasmid-free strains induce enteritis in the absence of the generalized infection. It thus appears that plasmid genes are involved in the ability of salmonellas to proliferate within the host and that in cattle both plasmid and chromosomal genes are essential for the full expression of the disease. The virulence plasmid may not be carried by all isolates of a given serotype, particularly *S. typhimurium*, and this may explain, in part, the variation in the degree of severity of salmonellosis observed in the field where some outbreaks involve enteritis only whilst in others this develops into systemic infection.

The mechanism by which the *spv* genes contribute to systemic virulence is not known, although one study suggests the locus promotes bacterial replication *in vivo*. The virulence plasmid does not contribute to persistence within macrophages *in vitro* and although carriage of the virulence plasmid increases the lysis of macrophages during *Salmonella* infection *in vitro*, this is not attributable to the *spv* locus. The lysis of macrophages during *Salmonella* infections *in vivo* has received little study and the relative contributions of macrophage persistence and lysis to pathogenesis need to be assessed. The TTSS-2-dependent secreted effector proteins are thought to promote bacterial net growth *in vivo* by two distinct mechanisms: firstly by promoting bacterial replication rates; and secondly by preventing killing of bacteria by macrophages.

Systemic spread and persistence may have several pathological consequences. Release of endotoxin in systemic organs may result in haemorrhages, leucopenia, leucocytosis, hypotension, hypoglycaemia and shock. Mutation of endotoxin to make it less inflammatory reduces the mortality in mice infected with *S. typhimurium* without affecting the net rate of bacterial growth in the liver and spleen. This suggests that fatal systemic infection, at least in mice, is due to the inflammatory response of the host to endotoxin. Bacterial spread to systemic sites may prolong enteritis by allowing continual reinfection of the intestines via the biliary system and may also lead to systemic complications such as pneumonia or abortion. Abortion may occur before, during, after or even in the absence of enteric symptoms. The placenta becomes infected and the subsequent rapid bacterial multiplication results in a pyrexic response, severe damage to the placenta and possible infection and death of the fetus *in utero* or the birth of infected calves. Systemic spread may also lead to the development of the carrier state, characterized by the continual faecal excretion of salmonellas.

Signs of disease

Adults

The disease in adult cattle is usually sporadic, although *S. dublin* has become endemic in some areas of the country and acute and subacute forms are recognized. In the characteristically severe form of the disease produced by *S. dublin* in adult cattle the onset is usually sudden. Fever, dullness, anorexia and abruptly depressed milk yield at first associated with firm faeces, which may contain blood, are rapidly followed by severe diarrhoea. The faeces often become watery and contain large numbers of salmonellas (up to 10^8 /g). The fever usually persists for several days, then animals rapidly become cold and recumbent and death, which may be preceded by abortion, occurs in approximately 75 per cent of untreated animals between four and seven days from the onset of clinical signs. In some animals the disease is more protracted and cattle may become emaciated and dehydrated and show signs of abdominal pain. A milder disease, characterized by diarrhoea and abortion, or abortion in the absence of other clinical signs, from which animals usually recover, also occurs. A similar disease is produced by other serotypes including *S. typhimurium*, although in these cases abortion is a less frequent event. Survivors of *S. dublin* infections often remain as carriers, possibly for life, while infection with other serotypes seldom results in the carrier state although excretion of types such as *S. saintpaul* for up to two years after infection has been reported.

Calves

In calves, disease usually occurs between two and six weeks after birth. Characteristically, calves become dull and anorexic and develop a fever. Diarrhoea follows, which in young calves involves the excretion of faeces with the colour and consistency of putty. This may be bloodstained and may contain fibrin and mucus. Eventually, the faeces become dark brown and watery with an offensive odour. More rarely the faeces are heavily bloodstained, become stringy due to the presence of undigested milk and pseudomembrane formation and may contain shreds of necrotic intestinal mucosae. In older calves the faeces are usually watery, dark brown and offensive. The calves become very weak and dehydrated and death usually occurs after five to seven days of illness in untreated individuals.

The disease is very variable; in some calves, especially those two to three days old, bacteraemia and septicaemia occur and the animals collapse and die without diarrhoea. In other animals the disease may be so mild as to pass unnoticed or may be associated with diarrhoea in the absence of systemic disease. Diarrhoea may be prolonged in some calves, which may eventually die as a result of dehydration, electrolyte loss and acid-base imbalance. In both calves and adults systemic infection may lead to complications such as pneumonia, meningitis and osteitis; polyarthritis and gangrene may occur when the disease has been prolonged. Mortality from acute salmonellosis may be as high as 70 per cent and all calves in a herd may become infected. Recovered calves do not normally appear to become carriers of either *S. dublin*, *S. typhimurium* or the exotic serotypes and consequently infected calves do not grow into infected adults. However, the disease is often slow to resolve and salmonellas have been isolated from calves up to six months after their initial infection. The disease produced by different serotypes in calves is usually similar, although the peak incidence of disease and mortality with *S. dublin* is at four weeks of age compared with three weeks for *S. typhimurium*. Calves from dams infected with *S. dublin* may be infected from birth and these are particularly likely to succumb to septicaemia rather than enteritis.

Diagnosis of salmonellosis

It will be apparent from the description above that diagnosis of salmonellosis presents several difficulties. The clinical signs and findings at post-mortem examination are not unique to salmonellosis and although a tentative diagnosis may be made this should be confirmed in diseased animals or at necropsy by isolation of the organism. Diseased animals showing signs of enteritis

usually excrete large numbers of organisms in their faeces and determination of viable counts, rather than enrichment cultures, should be used (see below). For this reason faecal samples rather than swabs should be taken and these should obviously be obtained before administration of antibiotics. It may also be possible to isolate the organism from oral secretions and by blood culture, although these are less reliable than faeces cultures and must be taken with care to avoid contamination. Animals that have died of salmonellosis usually have large numbers of salmonellas distributed throughout their tissues and samples of spleen, liver, hepatic, mediastinal and bronchial lymph nodes may yield counts in excess of 10^6 organisms/g. Similar concentrations may also be present in the wall and contents of the ileum, caecum, colon and associated lymph nodes. Samples should be taken from the gut and internal organs in order to distinguish animals that have died of enteritis without septicaemia. Samples of fetal fluids, vaginal mucus and cotyledons should be taken from animals that have aborted. Counts will again give a more reliable result since the cotyledons from animals that have aborted due to *S. dublin* infection will usually contain between 10^8 and 10^{10} organisms/g.

Identification of carriers by bacteriological examination is more difficult and an attempt must be made to distinguish 'active carriers' (persistent excretors) from 'passive' carriers and 'latent carriers' (intermittent excretors). Faeces samples are more reliable than swabs and should distinguish persistent excretors whose faeces usually contain in excess of 10^5 salmonellas/g. Animals should not be assumed to be excretors on the basis of one isolation, nor should they be considered to be free of infection unless at least three negative faecal samples have been obtained. Even in this latter case 'latent carriers' and animals that will eventually clear the infection, and yet are still harbouring salmonellas, will be missed. There may be an advantage in taking samples from adults at calving although care must still be observed to distinguish 'passive carriers'. Traditionally, samples of gall-bladder or bile have been taken to identify carriers at slaughter. Unfortunately, these may not always contain salmonellas unless animals are infested concurrently with *F. hepatica* and a variety of tissues including alimentary contents and superficial lymph nodes need to be examined. It may be possible to isolate salmonellas from the walls of the omasum, abomasum and rumen or from lymph nodes such as the bronchial node, prescapular node and retropharyngeal node when all other tissues are negative. Similarly, salmonellas have only very rarely been isolated from the tonsil although this has been the preferred site for some investigators. Identification of infected herds may be achieved by faecal samples but this may present similar difficulties to identifying individual infected animals,

particularly in the case of *S. dublin*. A simple, less expensive and probably more reliable method is to take samples of slurry where this is available.

A variety of enrichment techniques and isolation media are available for the cultivation of salmonellas. They rely on promoting the selective growth of salmonellas, whilst inhibiting the growth of contaminants, and identification on the basis of colony morphology and biochemical reactions. The choice of media depends upon the environment from which the organism must be isolated and often depends upon the subjective choice of bacteriologists who specialize in *Salmonella* isolation. In general, a range of liquid enrichment media and the use of at least two types of solid isolation media are necessary to guarantee the isolation of the majority of serotypes. Enrichment media depend upon allowing salmonellas to grow, albeit sometimes in an inhibited manner, whilst suppressing other bacteria through the action of chemicals, dyes, antibiotics and enhanced incubation temperature. In common use are media containing sodium selenite or tetrathionate and dyes such as brilliant green or malachite green to which salmonellas are relatively resistant.

After enrichment in liquid culture, colonies of *Salmonella* are isolated on solid selective agars such as MacConkey, Brilliant Green, Deoxycholate citrate, EF-18, Rambach, Hektoen, Bismuth sulphite and *Salmonella*-Shigella. These rely on the resistance of salmonellas to a variety of antibiotics, bile salts and dyes, which inhibit other bacteria, and lack of fermentation of sugars such as lactose and sucrose to differentiate colonies of *Salmonella* from other bacteria which grow on the media despite the presence of inhibitors. More recent techniques include the use of immunomagnetic separation (IMS) and PCR (polymerase chain reaction) or fluorescence PCR, but the use of these is usually confined to research laboratories. Once isolated, the identification of salmonellas to genus level is carried out on the basis of biochemical reactions for which a variety of rapid kits are available. Further identification is carried out by slide and tube agglutination tests, which define the serotypes according to the Kauffmann-White scheme. Since a large number of differential sera are required this is usually the province of dedicated laboratories.

Important serotypes such as *S. typhimurium* and *S. enteritidis* may be further subdivided by phagotyping (there are more than 200 phagotypes of *S. typhimurium* but one or two phagotypes predominate in the UK at any one time, although 20 to 30 are usually present), plasmid analysis or a variety of molecular techniques including ribotyping (rRNA gene restriction patterns), PFGE (pulse-field gel electrophoresis), IS200 typing (a method of comparing restriction patterns of DNA after hybridization to a probe to a unique (IS200) *Salmonella*

insertion sequence), DNA fingerprinting (RFLP: restriction fragment length polymorphism) and AFLP (amplified fragment length polymorphism where DNA fragments are amplified by PCR). Although used for research purposes, a phagotyping scheme for *S. dublin* is not available in the UK (recent studies identified 26 groups of *S. dublin* by phagotyping but more than 50 per cent belonged to one group) and this serotype is subdivided into biotypes. Unfortunately, although seven distinct, stable biotypes have been identified, the majority (approximately 75 per cent) of strains isolated in the UK belong to the same biotype and the scheme is of little use in epidemiological investigations.

A number of serological techniques are also used in an attempt to identify *Salmonella*-infected animals. Unfortunately, no single test has proved useful in distinguishing all infected animals, some of which do not mount an antibody response, and all suffer from an inability to distinguish infected animals from others which, although previously infected, no longer harbour the organism. Various techniques such as ELISA have been developed but they are usually no more successful than more traditional methods and are not in routine use.

Control measures and vaccination

Attempts to control salmonellosis in cattle have involved the use of strict hygiene measures, antibiotics and vaccination, either singly or in combination. Most of the control measures are obvious from the discussion presented above and the role of antibiotics and vaccination is described below. To prevent the introduction of salmonellosis to herds it is necessary to provide animals with uncontaminated feed and water, to control ingress of rodents and birds and limit human contact. When adult stock have to be 'bought in' these should be quarantined and examined bacteriologically. Exacerbating factors such as ketosis and liver fluke infestation should be controlled and particular care should be taken in maintaining the health and hygiene of animals at calving. This should include the use of individual calving boxes and thorough cleaning between animals. Calves should be encouraged to absorb sufficient colostrum. To prevent acquisition of infection in calf-rearing units only good quality calves from herds of known health history should be purchased and strict hygiene should be observed during feeding and cleaning. Units should be run on an all-in, all-out basis and calf houses should be thoroughly cleaned (preferably by steam-cleaning, disinfection or fumigation) between batches. In the event of a disease outbreak, affected animals should be quarantined and restrictions should be placed on the movement of susceptible stock.

Human contact with infected animals should be restricted and strict hygiene should be observed when moving between groups. During the course of an extensive outbreak of salmonellosis due to *S. saintpaul* in two large dairy herds many methods to control infections and reduce mortality were attempted. These included the use of an emergency vaccine, which had no effect on mortality but reduced the duration of faecal excretion, and treatment with oxytetracycline and ampicillin, which reduced mortality and the number of persistent excretors. Other measures included restriction of movement of stock and personnel, the use of impermeable clothing and disinfectant sprays, removal of predisposing factors such as dietary imbalance, reduction of stocking densities, segregation of susceptible animals, prompt antibiotic treatment of sick animals and removal of 'persistent excretors'. These measures were designed to reduce the level of environmental contamination. This is primarily due to contamination with the faeces of diarrhoeic animals and 'persistent excretors' from which calves may be infected either at birth, particularly when communal calving facilities are used, or when housed in the same buildings as adults. Once infected, calves may excrete such large numbers of organisms that less than 0.1 g of faeces may contain a lethal dose for other calves. Thus any measure that reduces environmental contamination may help to break the cycle of infection. Methods that appeared successful in this particular outbreak were prompt antibiotic treatment of sick calves, removal of adult carriers, reduction in stocking densities and segregation of susceptible animals.

Salmonellosis may be spread from farm to farm and amongst cattle on infected premises by the disposal or use of animal wastes on pastures as a fertilizer. The number of organisms contained in such materials is usually low and the risk can be reduced to an acceptable level if sensible restrictions are observed. The following code of practice designed to reduce the number of salmonellas should be followed:

- (1) When possible, slurry should be spread on arable land or land used for conservation. Salmonellas do not survive for long enough on grass to be a danger in hay, nor do they survive efficient silage making.
- (2) Composted waste may safely be spread on pasture to be grazed by animals but slurry should be stored for at least one month prior to spreading.
- (3) Pasture treated with stored slurry should not be grazed for at least one month after spreading. If the slurry cannot be stored, this interval between spreading and grazing should be extended. In addition, since young animals may be more susceptible to salmonellosis they should not be

allowed to graze pasture dressed with slurry for at least six months after spreading.

- (4) The principal danger to cattle occurs when fresh unstored slurry, particularly pig slurry or poultry manure, must be applied to pasture. This danger can be reduced by using low application rates and by leaving pasture as long as possible before grazing.
- (5) Consideration should be given to mechanical separation of slurry. This produces a solid fraction that readily composts and a liquid fraction in which salmonellas die off rapidly.
- (6) Slurry should not be spread by equipment which involves the production of spray.

These recommendations were designed to reduce the risk of infections from animal wastes but they may be applied, with minor modifications, to the disposal of human sewage sludge on agricultural land. However, water authorities disposing of sewage sludge produce their own codes of practice that should be followed.

Vaccination (see p. 1006)

Prevention of salmonellosis by vaccination has been attempted since the late nineteenth century. There has been considerable scientific debate on the relative importance of humoral and cell-mediated immunity, but it is now generally agreed that solid immunity probably depends on both humoral and cellular responses. Although the humoral response is not totally protective it plays an important role in the suppression of infection in its early stages. However, a cellular response is probably required for complete elimination of the organism. In consequence, both live and killed vaccines have been used for the prevention of salmonellosis in cattle and attempts have been made to protect calves actively and passively by transfer of maternal antibody in colostrum. In the UK only an inactivated vaccine is available. The inactivated vaccine, which is licensed for use in both adults and calves, is a formalin-killed preparation of *S. dublin* and *S. typhimurium*. This vaccine has been the subject of recent field and experimental tests and has been shown to be effective when used to induce antibodies in adults, which could be transferred to calves in colostrum.

The majority of recent attempts at developing new vaccines have utilized live, attenuated *Salmonella* strains. These have either been naturally occurring avirulent strains, laboratory-derived strains, spontaneous undefined mutants or, more recently, genetically-manipulated strains. Amongst the first of these, originally produced in the USA, were strains in which mutations were introduced into genes encoding enzymes in aromatic amino acid biosynthesis pathways

known as Aro deletants or Aro strains. Such strains are unable to synthesize chorismate from which *p*-aminobenzoic acid, a precursor of folate, and dihydroxybenzoate, a precursor of the iron-binding protein enterochelin, are produced. In the absence of *p*-aminobenzoic acid and dihydroxybenzoate, which are not found in mammalian tissues, they will not grow. Aro strains of *S. dublin* and *S. typhimurium* have been produced and tested experimentally in calves. They induce good protection when administered orally or parenterally, are claimed to cross-protect against challenge with heterologous serotypes and are claimed to be safe. They do not establish in the host, do not cause side-effects and are genetically stable. Their only disadvantages are that not all constructs are equally protective and that they may not be able to protect calves less than three weeks of age. More recently, constructs deficient in more than one enzyme or constructs with auxotrophic and other mutations have also been produced. These strains, which because they have two or more independent mutations are thought to be safer than strains with a single mutation, have also been shown to be effective vaccines for calves and may even be able to protect animals within the first month of life. As yet none of these strains are available commercially for use in the UK.

It is also probable that such strains are not able to protect against infection with a variety of serotypes. No study to date has shown good cross-protection between different serotypes for any significant period of time after vaccination. In one recent study wild-type *S. typhimurium* and *S. dublin* strains were used to infect ligated loops of calves previously immunized with either serotype. Although protection against bacterial invasion and induction of enteropathogenic responses was demonstrated it was clearly serotype-specific, despite the two serotypes being closely related and sharing common virulence mechanisms. It is difficult to imagine how effective cross-protection between serotypes may be obtained in future. It may be possible to include more than one serotype in a live vaccine. Recent evidence suggests, however, that distinct vaccine strains can interfere with each other when used in combination. Such interference could compromise efficacy.

Another problem with live vaccines that depend for attenuation on metabolic defects is that they are still equipped with a full battery of virulence mechanisms and may in some circumstances still be able to cause disease such as diarrhoea either in vaccinated animals, animals in contact or, in the case of food animals, in the human population who later consume their meat. A common problem with live vaccines has been mild diarrhoea and excretion of the vaccine strain in the faeces of vaccinated animals. Recent research on the mechanisms by which salmonellas induce enteritis may alleviate this problem. *Salmonella* type III protein secretion systems

are responsible for the delivery of effector proteins into host cells, which influence *Salmonella* intestinal invasion, induction of inflammation, fluid secretion, bacterial replication and avoidance of host defence mechanisms (*vide infra*). Targeted mutagenesis in *Salmonella* that results in the disruption of genes influencing *Salmonella*-induced inflammatory responses and net bacterial growth, but not invasion, can optimise the phenotype of vaccine strains such that they remain invasive, and thus immunogenic, but not virulent.

Since calves may become infected within the first few days after birth and the peak of mortality occurs between three and four weeks of age, passive protection by vaccination of adult animals would appear to be the ideal way of protecting calves. Unfortunately, attempts at passive protection have met with conflicting results. However, an experimental vaccination regimen based on dam vaccination and prolonged colostrum feeding has been described. Cows were vaccinated with formalin-inactivated *S. typhimurium* approximately seven weeks and two weeks preparturition. Calves were given the opportunity to suck from their dam for 48 hours following parturition and were then fed cold, stored colostrum from their own dam for a further eight days. These calves were resistant to a normally lethal challenge of *S. typhimurium* or *S. dublin* given five days after birth and excreted salmonellas in their faeces for only a short period after infection. Mortality was also reduced in calves that sucked from a vaccinated dam and were then fed on normal colostrum and in calves born to unvaccinated cows and later fed on 'immune' colostrum. In cases of outbreaks with exotic serotypes the use of emergency vaccines for control has been successful.

Vaccines may have an important role to play in the prophylaxis of bovine salmonellosis, but until improved vaccines become available they will not be a substitute for good husbandry and hygiene.

Antibiotic therapy

It is not intended to discuss treatment of animals infected with salmonellosis in detail here since this is based on the use of antibiotics and fluid replacement therapy as described earlier (p. 195). Although antibiotics are not used in the treatment of gastroenteritis in humans their use is justified for bovine salmonellosis, which can become a systemic disease with a high mortality in the absence of treatment.

The concern with the use of antibiotics is that they have the potential of predisposing to colonization with salmonellas, increasing levels and duration of excretion by carriers and of selecting for antibiotic-resistant strains (see p. 210). The effect of antibiotics on an

animal and its resident micro-organisms will depend upon the dose level, duration of administration and antimicrobial spectrum of the antibiotic. The effects of antibiotics to which salmonellas are sensitive at therapeutic doses must be distinguished from the effects of the same antibiotic at subtherapeutic concentrations and the effects at either concentration of antibiotics to which salmonellas are insensitive. Similarly, since the antibiotic may have an effect upon the salmonellas or the normal flora or both, the age of the animal host is important since age is often the principal factor in determining the composition of the normal flora. An antibiotic to which salmonellas are sensitive, used at the correct therapeutic dose, may be predicted to reduce excretion. The same antibiotic at a subtherapeutic dose may lead to increased multiplication of salmonellas due to a suppressive effect on the activity of growth-suppressing normal flora. Similarly, the use of an antibiotic to which salmonellas are resistant, but the normal flora sensitive, may be expected to result in increased multiplication and excretion.

Antibiotic therapy in uncomplicated *Salmonella* gastroenteritis in humans has not been recommended for more than 40 years. Therapy apparently does not shorten or otherwise alter the clinical course of infection and has frequently been shown to prolong postconvalescent excretion. However, antibiotics have been used extensively to treat salmonellosis in cattle without undue complications. It should be clear from the remarks above that the antibiotic sensitivity of the organism should be determined and the information used to choose the preferred antibiotic. The use of antibiotics for prophylaxis is more controversial and most authorities have reported that medication with antibiotics has no part to play in the prevention of salmonellosis. The use of antibiotics in the treatment of an outbreak of *S. saintpaul* infection has been described above. In the same outbreak antibiotics were successfully used prophylactically and have also been used to effect a bacteriological cure in adult carriers and calves.

Summary

- Salmonellosis is a disease which ranges in man and animals from severe enteric fever, through severe enteritis (with complications) to mild food poisoning.
- The disease has a worldwide distribution.
- Salmonellosis is caused by bacteria of the genus *Salmonella*, of which over 2400 types (serotypes) have been identified.
- The disease is characterized by host specificity. Some types cause disease only, or primarily in one animal species, whilst others are ubiquitous and cause disease in many species.
- The disease in animals in the UK is most severe in cattle and particularly calves, and can result in high morbidity and mortality. The principal serotypes involved are *S. dublin* and *S. typhimurium*. The former is endemic in dairy herds, particularly in the west of the UK, and may be maintained in herds by 'carriers'. The disease is also frequently mild or characterized by carriage of salmonellas in the absence of disease.
- The disease is controlled in cattle by vaccination and the application of strict hygiene.
- Some serotypes, and particularly *S. typhimurium*, have developed resistance to a number of antibiotics and multiple antibiotic resistance may be transferred between strains.

Introduction

The young calf is particularly susceptible to digestive disorders, with the major presenting clinical sign of scouring (diarrhoea) being a significant cause of economic loss due to ill-thrift and death. Immediately after birth the calf is exposed to a wide range of infectious agents, to which it must develop an immunity. Many calves are hand-reared and consequently within a few days their diet may change from whole milk to milk substitute. Later they must learn to eat solid food, to be weaned at six to eight weeks old. Such rapid changes of feed and feeding systems, in combination with a changing immune status, render the calf susceptible to a wide variety of infectious diseases and nutritional disorders. Infectious conditions are described elsewhere in this book (see Chapters 14, 15). This chapter discusses the common nutritional disorders.

Abomasal milk clot failure and milk scour

Abomasal volume in the newborn calf is 1.0–1.5 litres. It has a neutral pH, thus allowing the first feed of colostrum to pass through unclotted, so that immunoglobulin molecules can be absorbed whole through the intestinal epithelium. Initially, renin coagulates milk (optimally at pH 6.5), with clot formation

within minutes of ingestion. The clot contracts, expressing the whey proteins (albumin and globulin), minerals and lactose in liquid whey, which begins its passage into the duodenum 5–10 minutes later. After two to three days the number of parietal cells in the abomasal epithelium increases and they begin to secrete hydrochloric acid. Abomasal pH falls. This converts pepsinogen secreted by chief cells into the active form of pepsin. Both pepsin and renin are capable of clotting milk and both can digest the milk protein casein, but pepsin is most effective at pH 5.2 and, additionally, can digest a wider range of proteins. The pepsin digestion system is not fully developed until approximately seven to ten days old and until that stage calves should, ideally, receive either whole milk or a substitute consisting of whole milk. Similarly, the very young calf has an immature intestinal digestive system. Pancreatic proteases can cope with whey proteins, pancreatic lipases with fat and intestinal lactase degrades the milk sugar lactose into glucose and galactose. The ability to digest starch does not develop until the calf is at least seven days old and full activity of maltase, sucrase and amylase systems, allowing the calf to digest non-milk carbohydrate, is not complete until three weeks old.

Figure 16.1 is a flow diagram of digestion in the young calf. Complete digestion of the abomasal milk clot (or ‘curd’) by lipases and proteases may take 6–8 hours and hence calves fed twice daily are without nutrients for only a short period. Calves left with their dams may suckle seven to ten times each day and any remaining curd forms a nucleus for the next milk clot.

If abomasal milk clot formation is poor, then whole milk spills over into the duodenum, where casein cannot be digested. In addition to altering the osmotic balance, this provides an excellent medium for bacterial fermentation in the lower intestine and scouring results. Similarly, if excessive quantities of milk are provided (greater than 1.5l for the young calf), or if a hungry calf is allowed to gorge itself, then abomasal digestive processes become overloaded and whole milk spills into the duodenum. This can also be a problem with suckler calves, especially if the dam is a ‘milky’ Friesian or Holstein crossbred animal. Although the calf may suckle every few hours, overloading and

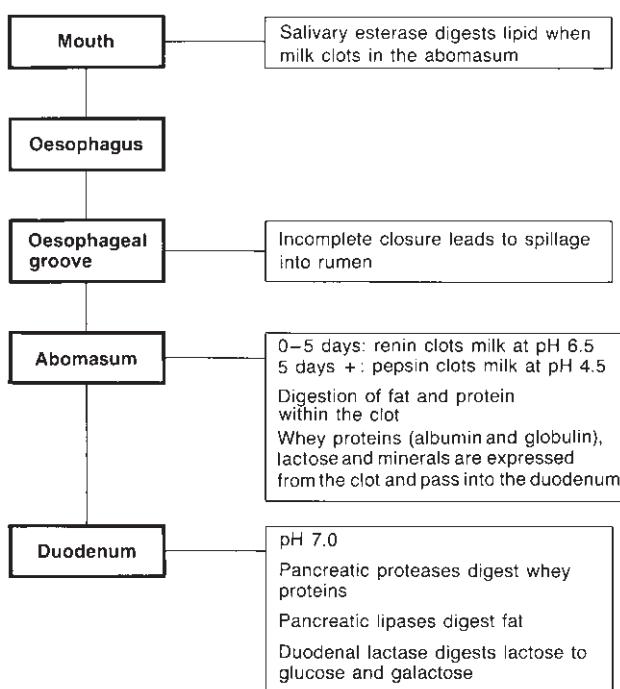

Fig. 16.1 Flow diagram of digestion in the young calf.

dietary scouring can still occur. This is particularly common if cows are put with the calves only twice daily.

On bucket-rearing systems a variety of management factors can lead to poor abomasal milk clot formation. These include:

- Nervous or stressed calves, for example feeding immediately after arrival from market, dehorning or some other stressful procedure.
- Irregular feeding times.
- Milk substitute fed at the wrong temperature or incorrect strength (see p. 233).
- Inflammation of the abomasum (see p. 237).

Many enzyme systems are induced, that is, enzyme activity develops following exposure to substrate. Calves should therefore be reared on a single type of milk substitute and, preferably, from a single batch purchased to cover the whole rearing period. A sudden change in the ingredients of the milk substitute could lead to incomplete digestion of protein, fat or carbohydrates, which later undergo putrefactive fermentation in the lower intestine, resulting in malabsorption, a fetid diarrhoea and weight loss. Such calves are more susceptible to colonization by pathogenic *Escherichia coli* and salmonellae.

Irregular feeding and its influence on abomasal pH can also have an effect on the susceptibility of a calf to infection. Most ingested enteric infections are killed at an abomasal pH below 4.5. The very young calf, which

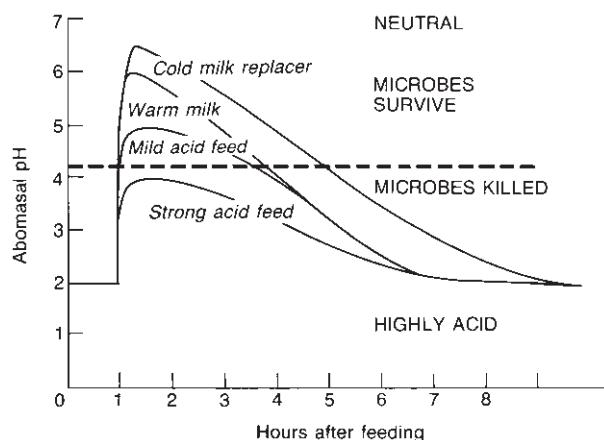

Fig. 16.2 The effect of type of milk and milk substitute on abomasal pH (Webster, 1984).

for the first few days of life has an abomasal pH of 6.5, is particularly susceptible to infection therefore. However, this is counteracted by surface-active antibodies contained in whole milk and colostrum. In the older calf, the acidity of the empty abomasum, i.e. after complete digestion of the curd 6–8 hours after the previous feed, may fall to as low as pH 2.0. Following a feed of milk, pH rapidly rises towards neutrality (e.g. pH 6.5), the extent and persistence of this rise depending on the volume and nature of the liquid milk ingested. With warm whole milk, abomasal pH falls to below 4.2 within three hours of a meal and bacterial killing once again becomes effective. Figure 16.2 indicates the periods required for other feeds.

Clearly, calves that develop a poor abomasal milk clot, or that have other abomasal disorders (e.g. abomasal dilation, p. 237), resulting in increased pH values, will be more susceptible to infection. In addition, improperly digested fats passed in the faeces produce steatorrhoea, with subsequent hair loss over the legs and perineal region (Plate 16.1). Affected calves will be unthrifty and in poor condition, due to poor absorption of nutrients.

Treatment with oral electrolytes for two to three days and dietary correction is normally effective.

Problems with milk substitutes

A full review of liquid feeds and feeding systems is beyond the scope of this book. Those interested should consult more authoritative texts such as Webster (1984). Because of the immaturity of the pepsin-HCl system, calves should receive colostrum and whole milk for the first three to four days of life. Most conventional milk substitutes are based on skim milk powder (SMP), to which is added lipids and fats from a variety of sources,

all highly emulsified to ensure even suspension throughout the milk when it is reconstituted. These SMP substitutes should clot in the abomasum. Addition of weak organic acids (e.g. citric or fumaric) reduces the pH to 5.7 and thus improves keeping quality. Fully acidified milk powders, with a pH of approximately 4.2, have an even better keeping quality. As casein would clot at this low pH it cannot be used and strong acid powders primarily consist of whey proteins (albumin and globulin) with added fat. Without casein they do not clot in the abomasum, but this does not seem to produce any increase in digestive problems. Such 'zero' replacers (so-called because they contain no skim milk powder) are commonly used in *ad libitum* calf feeding systems.

If skim milk powder is overheated during manufacture, casein is denatured, abomasal milk clot formation is poor, undigested casein passes into the small intestine and scouring may result from putrefactive bacterial fermentation. Most proprietary milk substitutes are carefully monitored and the majority of problems associated with their feeding are managemental in origin. The first golden rule must be *to read the manufacturer's instructions*. To achieve even dispersal of the product, and especially of the fat, many manufacturers recommend that milk is mixed at a higher temperature (45–50°C) and then cooled to just above blood heat (42°C) before feeding. A thermometer is needed to do this. The temperature cannot be judged manually. On a hot day milk will feel cool and consequently may be fed too hot. On a cold day the temperature may be overestimated and the milk substitute consequently fed too cold. Milk substitute mixed below the optimum temperature produces an inferior product. Added protein and minerals sediment to the bottom of the bucket and are wasted. In addition, poorly dispersed fats remain as a layer on the surface of the milk, forming a ring around the calf's muzzle after feeding, which produces secondary alopecia (Plate 16.2). If a long row of calves is fed from a single container, the milk for the last calf may be appreciably cooler. Again fat will rise to the surface and alopecia may develop on the muzzle. A fall of only 6°C in the temperature of the milk fed will double the time taken to form the abomasal clot. Undigested milk may then leak from the abomasum, thus reducing its nutritive value and possibly inducing diarrhoea. Conversely, however, if milk is fed too hot calves simply will not drink it, but no adverse effects have been observed. It is interesting to compare this with our own liking for hot drinks.

Milk fed at the wrong strength can cause problems. Powder is normally added at 125 g/l for twice-daily feeding and 150 g/l on once-daily systems. Abomasal milk clot will be optimal at these concentrations. If too dilute, clot formation is poor. Milk should not, there-

fore, be fed 'half strength' for scouring calves, as this may retard clot formation. Although some proprietary electrolyte preparations state that they can be used with whole milk and improve clotting time, there is some evidence that the clot thus formed is less stable. In general, therefore, it is best to avoid diluting milk substitutes and if electrolytes are to be given, they should be fed separately. Similarly, calves should not be allowed to drink large volumes of water immediately after milk, as this will have the effect of diluting the milk.

Probably the biggest problem with milk substitutes comes from careless mixing. Stirring with the hand is simply not adequate: a whisk, whether manual or mechanical, is essential. Carelessly mixed powders leave lumps and a sediment of protein in the bottom of the bucket and poorly dispersed fat rises to the top. Trials have shown that up to 60 per cent of the oils in a replacer may be wasted in this way, producing poor growth, stunted calves and possibly scouring due to inadequate abomasal clot formation.

Oesophageal groove dysfunction

From as early as two weeks of age the young calf begins picking at hay, grass or other solid foods. Bacteria ingested with this food, initially *E. coli* and lactobacilli, initiate ruminal fermentation. With increasing age, the rumen becomes progressively more anaerobic and an adult ruminal flora eliminates the early organisms. The inability of *E. coli* and salmonellae to survive for significant periods in the rumen is one reason for encouraging early ruminal development. However, at this age rumen fermentation alone would be unable to provide adequate nutrients for the rapidly growing calf and milk needs to continue 'monogastric' digestion in the abomasum. Milk entering the rumen is both wasteful and dangerous and hence it should bypass the rumen and reticulum to enter the abomasum direct. This is achieved via the oesophageal groove. In the anterior wall of the dorsal sac of the rumen there is a muscular channel that runs from the distal end of the oesophagus into the rumino-omasal orifice, as shown in Fig. 16.3. A reflex action from suckling results in muscular closure of this groove, to form an enclosed pipe, and milk is then transferred directly into the abomasum. As the calf gets older, the thought of being fed and the sight, sounds and stimuli associated with the arrival of its milk will be sufficient to evoke closure. It is most important that closure occurs prior to feeding and hence the establishment of a standardized feeding regimen is vital. The calf needs to know that it is about to be fed, that a pleasurable event is forthcoming. Ideally the calves should be able to both see and hear the feed being prepared, as this will induce a state of

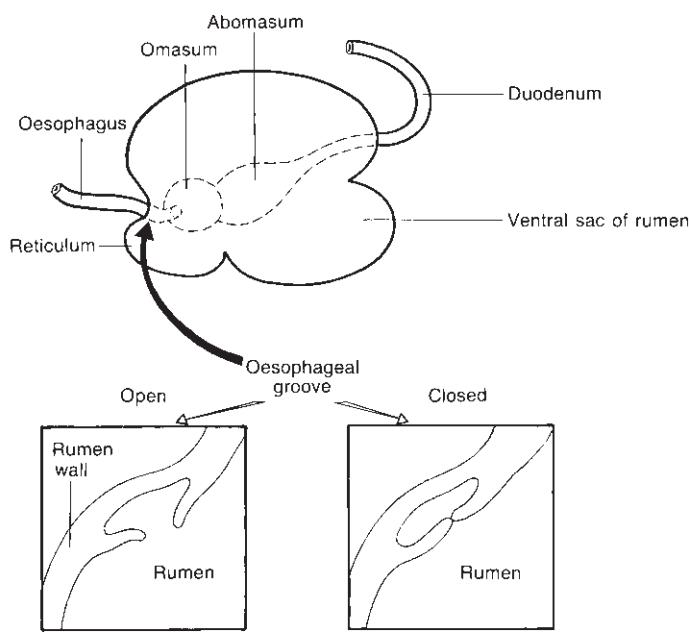

Fig. 16.3 The oesophageal groove.

expectation and stimulate oesophageal groove closure. Feeding times should be consistent each day. Milk should be provided at the correct and consistent temperature, in the same amount at each feed and of a similar taste and consistency. Calves with wagging tails and calves which butt the bucket (or udder, or teat) are enjoying their food and the oesophageal groove is well closed.

Calves on a teat need to work reasonably hard to get their milk – a pile of saliva beside the teat is a good sign. Conversely, if milk flow is too rapid, for example a badly damaged teat with an open orifice, the calf will almost choke with the rate of flow and milk could spill into the rumen. A sawn-off milking machine liner fitted onto a bottle and used by some farmers as a teat produces a much too rapid flow rate. Stressed calves, for example those that have just arrived from market, may not achieve groove closure and should therefore be given electrolyte solutions for their first feed. Similarly, calves should not be moved, handled, dehorned, etc. immediately before feeding. Slow drinkers present a problem. While the milk is warm, oesophageal groove closure may be adequate. However, if the bucket is left in front of the calf it may drink later, with possible milk spillage into the rumen. Some calves fail to learn to drink adequately and must be finger or teat suckled until weaning, although this is preferable to reluctant drinking with inadequate groove closure. Bucket height and teat position are important. The bottom of the bucket must be at least 30cm above the floor of the pen, which means that it must be raised as straw bedding accumulates.

Unfortunately, it is all too common to see calves on their knees trying to drink from a bucket some way below pen level. Teats for milk substitute should be positioned such that the calf has sufficient space to stand back to suckle and at a height that allows its nose to be tilted upwards and the oesophagus at least horizontal.

Milk spilt into the rumen undergoes rapid fermentation. This may produce an acute and sometimes fatal bloat and colic, within 15–30 minutes of feeding. In more chronic cases, ruminal development is retarded and abnormal products of digestion pass into the intestine, producing scour. Chronic pain restricts food intake and therefore growth and development. The Charolais calf in Plate 16.3 has a typically distended left flank caused by ruminal bloat. The superficial haemorrhage resulted from trocarization with a needle. A pasty scour is evident on the tail.

Treatment of oesophageal groove closure is, in effect, treatment of chronic bloat and is discussed in the next section.

Ruminal bloat (see also p. 832)

The development of normal rumen function is a complex process and any interference can produce bloat. Organisms ingested with feed from approximately two weeks onwards eventually establish an anaerobic fermentation. It is the ingestion and subsequent fermentation of solid feed that stimulates the

rapid expansion in size of the rumen, although full development is not complete until 12 weeks old, when the rumen comprises approximately 80 per cent of the total volume of the four stomachs. During this period, development of the rumen papillae is affected by the type of food offered. Inadequate long fibre and fermentation of a high-concentrate diet leads to low ruminal pH and acidosis. This can restrict development of papillae to such an extent that inflammation and ulceration of the ruminal wall permits bacterial 'leakage' and subsequent hepatic abscessation. The addition of 10–15 per cent chopped straw to concentrates, especially high-starch products, will improve rumen fermentation, thereby increasing the overall digestibility of the ration and promoting increased dry matter intake, since high acidity depresses the activity of cellulolytic bacteria. Calves that do not have hay on offer should therefore be bedded freshly each day, with ample palatable straw. Long fibre encourages rumination and subsequent saliva production, which in turn both neutralizes and dilutes ruminal acidity. Long fibre essentially acts as a 'scratch factor' and stimulates rumen motility. Silage or other forages may be used, but it seems critical that the fibre length is 5.0 cm or above. The rate of ruminal contractions and subsequent eructation and gas release varies with the physical presentation of the diet, as shown in Table 16.1, and with dietary constituents. High-forage diets produce greater ruminal activity than high concentrate. It has been suggested that concentrate intakes in heifer calves being reared for dairy replacements should be restricted, as this will encourage greater consumption of forage and the development of a larger rumen, capable of sustaining greater intakes later in life.

Irregularities at any stage of rumen development can lead to bloat, but the two most common causes are oesophageal groove failure, with subsequent fermentation of milk in the rumen, and acidosis caused by high-level feeding of improperly formulated concentrates. In both cases the bloat is caused by ruminal atony.

Table 16.1 Effect of the physical form of diet on ruminating behaviour of calves 6–9 weeks old (from Webster 1984, adapted from Hodgson, 1971).

| | Grass pellets | Long or chopped grass |
|----------------------------|------------------|--------------------------|
| Eating (min/24 h) | 132 | 276 |
| Ruminating (min/24 h) | 138 | 459 |
| Eating (min/kg DM) | 85 | 320 |
| Ruminating (min/kg DM) | 70 | 535 |
| Dry matter intake (g/24 h) | 1553 | 862 |

Signs

Typically, bloat is seen 15–30 minutes after a feed of milk or concentrate. Mild cases may deflate spontaneously over 3–4 hours, as ruminal contractions recommence. More protracted cases may remain bloated until the next feed, because bloat depresses feed intake and is therefore, to an extent, a self-perpetuating phenomenon. Affected calves are uncomfortable, with bouts of colic, often leading to kicking at their abdomen. Many develop a chronic scour (see colour plate 16.3), leading to general poor growth and unthriftiness. Death frequently occurs with acute cases.

Treatment

The syndrome may develop in both preweaned and postweaned calves and treatment is similar, the method used depending on the severity of the condition. Acute bloat must be deflated, either using a large bore needle through the rumen wall or, preferably, by stomach tube. Oral antibiotic will depress gas production. Penicillin may be the drug of choice, since lactobacilli proliferate in both concentrate overload acidosis and milk fermentation. Withdrawal of food and feeding electrolyte solutions for two to three days helps to remove the fermenting substrate. Calves should then be returned to a liquid milk diet for two to three weeks and eventually reintroduced to solid food. Even then, a proportion of cases recur and in many instances this protracted treatment is, for a variety of reasons, impractical. In such cases the construction of a permanent ruminal fistula in the triangle between the most caudal point of the last rib and the lumbar transverse processes is indicated. Under local anaesthesia, the rumen wall is sutured to the skin and a fistula is created. Although rumen contents may spill onto the flank, this does not appear to upset the calf and in many animals the improvement in growth and general condition following surgery is dramatic. A proportion of fistulae seal spontaneously after six to twelve months. Others require surgical correction, although this is not normally performed for beef animals.

On farms where bloat is a common problem, feeding and management systems should be examined, especially in relation to the encouragement of early ruminal development. Highly nutritious concentrates should be offered from two to three weeks old onwards, preferably in small amounts each day, to ensure freshness and palatability. Water should be freely available, especially on once-daily milk feeding. Inadequate access to water restricts concentrate intake and occasionally a long drink by a thirsty calf with a dry rumen leads to rapid fermentation of concentrates and subsequent bloat. In this respect the placing of buckets is important. Water

should always be freely available, but the calf must be 'programmed' to regard it as a drink, namely without stimulating the oesophageal groove closure reflex. However, milk is a food and as soon as the calf has finished, replace the milk bucket with another containing concentrate. (Many farmers leave the milk bucket *in situ* – to avoid the transfer of infection – and simply add the concentrate bucket.) The calf immediately puts its head in and starts to eat, thus encouraging concentrate intake and, at the same time, discouraging excessive water drinking. Even so, occasional calves will still drink to excess, looking bloated and uncomfortable when they do so. In such cases, water is best withheld until 2–3 hours after the feed of milk, accepting the risk of bloat following rapid fermentation of dry ingested concentrates.

Rumen impaction and 'pot-bellied' calves

Postweaning feeding is a critical stage of the calf's development. The rumen is not fully mature, being more acid (i.e. lower pH) than the adult and unable to synthesize sufficient microbial protein, relative to energy, to meet the calf's high requirements for growth. Preweaning, milk has passed directly into the abomasum and this source of undegradable protein must be replaced by high-quality undegradable foods, e.g. fishmeal or linseed meal, after weaning. The higher the growth rate required, the higher will be the requirement for additional undegradable protein. As feed conversion is much more efficient at a younger age (Table 16.2), it is still cost-effective to feed expensive, nutritious diets to freshly weaned calves.

If the diet largely consists of poor-quality forages, the calf's growth will be stunted, and the rumen will be distended with slowly fermenting foods. If concentrate intakes are inadequate, hungry calves may consume large amounts of forage. Fermentation rates will decrease and rumen distension is exacerbated. Affected calves have a 'pot-bellied' appearance, i.e. the lower abdomen is distended, often on the right as well

as the left flank, but overall body condition, in terms of fat and muscle cover, will be poor. Ruminal contractions may be slow and the rumen feels 'doughy' on palpation. In an extreme case, where poorly grown calves left without food for many hours were allowed unlimited access to palatable straw, the author has seen severe illness and even death due to ruminal impaction. However, this is rare. Rumen impaction is almost the reverse of bloat, in that it is associated with overconsumption of dry, fibrous and relatively indigestible foods, sometimes compounded by inadequate access to water. It may be a group problem of poor dietary management, or the result of inadequate trough space, when the smaller members of the group get pushed out and have to exist on forage alone.

Abomasal ulceration

Abomasal ulceration is common in artificially reared calves, the majority of cases being asymptomatic and seen only at post mortem (for example in veal calves). Surprisingly, perhaps, the incidence is higher in those veal calves that have had access to forage. Many clinical cases are seen at two to three weeks old, when they first start eating solid food, or in animals that have developed pica, often as a result of chronic illness. These points suggest that ulcers may result from large, inadequately digested particles of hay or straw, passing from the rumen to the abomasum. There is undoubtedly an increase in ulceration in calves with trichobezoars (hair balls), but whether the hair balls lead to ulceration, or whether chronic ulceration stimulates the calf to lick and eat hair (in the same way as chronic ruminitis) is uncertain. Ulceration occurs in association with abomasal dilation (see p. 237) and may also result from ruminal acidosis and starch overload, allowing undigested starch to spill over into the abomasum. Fungal hyphae are visible microscopically in a proportion of ulcers and may be involved in the pathogenesis.

Signs

The majority of ulcers in calves are subclinical although some may haemorrhage, producing melaena and anaemia, which is occasionally fatal. Others produce a localized peritonitis of the abomasal serosa, whilst perforating ulcers lead to acute peritonitis and death. The three-week-old Friesian calf in Plate 16.4 was recumbent, in considerable pain, with a subnormal temperature (37.5°C) and sunken eyes. Regurgitated rumen contents are visible at the mouth. Death followed within two hours, despite abomasal drainage, lavage and parenteral metoclopramide. On post mortem (Plate 16.5) two large ulcers, one perforated with a

Table 16.2 The effect of age on feed conversion (Blowey, 1999).

| Body weight (kg) | Feed conversion ratio |
|------------------|-----------------------|
| 50 | 2:1 |
| 100 | 3:1 |
| 300 | 5.5:1 |
| 500 | 8.5:1 |

white diphtheritic lining, were present, typically on the greater curvature of the abomasum.

Treatment

The treatment of abomasal ulcers is largely symptomatic. Valuable calves with extensive haemorrhage may be given a blood transfusion, but bleeding ulcers are less common in calves than in adult cattle. Kaolin has been used, but probably antacids such as magnesium oxide or magnesium silicate give a better response. Metoclopramide at 0.5–1.0 mg/kg body weight has been used to alleviate abomasal atony (Biggs *et al.*, 1989). Drainage and lavage may be indicated in concurrent abomasal dilation and ulceration. Antibiotics are indicated when peritonitis is suspected.

Abomasal dilatation

Also known as abomasal bloat, this condition of unknown aetiology produces a shock syndrome in calves, typically at two to three weeks old, when they first start eating solid food. Many cases are fatal. Affected calves are very dull, with sunken eyes and sub-normal temperature, and are often reluctant or unable to stand. Enteritis may occur, but it is not a consistent feature. The enlarged abomasum, distended by excess fluid and occasionally with gas to produce tympany, can be ballotted on the lower right flank. The accumulated fluid has a much higher pH (range 5–7) than a normal calf with an empty abomasum (pH 2–3), thus allowing the bacterial count to increase to 10^5 – 10^9 ml, with coliforms predominating. A normal calf has an abomasal pH range 2–4 and a bacterial count of 50000/ml, with mainly staphylococci and *Bacillus* species and very low numbers of *E. coli*. This has led to the proposal that abomasal dilation is an enterotoxaemia, similar to 'watery mouth' in young lambs (Price, 1989).

Abomasal drainage may be achieved by deep insertion of a stomach tube. With the calf in lateral recumbency on a straw bale and its head hanging down, the excess fluid is discharged under gravity. The abomasum can then be flushed two to three times with electrolyte solutions and, if the calves are treated symptomatically for shock and acidosis and fed electrolytes for 24–48 hours, recovery rates are acceptable. Metoclopramide at 0.5–1.0 mg/kg body weight has been reported useful to overcome abomasal atony (Biggs *et al.*, 1989), but the current author has met with very limited success.

In those cases that reach post mortem, a degree of abomasal ulceration, sometimes with fungal hyphae, is often present.

Acute abomasal bloat may also occur in milk substitute-fed calves within 20 to 30 minutes or less

after feeding. Affected animals are seen in severe distress, kicking at the distended abdomen or rolling on the floor. Some cases are fatal, others respond to relaxant therapy, for example pethidine or mepramizole. On post mortem the milk has often failed to clot, but no other lesions are seen and the cause remains unknown. It has been suggested that it is more common with infrequent and irregular feeding times.

Chronic peri-weaning diarrhoea

A well-recognized syndrome of a chronic persistent grey/brown scour occurs in calves 4–10 weeks old, i.e. before or after weaning (Blowey, 1988, 1994, 2000; Bidewell *et al.*, 1999) and when consuming concentrates. Morbidity is usually high but mortality is low and the few detailed post mortems reported have not shown consistent findings. There may be fibrous impaction of the rumen and a distended colon. Many cases of mild 'looseness' often pass unreported, but if the condition progresses, appetite falls and marked weight loss occurs. The diarrhoea may be unusually persistent, with many cases continuing for 4–6 weeks, leading to marked weight loss and stunting. The condition can be a major problem for feed companies because it often becomes apparent following (but not necessarily associated with) a delivery of food.

A range of treatments have been used, but none is particularly effective and most calves seem to eventually self-cure. Faecal examinations of affected calves reveal a range of organisms including *Giardia*, cryptosporidia, coccidiosis, *Campylobacter* species and rotavirus. Motile protozoa are commonly seen in fresh faecal smears and although calves can excrete giardial cysts asymptotically, *Giardia duodenalis* has been reported to cause chronic diarrhoea in calves in the USA (O'Handley *et al.*, 1999). Although faecal coccidian oocyst levels are often low, the author has examined an outbreak where intestinal histopathology was typical of coccidiosis and there was an apparent improvement in the remaining calves following the use of in-feed decoquinate at 1.67 kg/t if *ad libitum* or 2.22 kg/t if feed was restricted to 375 g/50 kg body weight of calf. It has been suggested that the syndrome is similar to colitis in pigs, where a primary dietary imbalance leads to proliferation of intestinal parasites. The rate at which the syndrome passes through several groups of calves would suggest that an infectious cause is also involved (Plate 16.6).

Management factors have been implicated, particularly those relating to digestive upsets. The syndrome is seen more commonly (but not exclusively) with calf pellets rather than coarse mix, presumably because calves eat coarse mix more slowly, chew it more thoroughly and saliva production is therefore increased.

Feeding rancid food, digestive upsets associated with poor abomasal groove closure and use of 'milking cow' concentrates and maize gluten, both of which are unsuitable for calves with an improperly developed rumen, have all been suggested as causes. Hygiene seems to be important and a thorough cleaning of the affected area helps. The syndrome is more common in group housed/fed calves rather than in animals penned singly and keeping calves individually penned until one to two weeks postweaning will help (Blowey, 2000).

Treatment is largely symptomatic and includes antimicrobials, anticoccidials and vitamins. Macrolides, for example tilimicosin, have been used and sulphonamides and other anticoccidial agents. Badly affected calves should be returned to a whole milk diet, without access to solid food, and possibly fed three to four times daily. One severe outbreak dealt with by the author appeared to improve through the use of in-feed decoquinate. Lasalocid could also be used. There is an urgent need for more epidemiological information on predisposing factors.

Colic (see also p. 845)

Colic is commonly seen in young calves. It occurs in association with many of the syndromes described earlier in this chapter, namely oesophageal groove dysfunction, acidosis, ruminal bloat, ruminal impaction, abomasal ulceration and abomasal dilatation. True intestinal spasmodic colic occurs and may precede enteritis and subsequent diarrhoea. Colic may also be a sign of a more serious abdominal disorder, for example torsion of the root of the mesentery, intussusception, acute peritonitis, cystitis with urethral obstruction or atresia ani/coli. The latter condition is seen within 24–48 hours of birth.

The treatment of colic therefore depends on the diagnosis and is discussed in the relevant section.

Necrotic enteritis (see also p. 213)

This syndrome, first reported in the UK in 1991, affects spring-born suckler calves at 2–4 months old, when they are at pasture. Morbidity is low but mortality is high (Penny, 1999). Clinical signs are a sudden onset of profuse haemorrhagic diarrhoea, which later becomes scant and mucoid with tenesmus. Coccidiosis is therefore an important differential. Pyrexia is common and the animal becomes progressively more depressed, anaemic and dehydrated, with death following in 7–10

days. There may be additional respiratory signs, with a muco-purulent oculo-nasal discharge originating from ulceration of the mouth and pharynx and in some cases crusting lesions of the nostrils are seen. On post mortem the characteristic findings are erosive ulcers throughout the gastro-intestinal tract, with some being sufficiently deep to produce areas of localized peritonitis. The ileum, caecum and colon are the organs most commonly affected. Kidneys may be pale and swollen, with infarcts, and there may be lesions of inhalation pneumonia as a consequence of the pharyngeal ulceration (Penny, 1999).

Typical haematological findings reflect the pathology and include anaemia, leucopenia, neutropenia and raised urea values. Treatment is symptomatic and includes antibiotics, NSAIDs and fluid therapy. The aetiology is unknown. Although the pathology is strongly suggestive of BVD (p. 853), the virus is rarely isolated from affected calves.

Introduction

Bovine respiratory disease (BRD) in calves in the developed world occurs under two main management systems. The *first* involves young, housed calves, usually dairy bred and either reared for beef or as dairy replacements. These are weaned from their dams within a few days of birth and then fed milk substitute or milk until weaned, usually between five and eight weeks of age. Under such conditions these calves can succumb to one of two different respiratory syndromes. Often one will lead into the other. The first is a problem of slow, insidious onset known as chronic or cuffing pneumonia, whereas the second is more sudden and acute in occurrence and is given a variety of names, the most common being calf pneumonia, acute pneumonia or enzootic pneumonia.

Fewer problems occur with calves suckling their mothers in the beef herd until weaning. However, on occasion similar types of acute and chronic pneumonia occur while the animals are housed. Unusually, outbreaks occur in suckler calves whilst with their dams at grass. These outbreaks are often precipitated by a stress such as a management change or marked alteration in the weather. However some of these are less obvious in their precipitating factors. Investigation of these problems often shows *M. haemolytica* to be present. However, *Haemophilus somnus*, infectious bovine rhinotracheitis (IBR), bovine respiratory syncytial virus (RSV) and parainfluenza III virus (PI3) have all been detected in various outbreaks. It must also be remembered that calves can pick up lungworm infection and this, when in low concentrations, will still cause lung damage. This on its own can create clinical signs or activate organisms present within the respiratory tract.

The *second problem* is in a management system involving weaned suckled calves, usually six months to two years old and mainly reared outside. This disease occurs following transport and housing and results in a condition best described as transit fever or shipping fever (see Chapter 20). All the syndromes are best defined by the circumstances in which they occur because their aetiology is complex and mainly multifactorial in nature. This involves the susceptibility of the animal, the environment in which it is kept, the management of the animal as well as the various disease agents to which it is subjected. In many BRD problems the causal agents will be similar in each of the syndromes and it is only the management conditions that will be different.

Enzootic and cuffing pneumonias

The aetiology of pneumonia in young calves is extremely complex in both the acute and the chronic form. It is fair to suggest that the disease is multifactorial. It is usually seen in calves reared indoors, particularly when they are reared for beef production and so have moved farms at an early age. Most cases occur between two and five months and usually following weaning from a milk-substitute diet. The causes of the problem are partly infectious agents, the environment, management and the animals themselves.

Epidemiology

Chronic

It is very difficult to determine the incidence of chronic or cuffing pneumonia as most affected calves are not treated and they do not die. In addition, by the time animals reach slaughter weight or are culled the residual damage is minimal. However, in a survey of dairy-bred animals reared on a farm it was found that 11 per cent had significant pneumonic lesions and it was estimated that this resulted in a 7.2 per cent reduction in liveweight gain (Thomas *et al.*, 1978).

Acute

Very few studies have been undertaken into the incidence of this condition. However, Thomas (1978) obtained health records for 12 beef farms in 11 British counties. The records covered 11 050 animals between 1970 and 1977. Mortality of bought-in calves is variable according to the rearing system used. However, a figure of 5.5 per cent is usual and it can be suggested that about half these deaths are due to enzootic pneumonia. This was seen in the Thomas study, which showed a death rate of 2.7 per cent from pneumonia out of a total mortality of 5.9 per cent. The overall number of animals treated for pneumonia was 32.6 per cent although the levels on individual farms varied from 3.1 to 52 per cent. Recent routine studies of individual outbreaks produced an overall incidence of signs of 68.4 per cent (range 41.7–90.5 per cent) (Andrews, 2000). It should also be remembered that some calves require more than one treatment for pneumonia. Again, there are few records for this but a level of retreatment of 10 per cent of all susceptible animals is probably not unrealistic. The recorded level was 8.9 per cent being treated on more than one occasion over a five-year period (Thomas, 1978) in a group of 2040 animals of which 22 per cent became ill initially. Another problem is that besides mortality, calves may become chronically affected and fail to thrive. Culling probably doubles the mortality due to disease and a level of 3.6 per cent was found in the study by Thomas. The reduction in liveweight gain in animals treated for pneumonia but which were not culled or died, compared with those untreated, was found to be 2.6 per cent (Thomas *et al.*, 1978). A study of eight outbreaks on dairy herds in 1997–99 showed an average cost per ill animal of £43 and a cost per animal within the group of £30. Veterinary and medicine costs amounted to only 40 per cent of the total costs of the outbreak (Andrews, 2000).

Aetiology

A large number of different infectious agents have been isolated and suggested to be involved in the aetiology of both chronic and acute calf pneumonia. Often the enzootic form is called 'viral pneumonia'. However, it is generally considered this term is a misnomer as it presupposes the aetiology and in most cases, even when viral agents are present, they only form part of the disease complex. It is usually considered that the most important agents involved in the chronic or cuffing form are mycoplasmal. They include *Mycoplasma dispar* and *Ureaplasma* spp. When it comes to the acute form there is a very long list of pathogens. Many have been seen in the disease but may not necessarily have produced the problem experimentally (see Table 17.1). However, certain agents do seem to be more commonly

involved. Thus the three main mycoplasmal agents are *M. bovis*, *M. dispar* and *Ureaplasma* spp., although *M. canis* is increasing. In the case of viruses, those most commonly implicated are bovine respiratory syncytial virus (BRSV), parainfluenza III (PI₃) virus, infectious bovine rhinotracheitis (IBR) and bovine viral diarrhoea (BVDV) virus.

The bacterial pathogens involved form a very long list and one or more tends to be isolated from most cases of disease. It is often postulated that these may be secondary invaders after primary damage by mycoplasma or viruses. The most commonly isolated organisms are *Mannheimia haemolytica*, *Pasteurella multocida* and *Haemophilus* spp., especially *Haemophilus somnus*. In addition, cases that involve toxæmia often include *Arcanobacterium* (formerly *Actinomyces*, *Corynebacterium*) *pyogenes* and *Fusobacterium necrophorum*. *M. haemolytica* serotype A1 is the most common serotype isolated, although serotype A6 is becoming increasingly common. The organism has also been involved in pleuropneumonia problems. The involvement of bacteria in this complex condition of enzootic pneumonia is also enforced by the fact that in most naturally occurring outbreaks of disease there is some clinical response following the use of antibiotics.

The environment

Various factors in the environment tend to be considered to be important. There is a popular belief that the disease is often associated with low environmental temperatures and a high humidity (see p. 974). Often a respiratory problem is associated with a sudden drop in temperature 24 to 72 hours previously. It is thought that the cold may allow infection to flare up partly by affecting the respiratory defence mechanisms and it also allows disease spread by encouraging calves to huddle together. It appears that the alveolar macrophages, ciliated and mucus-secreting cells are susceptible to the environment and cold stress inhibits clearance from the lungs. In the cold, animals reduce heat loss by slowing down their respiratory rate and by a partial reduction in the pulmonary ventilation rate (Webster, 1981b). This causes a reduced pulmonary oxygen tension and it has been shown that hypoxia reduces the clearance rate of some organisms in mice (Green & Kass, 1965), and there is a reduction in mucociliary rate and alveolar phagocytic activity (Thomson & Gilka, 1974). The probable role of hypoxia in respiratory infection is indicated by the fact that most lung consolidation occurs in the ventral parts of the apical and cardiac lobes and these tend to be the areas of lowest oxygen tension and the slowest rate of clearance of pathogens (Veit *et al.*, 1978).

At times, outbreaks of disease occur with a high temperature and a low humidity. Thus rearing at a temper-

Table 17.1 Infectious causes of enzootic pneumonia. The cause is often multifactorial, probably often mycoplasmal infection followed by viral and bacterial causes.

^a Thought to be the most important causes.

ature of 21°C (70°F) and 47 per cent relative humidity (RH) predisposed Friesian and Jersey calves to respiratory disease compared with those kept at a temperature of 14°C (60°F) and 36 per cent RH (Roy *et al.*, 1971). It does seem that a high relative humidity may be beneficial at a high environmental temperature as it increases the sedimentation rate of airborne particles and thereby reduces the bacterial count of the environment. These factors have formed the basis for the establishment of the sweat box system for pigs (Gordon, 1963) and this is why water drips are often used in buildings for veal production.

Although it is generally recognized that respiratory disease commonly occurs at certain times of the year, and under certain weather conditions, it is only recently that attempts have been made to determine why. In housed dairy-bred calves on one farm two peak levels of enzootic pneumonia occurred; the first was between

October and December and the second from February to May (Thomas, 1978). A study of a veal-calf unit over a 14-month period showed extensive outbreaks of disease in October, April and early June (Miller *et al.*, 1980).

The relationship between season and respiratory disease is probably partly due to management influences, particularly the housing of animals in close proximity, thereby assisting in the build-up and transfer of infection. However, the correlation between weather and disease is harder to prove, and in a disease outbreak involving veal calves no relationship was found (Miller *et al.*, 1980). A sudden drop in environmental temperature is often followed one to three days later by an outbreak of respiratory disease in housed, dairy-bred calves or housed single-suckler calves (Wiseman, 1978). Pneumonia in Irish calves housed in naturally ventilated buildings also tended to be precipitated by change

in weather, such as frost, rain and wind or damp, humid conditions (Bryson *et al.*, 1978).

Body temperature regulation in cattle is well developed, so they can tolerate both heat and cold (Webster, 1981a). However, draughts in buildings can result in chilling, which increases the metabolic rate and perhaps reduces resistance to infection (Webster, 1981b), but high relative humidity on its own does not chill cattle (Webster, 1979). Webster (1981b) therefore postulated that the main effect of weather was compounded by the building itself. Thus a badly constructed building with poor ventilation would reduce ventilation rate, and the water-carrying capacity of the air would be detrimentally affected by bad ventilation and possibly poor drainage. Such conditions could lead to the relative humidity remaining at more than 90 per cent for several days, and this in turn would increase the survival and spread of pathogenic organisms. Some support for this view has been obtained by work showing an increased survival of small airborne bacteria at high relative humidities (Jones & Webster, 1981). There is thus an increase in the number of infective particles that are not removed in the nasal passages and these are deposited further down the respiratory tract, possibly causing disease.

Management

The time of weaning appears to be important in that more lung lesions are found in calves weaned at five weeks than those on an *ad libitum* milk substitute diet until 14 weeks old (Roy *et al.*, 1971). The reason for this is not clear but it might be due to the lower levels of energy intake, or lower availability of a micronutrient (Roy *et al.*, 1971); or perhaps inhaled dust or fungal spores, which are more prevalent when dry feed is eaten, exacerbate the problem (Lacey, 1968); or due to weaning being less stressful or the calf more resistant to respiratory disease at an older age.

There is a relationship between colostral antibody levels and respiratory disease (Thomas & Swann, 1973). This apparent resistance to disease might be due to the ingestion of increased levels of specific antibody or due to an indirect effect resulting from a reduced amount of enteric disease, or possibly the gradual reduction in passive immunity allowing a more orderly exposure of the calf to respiratory pathogens. When colostral antibodies are low there is a relatively fast loss of antibody, which may then allow the invasion of many pathogens (Williams *et al.*, 1975).

The purchase of a large number of calves from different sources for dairy and beef production and keeping them in the same housing allows the easy spread of potential respiratory pathogens to other animals in close proximity. It is considered by many

authors (Wiseman, 1978) that it is the collection of a large number of young calves of a similar age and putting them into the same air space that is the main reason for the problem of pneumonia in intensively reared calf systems. It is not always accepted that the number of calves in a single air space is more important than the air space or floor area per calf. However, over-crowding is a major factor in allowing disease development and spread. Other factors involved in increasing disease levels are the inadequate cleaning and disinfection of the building between batches, as well as not allowing the accommodation sufficient rest between calf intakes. In some cases younger animals are mixed with an older group, thereby allowing transmission of micro-organisms from the old, apparently clinically normal animals. Economic considerations may also influence the picture if there is a reluctance to employ preventive measures such as vaccination, etc. Several management procedures such as castration, disbudding and weaning all appear to have an effect on the level of disease. The importance of microbial agents is indirectly indicated by the importance of adequate uptake of colostrum (Phillips, 1975; Thomas, 1979).

The calf

There appear to be some breed differences in susceptibility to respiratory disease and Friesian and Jersey calves are more likely to be infected than Ayrshire or Hereford × Friesians (Roy, 1980). It has been postulated that this may be due to an increased skin thickness in some breeds, which provides better insulation.

Signs

Chronic: The condition is one of gradual onset. There is generally no illness and so the calf is bright, eats well, but it may have a slight mucoid or mucopurulent oculo-nasal discharge. The temperature is normal or slightly raised at 38.5–39.5°C (101–103°F); the respiratory rate may be at any level from normal to 100 per minute with a normal pulse. There is a dry, explosive cough that is usually produced singly. On chest auscultation there are noises of whistling, wheezing or squeaking and these are more commonly heard at expiration, although often they occur at both inspiration and expiration. The sounds are most common in the anterior and ventral parts of the chest.

Acute: Although one calf may be seen to be ill to begin with, several animals will usually become sick within the next 24–48 hours. There is normally a reduction in feed intake of the group and widespread coughing will be apparent. The affected animals appear dull and the head tends to be carried lower than normal. There is

inappetance, pyrexia (40–40°C, 104–107°F) and a dull, sweaty coat. Other signs including a mucoid or mucopurulent oculo-nasal discharge, tachypnoea (respirations are usually over 40 per minute), dyspnoea and hyperpnoea are normally present. In all but very severely ill calves there tends to be an increase in the amount of coughing; the cough itself may be of a harsh, dry, hacking type, but in others it will be moist. Pinching the upper trachea often elicits a cough. On auscultation of the thorax there are usually loud, harsh sounds or whistling, wheezing or squeaking. These sounds may be present at inspiration or expiration, but more commonly they are heard at the latter and in some cases there are fluid sounds such as bubbling or gurgling, which will be audible in the cranio-ventral parts of the lungs. In some bacterial infections, where there is marked lung consolidation, few sounds are present.

Necropsy

Chronic: Lesions tend to be confined to the ventral parts of the lung lobes and involve, in decreasing severity, the apical, cardiac and cranial parts of the caudal lobes. The area involved may be 5–40 per cent of the lung tissue and it tends to be red or purple in colour and to be indurated. Histologically, there are accumulations of lymphocytes in the peribronchiolar tissue and it is this that produces a cuff; macroscopically it is seen as a mottling of the lesion's cut surface. When accumulation is great, then the lymphocytes can cause a narrowing of the bronchiolar lumen and cause the surrounding alveoli to be compressed. Resolution of the lesions occurs over several months provided that they are uncomplicated. The bronchial and mediastinal lymph nodes are usually enlarged and there is often a fibrinous pneumonia.

Acute: Within the clinical entity of acute pneumonia there are three types of pathological entity that can be recognized involving the lungs (Pirie, 1979).

Type 1. There is localized consolidation particularly of the cranial lobes and the tissue is dark red, friable and there is no gross evidence of necrosis. Interstitial emphysema may be present. Histologically, there is an absence of peribronchiolar cuffing, but there is necrosis of the bronchiolar epithelium. The changes are often suggestive of a viral infection, but in many cases the presence of a virus cannot be proven because of the absence of inclusion bodies or positive immunofluorescence. PI3 infection can be suspected when there is alveolar and bronchiolar epithelium proliferation and eosinophilic intracytoplasmic inclusion bodies are present. RSV infection can result in alveolar epithelium hyperplasia and large multinucleate syncytial cells. Bronchial collapse occurs with adenovirus infection due

to bronchiolar necrosis; there are basophilic and eosinophilic intranuclear inclusion bodies in epithelial and other cells. Intranuclear inclusion bodies, particularly in the epithelial cells of the trachea and bronchi, are seen in IBR.

Type 2. There is often marked consolidation of the cranial lobes with red or red/grey hepatization with widespread tissue necrosis and in many cases suppuration and this may involve up to 70–80 per cent of the lung. This type of lesion is often characteristic of bacterial infection. Extensive consolidation and suppuration are particularly seen in *A. pyogenes* and *F. necrophorum* infections.

Type 3. This is characteristic of calves that suddenly develop respiratory distress. The syndrome is often called atypical interstitial pneumonia. At post-mortem examination there is interstitial emphysema, pulmonary oedema and congestion, with alveolar epithelial hyperplasia and hyaline membrane formation.

Besides the lungs, there is usually gross enlargement and congestion of the mediastinal and bronchial lymph nodes. In some cases there is fibrinous pleurisy and the heart may be enlarged with epicardial and endocardial haemorrhages. Sero-sanguinous fluid may be present in the thorax and pericardial sac (Thomas, 1979).

Lesions of pleuropneumonia result in a thickened pleura with the lung showing thickened interlobular septa with variable amounts of lung consolidation showing dark red to grey hepatization.

Diagnosis

Chronic: Several animals are affected and are usually indoors. The problem is gradual in onset and although the animals show respiratory signs they are bright and eat well. The respiratory signs include single, dry coughing.

Acute: Again this affects a group of calves. Respiratory signs are present and the animals are usually obviously ill. Nasopharyngeal swabs or broncho-alveolar lavage can be undertaken to examine for bacterial, viral or mycoplasmal presence. The last two groups require placement in a transport medium. Fluorescent antibody tests are available for most of the more important viral causes. Even when a potential pathogen is recovered it does not always mean that it is the same agent as is causing trouble in the lungs. Paired serum samples can be taken two weeks apart. This may indicate the cause but is only of value if control measures can then be implemented for the future. Post-mortem material can be checked for the presence of organisms and for histology to indicate the type of pathogen which might be involved.

Differential diagnosis

Chronic: This needs to be differentiated from acute pneumonia but in the latter case the animal is ill. Inhalation pneumonia is likely only to involve a single animal, which again is ill, and there is usually a related history. Tuberculosis may cause problems but usually there is a herd history and the dam may be showing signs. Muscular dystrophy (see p. 258) can produce respiratory signs but usually such animals have a fast pulse rate and raised serum creatine kinase, and aspartate and aminotransferase levels. Congenital heart defects (see pp. 173–4) will usually only involve one animal and there is a heart murmur, possibly with signs of cyanosis. Salmonellosis can result in signs but the calf is noticeably ill with diarrhoea (see p. 226).

Acute. Chronic pneumonia is a major differential diagnosis but the animals are not really ill in such cases. Uncomplicated IBR infection (see p. 289) could cause difficulties but there are mainly upper respiratory signs and a noticeable conjunctivitis. Salmonellosis (Chapter 15) will usually present with enteric signs. Although mucosal disease (see p. 853) can give rise to respiratory signs, there is usually also diarrhoea and, in some cases, mouth ulceration. Inhalation pneumonia mainly involves a single animal and there is an appropriate history. Tuberculosis will be detected by a history of disease in the herd. Congenital heart defects (see pp. 173–4) involve a single animal and there is usually a heart murmur. Calf diphtheria (see p. 251) results in stertor and is again a single animal problem. Malignant catarrhal fever (see p. 935) affects single animals and there is lymph node enlargement, corneal opacity and often nervous signs present. Acidosis (p. 829) can mimic pneumonia.

Treatment

Chronic: Therapy is usually not necessary unless the calf is showing severe coughing. Several antibiotics are of use, including tylosin at 4–10mg/kg (2–5mg/lb) body weight, oxytetracycline at 10mg/kg (5mg/lb) body weight, spiramycin at a dose of 20mg/kg (10mg/lb) body weight or spectinomycin at 20–30mg/kg (10–15mg/lb) body weight. The macrolide antibiotics (tilosin, erythromycin, spiramycin) are all concentrated in the lungs and have good efficacy against mycoplasmal infections. The fluorquinolones have activity against mycoplasma but probably cannot be recommended for this purpose due to human health implications.

Acute:

(1) Antimicrobials. If more than 30 per cent of the animals are affected at one time and need treatment it is probable that many others are incubating the condi-

tion, so that it is often a good policy to persuade the farmer to treat all the cattle in the group, ideally using a different antibiotic. As with most disease, the earlier treatment is started, the less the mortality and the fewer the animals that have to be culled because of chronic disease. The drugs commonly used are given in Table 17.2. The therapeutic agent administered should have a broad spectrum of activity and ideally it should be bactericidal. The choice will most probably have to be based on previous successful usage on that farm or elsewhere. It is best not to use long-acting preparations because if there is no response to treatment it will make the initiation of subsequent therapy very difficult. If an animal dies then culture of swabs from the lung, bronchial and mediastinal lymph nodes and the subsequent antibiotic sensitivity of the isolates may be of use. The ideal is to culture swabs from material in carcasses that have not been treated. The culture of nasal or pharyngeal swabs from live infected calves is of less value as it cannot be certain that the organism cultured will be the same as the one causing disease in the lungs. However, it does indicate possible pathogens.

Therapy should be continued for three to five days, depending on the drug used and the response to treatment. In acute cases the choice of antimicrobial agent is normally dictated by those that can be given intravenously. Intratracheal administration of antibiotics has been advocated by some practitioners and in such cases those in aqueous solution are preferable to those in organic solvent. No antibiotic is at present licensed in Britain for this route of administration. Those compounds most commonly used have included erythromycin, trimethoprim and sulphadoxine.

(2) Corticosteroids. Some of the compounds available are shown in Table 17.3. The drugs commonly in use today include betamethasone, dexamethasone, prednisolone, flumethasone and triamcinolone. These compounds provide symptomatic relief only and do not cure the condition. Many people consider them to be overused (Pirie, 1979), but often an animal will show little or no improvement on antibiotic therapy alone, only to recover rapidly once corticosteroids are added to the treatment regimen. Their action is to suppress all stages of inflammation regardless of whether the cause is physical, chemical or immunological in origin. Thus in the acute stage, corticosteroids reduce vasodilation, oedema formation and leucocyte infiltration (Eyre, 1978). The drugs also have a 'euphoric' effect on the dull animal and this may allow the calf to eat and otherwise speed its recovery (Pirie, 1979).

The main problem with corticosteroids is the unselective suppression of inflammation that therefore includes those parts of the inflammatory and immune response, such as macrophage infiltration, which are

Table 17.2 Some of the antimicrobial compounds used in calf pneumonia therapy.

| Antimicrobial compounds | Bactericidal (C) or bacteriostatic (S) | Route of administration | Dosage | |
|------------------------------------|--|-------------------------|--------------------------------|--------------------------------|
| | | | (mg/kg) | (mg/lb) |
| Amoxycillin | C | i.v., s.c., i.m., oral | 7 (15 LA) | 3.5 (7 LA) |
| Amoxycillin and clavulanic acid | C | i.m., s.c. | 8.75 (am) | 4.38 (am) |
| | | | 1.75 (cl) | 0.88 (cl) |
| Ampicillin | C | i.v., s.c., i.m., oral | 2–7 | 1–3.75 (7.5 LA) |
| Baquiloprim and sulphamidine | C | oral | 4–8 (baquil) 36–72 (sulpha) | 2–4 (baquil) 18–36 (sulpha) |
| Ceftiofur | C | i.m. | 1 | 0.5 |
| Chloramphenicol (some countries) | S | i.v., s.c., i.m., oral | 4–10 | 2–5 |
| Danofloxacin | C | i.m. | 1.25 | 0.6 |
| Enrofloxacin | C | s.c. | 2.5 or 7.5 | 1.25 or 3.75 |
| Erythromycin | S | i.m. | 2.5–5 | 1.25–2.5 |
| Florfenicol | S | s.c., i.m. | 40 (s.c.), 20 (i.m.) | 20 (s.c.), 10 (i.m.) |
| Marbofloxacin | C | i.v., s.c., i.m. | 2 | 1 |
| Oxytetracycline | S | i.v., s.c., i.m., oral | 10 (20 LA) 10–15 (pen) | 5 (10 LA) 5–7.5 (pen) |
| Penicillin plus streptomycin | C | s.c., i.m. | 10–20 (strep) | 5–10 (strep) |
| Spectinomycin | C | i.m. | 12.5–30 | 6.25–15 |
| Spiramycin | S | i.m., oral | 20 | 10 |
| Sulphadimidine initial maintenance | S | i.v., s.c., oral | 200 100 | 100 50 |
| Sulphamethoxyypyridazine | S | s.c., i.m. | 22 | 11 |
| Sulphapyrazole | S | i.v., s.c., i.m. | 30–100 | 15–50 |
| Tilmicosin | S | s.c. | 10 | 5 |
| Trimethoprim and sulphadiazine | C | i.m., oral | 15–22.5 (active) | 7.5–12 (active) |
| Trimethoprim and sulphadoxine | C | i.m. | 15 (active) | 7.5 (active) |
| Tylosin | S | i.m., oral | 4–10 | 2–5 |

LA, long-acting; am, amoxycillin; cl, clavulanic acid; baquil, baquiloprim; sulpha, sulphadimidine; pen, penicillin; strep, streptomycin; active, active ingredients.

Table 17.3 Corticosteroids used in respiratory disease in calves.

| Drug | Dose per animal (mg) |
|----------------|----------------------|
| Betamethasone | 2–10 |
| Cortisone | up to 500 |
| Dexamethasone | 2–5 |
| Flumethasone | 0.5 |
| Hydrocortisone | up to 300 |
| Prednisolone | up to 20 |
| Triamcinolone | up to 5 |

concerned with the control and removal of infectious organisms. In such an environment an organism can multiply and spread within the animal. This may be the agent that caused the pneumonia or an opportunist organism that enters the body. The reduction in the

immune response can also increase the ability of the same organisms to reinfect the animal following recovery. It is therefore essential that antibiotic therapy is administered concurrently with corticosteroid therapy and in most circumstances it is probable that a bactericidal drug is indicated rather than a bacteriostatic drug. Adequate therapeutic doses of the antibiotic should be given and maintained for sufficient time. Another problem with the prolonged use of corticosteroids is that there is a risk of inducing permanent adrenal insufficiency, but this has produced little worry in cattle.

(3) Non-steroidal anti-inflammatory drugs (NSAIDs) (see Chapter 62). These drugs are salicylate-like compounds and although many are not registered for use in cattle, they do help reduce inflammatory reactions by blocking the synthesis of prostaglandins and inhibiting kinin formation (see p. 1050). They also antagonize the actions of some of the chemical

Table 17.4 Some non-steroidal anti-inflammatory drugs.

| | Route of administration | Dose ^a |
|-----------------------|-------------------------|-----------------------|
| Acetyl salicylic acid | Oral | 1.0–4.0 g/animal |
| Carprofen | Injection (i.v., s.c.) | 1.4 mg/kg (0.7 mg/lb) |
| Flunixin meglumine | Injection (i.v.) | 2.2 mg/kg (1.0 mg/lb) |
| Ketoprofen | Injection (i.v., i.m.) | 3 mg/kg (1.5 mg/lb) |
| Meclofenamic acid | Oral | 2.2 mg/kg (1.1 mg/lb) |
| Meloxicam | Injection (i.v., s.c.) | 500 µg/kg (250 µg/lb) |
| Naproxen | Oral | 10 mg/kg (5 mg/lb) |
| Phenylbutazone | Oral/injection | 4.4 mg/kg (2.2 mg/lb) |
| Sodium meclophenamate | | |

^a Doses are only guidelines. Note that many of the drugs are not registered for use in cattle in some countries.

mediators in the lungs such as 5-hydroxytryptamine (5-HT) and histamine, which are mainly released from mast cells in response to antibody-antigen reactions (Pirie, 1979). Besides an anti-inflammatory action, NSAIDs have two properties that corticosteroids do not possess, namely they are anti-pyretic and analgesic. Until the availability of flunixin these compounds were little used in Britain although they are frequently prescribed in Holland where corticosteroids are not allowed to be used for respiratory diseases in calves. Some of the main drugs available are shown in Table 17.4. The drugs most commonly used in Britain are carprofen, flunixin meglumine, ketoprofen and meloxicam.

(4) Antihistamines (see Chapter 62). These drugs have been used in the past but most clinicians have found them to be of little use in calf pneumonia. This is probably because the main chemical mediator of cattle is not histamine but 5-HT. The histamine that is released occurs very quickly following the antibody-antigen reaction so that antihistamines can only be of use in the early stages of the inflammatory response (Pirie, 1979).

(5) Sympathomimetics. These drugs are all adrenaline-like and their actions to a varying degree are similar to it.

Although both adrenaline and isoprenaline are of some use in relieving respiratory signs, they are little used because of their stimulatory effects on the heart. This is because adrenaline acts on many types of receptors that are designated α and β , those of the heart and lung being β_1 and β_2 receptors, respectively. Recent work has produced compounds that will act on only one type of receptor and not on the others. For various reasons including some of their other potential properties their use has been curtailed in many countries.

(6) Xanthine derivatives. Those commonly in use are etamiphylline camsylate and diprophylline, but

others are available and are given. Their actions are relatively similar to those of adrenaline. There is stimulation of the central nervous system where caffeine is the most powerful, myocardial stimulation where aminophylline and diprophylline are strongest, bronchodilation and diuresis. Their main uses in respiratory disease are bronchodilation and, to a secondary extent, fluid removal. The mild action of these drugs compared with substances such as adrenaline means that they are all relatively safe.

(7) Expectorants. One drug used at present as a spasmolytic is bromhexine hydrochloride, which can be given orally or by intramuscular injection at a dose of about 0.5 mg/kg body weight for five to seven days. Its action is mainly to reduce the viscosity of mucus and thereby help in its expulsion, resulting in improved respiratory function. Other expectorants have often been used in chronic cases of coughing. These include a mixture of strichnine hydroxide, arsenic trioxide and ferric ammonium citrate given at a dose of about 5 ml orally twice daily, or diphenhydramine hydrochloride, ammonium chloride, sodium citrate and menthol at 5–10 ml orally two or three times daily. There is limited benefit from the antihistaminic action of diphenhydramine hydrochloride in cases of calf pneumonia.

(8) Antisera. Several antisera are available in some countries that have been produced either in cattle or horses against *P. multocida*, the septicaemic and pneumonic strains of *M. haemolytica* and, in some cases, diplococci. Little experimental work is available to demonstrate their efficacy or lack of it and so their use is speculative (Thomas, 1979). As has already been indicated there are numerous organisms involved in the aetiology of calf pneumonia and it would be only right to expect benefit in some cases where the organisms in the anti-sera are a major factor in the disease process.

(9) Supportive therapy. During the disease phase many animals become partially or completely anorexic

and it has been suggested that multivitamin injections, particularly of the vitamin B group, may be of use in overcoming any temporary deficiencies that might occur as the result of the low storage of vitamins (Thomas, 1979). As vitamin A is of use in epithelial repair it may be advantageous to inject this compound to ensure speedy respiratory mucosal regeneration.

(10) **Nursing.** As with many other diseases, although nursing is important, it is often neglected. Affected animals should be removed from the in-contact group partly to reduce spread of infection and also to allow access to feed and water away from competition. Feed supplied should be highly palatable and non-dusty to encourage uptake. The environment of the convalescent calf should include plenty of bedding, and draughts must be avoided. The provision of oxygen by means of a mask and reducing valve has been used in animals at indoor agricultural and fatstock shows.

(11) **Vaccination.** It is possible to obtain rapid confirmation as to the aetiology of outbreaks of calf pneumonia. If the cause is viral it is possible to use live vaccines and to vaccinate in the face of an outbreak. This can be very effective provided it is undertaken in the early stages of disease among the group. It appears to produce non-specific interferon followed by good specific immunity to the virus vaccinated against. To be effective a live vaccine needs to be used and it must be administered intranasally.

Prevention (see pp. 1007–11)

As the disease is multifactorial, preventive measures include attention to management as well as possible vaccination. Thus ensuring there are no more than 30 calves in any one air space as well as making sure that different age groups are not mixed is helpful. If disease tends to follow particular patterns it is best to alter the time of undertaking stressful procedures such as weaning, castration and disbudding. Often ensuring castration and disbudding are undertaken more than two weeks before weaning can be helpful. Increasing the duration of feeding milk substitute can also be useful, as well as ensuring weaning is not undertaken at a time when this is likely to result in pneumonia. Gradual weaning is often helpful, particularly when cattle are fed in groups on a milk dispensing machine that will provide feed throughout the 24 hours.

When calves are home-reared, it should be ensured that they receive adequate amounts of colostrum. All calves should be given adequate good quality feed. If calves are bought-in they should be examined at entry and any which show purulent ocular or nasal discharge rejected. Calves should not receive dusty or overmilled feed. As disease occurs on the same farms year after

year, the time when disease starts should be noted and checked to see if it can be associated with any changes in management, etc. Calves bought as batches should be kept together and not mixed with other batches. An all-in all-out policy for rearing calves is best advocated. Ideally, calves should be reared before and after weaning in the same building for at least a month and preferably longer.

There are various vaccines available and, as might be expected with a disease of such complex aetiology, the results experienced by different farmers and veterinary surgeons are extremely variable (see p. 1007). In some cases this may be due to the type of vaccine used. It is thought that the age incidence of enzootic pneumonia may well coincide with the decline in colostral immunity. Thus peak onset of pneumonia in housed calves is often at two to four months old when concentrations of serum IgG₁, IgG₂ and IgA are at their lowest (Corbeil *et al.*, 1984). It must also be remembered that several of the pathogens involved in the disease complex are immunosuppressive. These organisms include *M. dispar*, ureaplasmas and *M. bovis* as well as BRSV. In consequence, vaccination of calves where the organisms are already present in the animals is likely to reduce the immune response.

Dead vaccines are used to provide immunity against *P. multocida* and septicaemic and pneumonic strains of *M. haemolytica*. Following successful experiments (Gilmour *et al.*, 1979) several *M. haemolytica* vaccines for serotypes 1 and 6 are now available in Britain. Killed polyvalent vaccines are used in some countries, and contain antigens such as RSV, PI₃, IBR and BVDV. They are usually administered parenterally and usually require two injections to produce immunity. Recent developments have included combined live and dead viral components of the four main antigens which are injected intramuscularly. When live vaccines are used, the integrity of the vaccine must ensure absence of other potential contaminants, both viral and other pathogens. Subsequently, modified live intranasal vaccines have been available. A study of the live IBR vaccine in the absence of disease showed virus could be isolated from most animals (10/11) and there was seroconversion in 7/11 (Lucas *et al.*, 1982). Although good immunity was conferred to animals by modified live vaccination, it was shown that some cattle became carriers after exposure to field strains of IBR (Nettleton & Sharp, 1980).

A dead vaccine has been produced against *M. bovis*, but it has had only limited success experimentally. There are several live vaccines used in Europe including ones against respiratory syncytial virus and parainfluenza III virus. A vaccine for PI₃ has been licensed and it is possible others will eventually be available in Britain and elsewhere.

From experience, the vaccines themselves do appear to have variable results on individual farms. This is probably due to the type of vaccine used, i.e. live or dead, other underlying pathogens, the level of infective dose and whether or not the particular pathogens present in the vaccine are responsible for disease on that farm. Before embarking on a vaccination programme it is important to ensure that the pathogens on the farm are correctly identified so that the programme can be introduced correctly. Such regimens will usually work well on farms housing just home produced cattle. However, there is a particular problem for farmers who continually buy in batches of calves as the pathogens introduced with each group are likely to be different. Thus it is very difficult to create a suitable vaccination policy to prevent pneumonia, unless several vaccines are used to cover most of the major pathogens. Such a policy is obviously costly and at times very wasteful as it will result in immunization for diseases that are not present. This has led to the suggestion that in such units it is best to make a diagnosis as to the likely cause of enzootic pneumonia in the first animal(s) to be affected. If the agent is primarily viral then the calves can be vaccinated in the face of an outbreak.

Stillbirth/perinatal weak calf syndrome

This is an important cause of losses in the young calf and has considerable economic consequences to the farmer. Very few studies have been undertaken to determine the factors involved. However work done in Northern Ireland (McCoy *et al.*, 1997) showed that nearly half (46 per cent) of the animals examined had non-inflated lungs and so were true stillbirths and another 22.7 per cent had severe trauma (mainly rib or spinal fractures) from calving. Otherwise the largest number of weak calves (36.7 per cent) had thyroid abnormalities and within the study 20 per cent had low thyroid iodine levels. Other problems were of an infectious nature including leptospirosis (13.4 per cent), pneumonia (9.1 per cent) and bacterial isolation (9 per cent); virus isolation was low.

Iodine deficiency is more common than recognized in suckler herds and dairy and suckler heifers who receive limited feed supplementation. The problem normally arises from increased calf mortality as abortion, stillbirths, weak calves and neonatal mortality. The calves

have enlarged thyroids (greater than 14g is suspect), parturition is slow and often there are retained placentae. Poor fertility may be seen with suboestrus and delayed ovulation, lowered milk yield, lowered libido in bulls, ill thrift in cattle and lowered herd immunity.

Joint ill or navel ill (see p. 455)

Joint or navel ill is a common problem in the calf. At birth there is a sudden change from the fetal circulation to that of the newborn calf. The blood vessels in the umbilical cord rapidly lose most of the blood within them but still remain patent, thereby allowing the introduction of infection. Infection can be caused by a single organism or a mixture. A wide variety can be involved including *Streptococcus* spp., *Escherichia coli*, *Erysipelothrix insidiosa*, *Pasteurella multocida*, *Arcanobacterium* (*Actinomyces*, *Corynebacterium*) *pyogenes* and *Fusobacterium necrophorum*. The problem normally arises from calving taking place in conditions with poor hygiene. Often the calf will not have had sufficient intake of colostrum and usually the navel will not have been treated. Many infections also enter via the tonsils.

Infection entering the umbilicus may result in a local reaction at the point of entry into the body, between the muscle layers or in the peritoneum. In other cases entry is via the urachus and can lead to local infection. Otherwise the bacteria may pass via the umbilical vein to the liver and then in the blood to the body. When infection is present in the blood it may cause a septicaemia or eventually result in chronic illness due to localization in organs such as the heart, brain, eye and most often the joints, leading to joint ill.

Signs

The signs vary and can be restricted to local inflammation of the navel or the abdominal wall muscles. In such cases the navel is swollen, soft and usually painful. The umbilical blood vessels are swollen at their base. Localized peritonitis may be difficult to detect. Where there is septicaemia, the calf rapidly becomes ill with depression, pyrexia (40.5°C, 105°F) and accelerated respira-

tory and pulse rates. The mucous membranes become reddened and there are often petechial haemorrhages. There may be a varying degree of dehydration, followed later by acidosis, recumbency and death.

In cases of bacteraemia that localize, the signs are often missed for several weeks or even months. In some animals there is inappetance, dullness and an intermittent slightly raised temperature (39–40°C, 103–104°F). Other signs depend on the organs affected. When there is local infection of the urachus the animal will become unthrifty and slightly slow to move. There may be a slightly raised tail with micturition. In animals with localization in the heart valves, endocarditis results with a heart murmur. If the eye is involved there is panophthalmitis with hypopyon. In the case of meningitis there is likely to be nystagmus, hyperaesthesia and tonic-clonic convulsions. The most common form is joint ill and one or more joints may be involved. In many cases there is bilateral involvement with pain and swelling, commonly of the carpal joints. Aspiration of the affected joints usually reveals thick pus. The animal tends to become lame and to have an altered stance.

Necropsy

Post-mortem examination may reveal the presence of infection in the umbilical vessels, which are swollen and contain blood. There may be localized peritonitis. In the septicaemic form petechial and ecchymotic haemorrhages are evident on the subserosa and submucosa of various organs. In the more chronic form various organs will show inflammation and abscessation.

Diagnosis

Diagnosis is aided by the presence of a swollen navel as well as by the signs. There may be a neutrophilia and blood culture may be helpful. The main difficulty is in differentiating the condition from other forms of enteritis, septicaemia and locomotor problems such as muscular dystrophy (see p. 258). If surgery is contemplated it is best to X-ray the joint lesions first.

Treatment and control

Treatment of the septicaemia will usually involve the use of antimicrobials, which in the main should be given intravenously. Appropriate antibiotics include amoxycillin, ampicillin, oxytetracycline, sulphonamides or potentiated sulphonamides. Chloramphenicol can be of use in some countries and florfenicol has been used successfully although not licensed for the purpose. In less severe cases other treatments such as penicillin and streptomycin may be given by the parenteral routes. The duration of therapy should be at least five days. If

the animals are dehydrated, parenteral or oral electrolyte solutions will be required. In the more localized forms involving the navel or urachus, the infected material should be removed. There are problems in the treatment of localized chronic infection such as joint ill. In some cases the use of potentiated sulphonamides or lincomycin by injection has given good results. Surgical opening of the joints with removal of pus and affected tissue and joint flushing can be useful. Slow release gentamicin polymethylmethacrylate (PMMA) beads have been used in cases of septic arthritis with evidence of concurrent osteomyelitis. The beads are inserted after debridement of osteomyelic bone via an arthrotomy incision or with arthroscopic examination. Success rates in early cases have been good (Butson, 1994).

Control is dependent on whether the calves are on their farm of origin or have been bought-in. If the former, then all navels should be dipped immediately after birth in an appropriate disinfectant. Tincture of iodine or iodine teat washes are useful for this purpose. Generally they allow the navel to be sterilized and help to cause desiccation. Antibiotic aerosols are used but it is often difficult to ensure the whole navel is completely covered. In purchased animals the navels should be examined, and calves with enlarged navels rejected. The joints of the animals should also be inspected. The navels should be dipped in an appropriate disinfectant solution on arrival at the farm.

Oral and laryngeal necrobacillosis

This is also known as calf diphtheria and there are two forms: oral which is most common, and laryngeal. The condition is caused by *Fusobacterium necrophorum*.

Oral form (see also p. 822)

This is quite common and is usually sporadic in occurrence although there may be outbreaks where hygiene is poor. In such cases it is probably spread by dirty milk pails, machine teats or feeding containers. Individual cases sometimes occur where fibrous and coarse food is offered. Although mainly seen in housed calves, it can also occur at pasture. Affected calves are usually up to three months old and often have intercurrent disease, nutritional deficiency or their teeth are erupting. The incubation period is about four days.

Signs

The major sign is a swelling of the cheek, particularly in the region of the first cheek teeth. The calf is often bright and active with a normal temperature. Opening the mouth reveals a necrotic swelling in the cheek, in

which may be impacted food material, and there may be a foul smell. The animal may salivate a little. In a few cases there is also involvement of the tongue, which may become swollen and protrude from the mouth. Neglected cases may extend to the nasal cavity, pharynx, lungs, abomasum and coronets of the legs.

Necropsy

On post-mortem oral lesions are usually well circumscribed with an area of oedema and a necrotic centre. If the necrotic area is lost, an ulcer is seen.

Diagnosis

The main differential diagnoses are foreign bodies in the mouth, papular stomatitis, mouth and jaw injuries and BVD/mucosal disease. All are quite easy to eliminate by thorough oral examination.

Laryngeal form

This form is less common and is sporadic in occurrence. It has been seen in animals up to and over a year old.

Signs

These cattle tend to be dull with inappetance or anorexia. Often there is pyrexia (40.5°C , 105°F) and there may be stertor. Usually respirations are dyspnoeic to a varying degree. There may be a cough that is moist and painful. Palpation of the larynx is resented and can elicit the cough. The mouth may be foul smelling. Many of these animals do not respond well to treatment and the diphtheritic area may become detached resulting in sudden asphyxiation or lung infection.

Necropsy

The lesion in the larynx is normally well embedded into the laryngeal cartilage. When lung lesions occur there are necrotic areas present surrounded by a catarrhal pneumonia.

Diagnosis

The main differential diagnoses are laryngeal oedema, laryngitis, necrotic enteritis and vocal cord paralysis. These may be hard to eliminate unless an endoscopic examination is undertaken or an exploratory laryngotomy is performed.

Treatment

In either case the animal should be isolated from the others. It should have its own feed and water buckets.

In the oral form, parenteral or oral therapy is usually successful. Suitable antibacterial agents include oxytetracycline, potentiated sulphonamides, streptomycin, sulphonamides orally or parenterally or penicillin parenterally. Therapy for three to five days is usually sufficient in the oral form. When the animal is inappetant it should be encouraged to eat. In the laryngeal form, therapy needs to be continued for longer (e.g. 2–3 weeks) and should be parenteral. If breathing is very laboured then it may be necessary to undertake a tracheotomy and insert a tracheal tube. In some cases success is only achieved by surgical removal of the necrotic area and then using an intratracheal tube until the laryngeal oedema has reduced.

Control

If more than a single case occurs, hygiene should be improved. The calves should be fed with their own buckets and quality feed should be used. The milk and water buckets should be cleaned and disinfected after each feed and the feed bucket disinfected at least twice a week. Occasionally, it is necessary to give oral antibiotics as a prophylactic measure. Suitable agents include chlortetracycline and oxytetracycline.

Meningitis (see p. 901)

This is an inflammation of the meninges. The condition is uncommon and most often occurs following a pre-existing disease such as septicaemia. The organisms that can be involved are usually bacteria and include *Listeria monocytogenes*, *Escherichia coli*, *Pasteurella multocida* and *Haemophilus somnis*. A secondary meningitis can follow infection with *Mycobacterium bovis*. Although most cases are haematogenous in origin, a few result from spread of local infection or can follow disbudding, skull injuries, otitis media or frontal sinusitis. In most instances meningitis is the result of central infection causing local swelling and inflammation around the nerve trunks. Spinal meningitis will often lead to hyperaesthesia of the body, muscular tremors in the limbs and neck and an arched back.

Signs

The condition usually starts with a sudden onset of pyrexia and in many cases toxæmia. There is hyperaesthesia to any cutaneous sensation and muscular tremors of the neck and head with opisthotonus and paddling movements of the limbs. There may be ocular lesions with hypopyon and ophthalmitis. The animal may appear blind and the pupillary reflex may be sluggish.

Ophthalmoscopic examination may show the retinal irises to be engorged with oedema of the optic disc.

Necropsy

On post-mortem examination the meninges are thickened and opaque, especially ventrally, and there is engorgement of the meningeal vessels with haemorrhaging. The cerebrospinal fluid (CSF) is often cloudy.

Diagnosis

This is difficult in the live animal but the nervous signs are an indication and there is a leucocytosis. Confirmation can only be obtained by examination of the CSF, showing it to be cloudy with a high white cell count and possibly bacteria present. The differential diagnosis includes coccidiosis (see p. 282), septicaemia (see p. 204), vitamin A deficiency (see p. 256), hypomagnesaemia (see p. 255) and poisoning with various substances (see Chapter 54)

Treatment and control

Treatment involves the use of a broad-spectrum antimicrobial that will penetrate the blood-brain barrier. The potentiated sulphonamides or chloramphenicol in countries where available are probably most useful. Florfenicol has also been used although it is not licensed for this use. These preparations are able to diffuse into the CSF. Results of therapy are generally disappointing. Prevention is difficult but should involve the rapid treatment of all septicaemias, otitis or local injuries. Disbudding should always be undertaken with care.

Otitis (see also p. 903)

Otitis media and externa both occur. The condition has recently been more frequently diagnosed in calf-rearing units in America and Britain. The cause is unknown but most outbreaks have been preceded by enzootic pneumonia and it is thus possible that an ascending infection occurs along the Eustachian tube. In some outbreaks up to 30 per cent of calves have been involved. In individual cases of otitis media there may be extension from an otitis externa or from navel infection via the haematogenous route. The organisms involved vary but vitamin A deficiencies have been reported in some outbreaks. The external ear form is such that there are often streptococci and staphylococci present. When there is middle ear infection these two species may be present, or *M. haemolytica*, *Haemophilus* spp. or *Neisseria catarrhalis*.

Signs

In otitis externa the animal is well and has a normal temperature but the ear tends to be droopy with a foul-smelling purulent discharge. In middle ear infection, unless bilateral, the head is rotated and there is a degree of incoordination. The animal is often dull and there is inappetance. Radiography may show rarefaction of the tympanic bulla.

Diagnosis

This condition is differentiated from brain or spinal abscesses or injury by the rotation of the head.

Treatment and control

Treatment of the external form is relatively simple and involves the local application of antibiotics, in practice often from intramammary tubes. Suitable antibiotics include cloxacillin, chlortetracycline and penicillin and streptomycin. Otitis media is much less satisfactory to treat and involves puncturing the tympanic mucosa, irrigation with antiseptic solutions and local and parenteral antibiotics. Prevention is difficult as the cause is often unclear but it should involve adequate treatment of all cases of calf pneumonia.

Bovine papular stomatitis (BPS)

This is caused by a virus of the genus parapoxvirus. The condition is very common throughout the world. Lesions can occur in any age of animal and both sexes. However, most lesions are seen in young cattle. The virus causes pseudocowpox in cows (see p. 364). The organism has a high morbidity and is found in the saliva and nasal secretions. Spread is by contact. The disease is usually of little importance except in the differential diagnosis of other oral lesions, although occasionally it can be of financial significance. The condition found is variable but can be seen in calves of seven days old or more. It can be transferred to others, particularly following a bite, cut or scratch. Most lesions are local but may take many weeks to heal. Occasionally, systemic signs occur (see p. 822).

Signs

The lesions vary in severity. The mild form is the most common with the animal remaining healthy, eating well with no evidence of pyrexia, diarrhoea or respiratory distress. The lesions tend to be ring-like and pathognomonic. The periphery of the lesion is a thin red zone, within which is a white, slightly raised area of hyper-

plasia, with a yellow or brown centre due to tissue necrosis. Lesions heal from the middle outwards. Most involve the rhinarium and mouth and are often found near erupting teeth. Occasionally, a second type of lesion is a brownish-purple colour and usually the size of the ring lesions. It heals from the middle outwards producing a horseshoe shape lasting from four days to about two weeks. However, areas of lesions may last several months overall.

The severe form is less common and often associated with other intercurrent disease, e.g. parasitism. Lesions are slightly raised, diffuse and roughened, and are yellow or grey in colour. They are seen in any part of the mouth and can involve marked sloughing of the mucosae. As the more diffuse lesions heal, an underlying circular form often remains. In some cases saliva is held in the mouth making the lips wet.

Necropsy

Death from BPS is rare. Most lesions are in the mouth or rhinarium but may occasionally be seen in the oesophagus, rumen, reticulum and abomasum. Typically, there are no vesicles and on histology there is a ballooning degeneration of the stratum spinosum cells, which may contain eosinophilic intracytoplasmic inclusion bodies.

Diagnosis

Diagnosis is dependent on examining the lesions, the animal remaining healthy, viral isolation, histopathology and use of an electron microscope. Immunity can be measured by the serum neutralization test but levels are usually low. The main conditions to be differentiated are foot-and-mouth disease, mucosal disease, malignant catarrhal fever, rinderpest, vesicular stomatitis, BIV, BLAD and mycotic stomatitis.

Treatment

Treatment is not justified but in severe cases concurrent infections can be treated. Antibiotic therapy is recommended to resolve secondary infections. Prevention is not practical at present but the condition is less severe in healthy herds so good nutrition and freedom from parasites are important.

Calcium, phosphorus and vitamin D deficiency (see p. 462, 791)

These conditions are all closely related and it is best to consider them together. All three compounds can lead

to primary and secondary deficiency, but conditions relating to their lack are very rare in calves. The diseases of the skeleton that do occur are usually associated with faulty mineral supply rather than vitamin D problems.

Calcium is well absorbed in the calf's small intestine. Therefore, primary deficiency is extremely unlikely, as is secondary deficiency, which could possibly occur if very high levels of cereals were fed without additives or high phosphorus levels were used. The daily calcium requirement of calves is 10–30g ($\frac{1}{3}$ –1 oz) depending on size and growth rate.

Phosphorus is very efficiently absorbed from milk, but less so from dry feeds. Primary deficiencies may resemble rickets. Secondary problems resulting from low vitamin D levels, high calcium or high vitamin A are rare. Phosphorus deficiency is widespread due to the types of soil present in an area. Leaching by rain or constant removal by cropping can lead to phosphorus-deficient soil. Excessive calcium, iron or aluminium can also result in the problem. The optimum calcium : phosphorus ratio is 2 : 1.

Vitamin D is usually provided by good quality hay and exposure to sunlight. Present feeding systems include supplementation of milk substitutes and so do not normally predispose to the problem, although lush green feeds contain much carotene and other substances that have anti-vitamin D properties. The optimal daily intake is 7–12 iu/kg body weight (3.5–6 iu/lb).

Signs

The signs are usually only seen in the best-growing calves. There is some degree of lameness, particularly of the forelimbs, which are bent forwards or laterally. The limb joints and costochondral junctions are swollen. In some calves the back will be arched and in severe cases the tail is elevated. There may be a marked tendency to lie down.

Necropsy

On death the animal is in poor condition. The ribs are easily cut and the limb bones are soft with thin, compact bone and they are easily fractured. The joints tend to be enlarged with thickened epiphyseal cartilage.

Diagnosis

Diagnosis is usually on clinical signs. The alkaline phosphatase level will be raised. The levels of serum calcium and phosphorus will depend on the cause of the condition but phosphorus will be low if it is due either to vitamin D or phosphorus deficiency. Radiographic

examination shows the bones to lack density and the ends have a diffuse appearance. The epiphyses tend to be widened and irregular. The ash content of the bone is reduced from 60 per cent to 45 per cent and the ash:organic matter ratio will be reduced from the normal 3:2. The main problems to be differentiated are copper deficiency (but the plasma and/or liver copper concentrations will be low), arthritis and epiphysitis.

Treatment and prevention

Treatment varies according to the cause. In minor Ca:P imbalances sufficient vitamin D is all that is necessary. Where the skeletal deformities are pronounced, treatment will have only limited effect. Otherwise in calcium deficiency check there is no excess phosphorus present. Calcium should be provided but not to excess as this may cause other deficiencies. If phosphorus is deficient, dicalcium phosphorus or disodium phosphate should be used. The ratio of calcium:phosphorus of 2:1 should be provided by the diet. A vitamin D injection of 3000–5000iu/kg body weight will provide adequate levels for one to three months. Response to treatment is usually slow. Prevention requires ensuring adequate levels of minerals and vitamin D in the diet. Bone meal and dicalcium phosphate are ideal sources of both calcium and phosphorus but they are expensive and cannot be used in many countries. Ground limestone is a useful cheap method of ensuring adequate calcium in the diet, but its overuse can result in other mineral deficiencies.

Copper deficiency (see Chapter 21)

This is either primary due to a lack of copper in the diet or secondary when the dietary level is adequate but there is a failure in digestion, absorption or metabolism of the copper. In calves, deficiency can be seen at a few weeks old although it is much more common when three or four months old. This is because copper is stored in the liver and there is preferential absorption from the dam. Milk contains little copper although levels are high in colostrum. In the milk-fed animal absorption in the small intestine is high (up to 80 per cent) but this falls as the animal becomes a ruminant (2–10 per cent). Milk substitutes tend to be supplemented with copper and so most cases arise in calves sucking their dams or at grass. Problems often occur in the spring or summer when the mineral content tends to be lower.

Primary deficiency depends on the soil type and is common on sandy soil, particularly where there is much rain and leaching, and on peat. Secondary deficiencies are probably more numerous than primary. They can be due to high molybdenum levels and this effect is

increased by the presence of sulphur, which may be in the form of protein. High levels of iron, zinc, lead, cadmium and calcium carbonate also reduce copper absorption.

Copper is concerned with the formation of cytochrome oxidase, which regulates oxidation processes and electron transfer in tissues. It is also part of the enzyme lysyl oxidase, which is used for elastin or collagen synthesis and deficiency results in skeletal defects and blood vessel fragility. Copper is also present in caeruloplasmin, which releases iron from stores into plasma for erythropoiesis and deficiency results in anaemia.

Signs

The signs of *primary deficiency* are that the calves have a reduced growth rate; sometimes there is a scour but not usually as pronounced as in secondary deficiency. There may be a stilted gait with some ataxia developing after exercise, but recovery occurs after rest. Ribs and limb bones may develop spontaneous fractures, the shaft thickness may be reduced and there is osteoporosis. Thickened epiphyses, particularly in the fetlock region, may be noted, and stiffness of the joints.

Secondary deficiency is usually seen in calves sucking the dam or grazing. There is again a stiff gait and unthriftiness. Molybdenosis is characterized by severe scours. Some calves become very lame with epiphyses that are painful to palpate and usually the distal ends of the metapodial bones are enlarged. On radiography there is a thickened irregular epiphyseal plate, and the metaphyses are thickened. In some animals depigmentation of the hair occurs.

Necropsy

On post mortem there is usually emaciation with anaemia seen as thin, watery blood and pale tissues. Where copper levels are low there are deposits of haemosiderin in the liver, kidney and spleen. The limb bones may show evidence of rarefaction and fracture. A thickening of the epiphyseal plates, particularly of the metapodial bones, may be present. In the small intestine there may be villous atrophy. Histologically, the bones show osteoporosis.

Diagnosis

In practice the majority of cases are diagnosed because of the area where the animals have lived, and most calves will be sucking a cow or at pasture. The signs give an indication of the condition and it usually affects several animals. Examination can involve looking for anaemia with a reduced erythrocyte count ($2\text{--}4 \times 10^{12}/\text{l}$);

normal, $5-10 \times 10^{12}/l$) and low blood haemoglobin (5–8 g/100 ml; normal, 8–15 g/100 ml). Plasma copper levels are low (normal, $>15 \mu\text{mol/l}$; deficient, $<0.9 \mu\text{mol/l}$) as are liver levels (normal, 100–200 ppm dry matter (DM); deficient, <50 ppm DM). Cytochrome oxidase (normal, $>7.0 \mu\text{mol/g}$ wet liver) and caeruloplasmin levels are low. Copper can also be estimated in the diet, pasture and soil. Often response to copper therapy gives an indication.

Treatment

When therapy is undertaken it is important to confirm the presence of copper deficiency, as overdosing is toxic. Oral administration of 1.5 g copper sulphate weekly is very useful, but requires constant handling of the calves. Parenteral administration of copper can overcome the problem. Copper sulphate has been used at a dose level of 200 mg/calf. A methionine copper complex can be administered as a deep intramuscular injection at a dose of 40 mg/calf, as can diethylamine copper oxyquinoline sulphonate at a rate of 0.24 mg/kg body weight by subcutaneous injection and copper edetate as a subcutaneous injection of 50 mg. Experiments in sheep have shown high doses of copper methionine subcutaneously to be safer than calcium copper edetate and diethylamine copper oxyquinoline (Mahmoud & Ford, 1981) but it was considered that this might have been the result of the rapidity of absorption depending on the route of injection. A comparison of the efficacy of copper preparations in cattle showed copper edetate to be best with copper diethylamine oxyquinoline sulphonate 19 per cent worse, aqueous copper methionate 36–48 per cent worse, and cupric sulphate producing the second-best result. The injections also cause a local reaction, with copper diethylamine oxyquinoline sulphonate giving least damage, copper edetate producing an intermediate reaction and copper methionate causing most swelling (Suttle, 1981a).

Prevention

Prevention is to ensure that the level of copper in the diet of dams and calves is at least 10 mg/kg dry matter of feed. When deficiency has been determined it may be necessary routinely to inject or drench the cattle. However, no such programme should be undertaken unless a sample of the animals has been checked to ensure blood copper levels are low. The timing of the first injection (in severely affected herds) is at about six weeks old, but subsequent injections need to be based on further blood sampling. Copper sulphate can be used as a drench at a level of 1.5 g weekly. Cupric oxide needles have been used to alleviate hypocupraemia in heifers (Suttle, 1981b). A form of soluble glass has

been used to release copper slowly from an intraruminal bolus. The use of pasture dressing annually with 5.6 kg/ha (5 lb/acre) copper sulphate is effective. As there is a possibility of poisoning, animals should not graze the pasture until after heavy rain or three weeks after application. The copper supplementation of water has been advocated (Farmer *et al.*, 1982). Salt licks containing 0.5 per cent copper sulphate are safe in use but are not permitted in all countries.

Hypomagnesaemic tetany of calves (see p. 787)

The condition occurs most commonly in calves on high-milk or milk-substitute intakes that are receiving little other feed. It results from a hypomagnesaemia that may be associated with hypocalcaemia. The young calf has a serum magnesium level similar to the dam and receives extra magnesium in its colostrum. However, milk is deficient in this element and if it constitutes most of the feed then there will be a gradual fall in circulating magnesium levels. This is partly allayed by the absorption of magnesium from bones. The calf is also able to absorb magnesium very efficiently from the small and large intestine in early life but this capacity reduces so that by three months old it becomes poor. The problem is often seen in veal or suckler calves after two months of age. Occasionally, hypomagnesaemia is seen in the young calf about two weeks old and this is due to poor absorption, which can occur with diarrhoea, the feeding of liquid paraffin or the use of fibrous feed, which increases salivation and thereby causes the body to lose magnesium. A calf requires 1–5 g daily, according to size and growth rate.

Signs

In the early stages there is hyperexcitability to stimuli with increased ear movements, interspersed with the ears being held back. There tends to be opisthotonus, ataxia and head shaking. The animal may have trouble drinking from a bucket on the ground. The temperature is normal and the pulse rate rapid. Later on there are muscular fasciculations with jaw champing, frothing at the mouth and a spastic gait. Convulsions may occur starting with the calf stamping its feet, pricking its ears, retracting its eyelids and the head being held up. The animal may fall and show tonic-clonic movements of the legs with uncontrolled passage of urine and faeces, a fast pulse over 200/min with heart sounds audible away from the chest and respirations ceasing. The temperature is often raised to 40.5°C (105°F) due to muscular exertion. If the convulsions are severe the pulse is often imperceptible, cyanosis develops and the

animal dies within about 30 minutes. In some cases there are periods of relative normality between bouts of convulsions.

Necropsy

On post-mortem examination there is usually extensive haemorrhage and congestion of the organs including the aorta, mesentery, pericardium, gall-bladder and intercostal walls.

Diagnosis

Diagnosis depends on the history of the feeding regimen used or presence of diarrhoea as well as the signs present and serum magnesium levels (normal, 0.9–1.4 mmol/l, 2.2–3.4 mg/100 ml). Clinical signs may occur at 0.12–0.33 mmol/l (0.3–0.8 mg/100 ml). In animals that die the Ca:Mg ratio in the caudal vertebrae or rib bone is increased from a normal of 70:1 often to over 90:1. The aspartate aminotransferase and creatine kinase levels also tend to be raised because of the increased muscular activity. The main differential diagnoses involve conditions resulting in clonic convulsions. These include tetanus (but the course is usually longer) (see p. 733), arsenic, lead or mercury poisoning (but in all these there is colic and diarrhoea and with lead there is blindness). Strychnine poisoning can occur and results in a stiff gait. Hypovitaminosis A may well result in night blindness. Encephalitis (which may be viral or bacterial in origin) or meningitis may be difficult to determine. *Clostridium perfringens* (welchii) type D produces apparent blindness and a raised blood glucose level (normal, 2.5 mmol/l, 45 mg/100 ml).

Treatment and prevention

Treatment should include the use of magnesium sulphate (50ml of 25 per cent solution) subcutaneously and possibly calcium borogluconate intravenously. Magnesium given intravenously can lead to medullary depression and cardiac embarrassment. If necessary the animal should be sedated with acepromazine or xylazine. When the problem is the result of diarrhoea then this should be rectified. The condition in the older calf is prolonged and there will be greatly reduced magnesium levels in bone, etc. Thus these animals will need to be supplemented with 2–4 g magnesium oxide or 4–8 g magnesium carbonate daily.

Prevention involves the provision of roughage, usually as good quality hay, from ten days of age. This is difficult in suckler calves but can be overcome by feeding the cows with magnesium oxide (calcined magnesite) at a level of 60 g daily. Magnesium can also be

given to calves in the form of magnesium boluses or in molassed creep feed.

Vitamin A deficiency

The condition results from a deficiency of the fat-soluble vitamin A or its dietary precursor carotene. Secondary deficiency can arise where there is sufficient vitamin A/carotene in the diet but it does not reach a normal tissue level due to a failure in digestion, absorption or metabolism. In calves the condition may result in skeletal changes, which can affect the brain or spinal cord. The condition can be congenital or postnatal and is often partly due to the nutritional status of the dam. Usually, a diet of green food will provide sufficient of the precursor carotene and hence vitamin A. Thus problems do not occur at pasture until there are periods of prolonged drought, which can cause deficiency in the calves of affected dams or beef calves about six months old.

The condition is more common in housed animals fed diets likely to be deficient in vitamin A such as straw, cereals or sugar beet pulp. The dam's nutrition is important in that carotene in green food does not pass across the placental barrier until it is converted to vitamin A. It can then be taken up by the fetus and stored in the liver, as also can the vitamin A in water-soluble injections or fish oils. Colostrum is a major source of vitamin A for the calf and the introduction of extra carotene or vitamin A to the dam's diet precalving can be useful. The vitamin A requirement for a pregnant cow is about 80 iu/kg body weight daily and that for a calf is about 40 iu/kg.

Calves that are fast-growing, stressed or in a high environmental temperature require more vitamin A. Many factors that influence the vitamin A and carotene contents of feeds can lead to secondary deficiencies. Vitamins C and E help to prevent vitamin A loss, and the uptake of the vitamin is inversely proportional to the phosphate present in the diet. The vitamin is not very stable and so pelleting of the rations, storage at high temperatures and rancidity all decrease the content of the diet. Wood preservatives such as chlorinated naphthalenes inhibit carotene conversion to vitamin A and prolonged oral use of liquid paraffin or other mineral oils can produce a deficiency. Vitamin A is used to produce visual purple for the retina, normal epithelium and bone, and for normal CSF absorption.

Signs (see p. 925)

Congenital: Calves are born blind due to impingement of bone on the optic nerve. Other signs are due to increased CSF resulting in syncope with the calves

showing tonic-clonic convulsions, ventral flexion of the head and neck, retraction of the eyeballs and tetanic closure of the eyelids. The calves are not blind. They may die during convulsions. In some outbreaks the affected calves develop severe diarrhoea and occasionally otitis media.

Postnatal: One of the most common lesions is the presence of large amounts of brown, bran-like scales in the coat and this is particularly seen in fast-growing animals. A reduction in growth rate may occur but is usually also the result of other deficiencies combining with that of vitamin A. Classical xenophthalmia with thickening and whitening of the cornea is unusual. When it does occur, it may be accompanied by serous ocular discharge. Nervous signs usually start with ataxia and weakness of the hind limbs and then the forelimbs. Increase in CSF pressure results in nerve compression and can lead to fainting with animals showing tonic-clonic convulsions for up to half a minute. The signs are similar to those for congenitally affected animals. Night blindness is more likely to be seen in yearling cattle.

Necropsy

Following death it may be possible to see the constrictions of the optic nerve, or the cranial cavity or vertebral cord may be reduced in size leading to injury to the spinal nerve roots. Histologically, there is squamous metaplasia of the interlobular ducts of the parotid salivary gland that is pathognomonic. The epithelium of the prepuce, reticulum and rumen shows hyperkeratosis. The liver may show focal necrotic areas.

Diagnosis

Diagnosis depends on post-mortem findings, plus a history of a lack of green feed and the signs. The deficiency can be confirmed by determining plasma vitamin A levels (normal, 25 µg/100 ml; deficient, <10 µg/100 ml) and CSF pressure (normal, <100 mm H₂O).

The condition needs to be differentiated from hypomagnesaemia where the animal is not blind, lead poisoning where there is abdominal pain, tetanus where there is no blindness and *Clostridium perfringens* (*welchii*) type D where there are high blood glucose levels. Bacterial and viral encephalitis and meningitis (see p. 251) usually result in pyrexia.

Treatment and prevention

Treatment involves the parenteral administration of aqueous vitamin A at a rate of 400 iu/kg body weight. The animals often respond quickly to treatment even

where convulsions are occurring. Subsequently, an adequate level of vitamin A should be present in the diet to provide 40 iu/kg body weight. Often in practice daily allowances are doubled. Green feed or early-cut hay, good quality silage or dried grass should be given. However, very high daily levels of vitamin A supplementation in the diet can lead to exostoses on the digits and loss of epiphyseal cartilage. This produces lameness, ataxia and poor hoof development. Where it is difficult to supplement the diet, injections of vitamin A can be used every two months at 5000 iu/kg body weight, but dietary supplementation should be the primary aim.

Iodine deficiency (see p. 301, 586)

This can be the result of a primary lack of iodine. Secondary deficiency is recorded following high intakes of brassicas, high calcium ingestion, heavy bacterial contamination of feed or water, a low level intake of linseed meal or other plants containing cyanogenetic glycosides. Iodine deficiency occurs in most parts of the world where there is a high rainfall and there is little exposure to oceanic iodine. Soils with a high calcium content are likely to be deficient. The condition is mainly seen in the newborn calf of a deficient dam, usually in suckler herds. Iodine forms part of the hormone thyroxine, and a deficiency will result in the pituitary increasing the production of thyrotrophic hormone. This in turn leads to goitre. Calves born alive are prone to die if chilled, etc.

Signs

Many of the affected calves are aborted or stillborn and usually there is evidence of thyroid enlargement (goitre). If the animal is born alive it will be weak and disinclined to suck. Occasionally, the gland will be felt to pulsate. Very rarely areas of alopecia are apparent. The cow is often slow in calving.

Necropsy

The thyroid glands are enlarged and heavier than usual (normal fresh weight 6.5 g; a weight greater than 14 g is suspect). Histologically, there is thyroid hyperplasia.

Diagnosis

Diagnosis depends on the area or a diet containing goitrogenic plants. There is thyroid enlargement in the calves and several heifers or cows abort or produce stillborn or weak calves. Plasma protein-bound iodine levels are low (normal, 24–140 µg/l). The plasma inorganic iodine can be used (optimum 100–300 µg/l;

marginal 50–100 µg/l; low 20–50 µg/l; very low <20 µg/l). Most (90 per cent) of circulating iodine is bound as thyroxine and normal values are 36–89 µg/l (80–160 nmol/l). The thyroid weight is increased and the iodine content of the gland is low (normal, 15.6–39.0 mmol/kg DM; deficient, 9.5 mmol/kg DM). Differential diagnosis is mainly to eliminate other causes of abortion (see Chapter 37).

Treatment and prevention

Treatment is to ensure that the calf sucks and is kept in a warm, draught-free environment. Thyroid extract can be used at a dose of 1–2 mg/kg body weight (0.5–1 mg/lb). Intravenous sodium iodide can be used at a dose of 5–7 g for the young calf, but it is not without risk; potassium iodide can be used orally at about 3 g per calf. Iodism (iodine poisoning) can sometimes develop (see p. 261).

Prevention involves allowing the dams adequate iodine in the diet. A recommended level is 0.8 mg/kg DM for pregnant and lactating cows. The level for calves should be 0.12 mg/kg DM. Pouring on to the coat 7 ml of 5 per cent tincture of iodine weekly can be helpful. One millilitre of tincture of iodine per cow per day in the water or 800 mg potassium iodide per cow every two weeks by drench or added to the drinking water can work. Injections of iodized poppy seed oil can assist. A bolus of 3400 mg iodine with selenium and cobalt can release iodine for five to six months. Some fertilizers are high in iodine and seaweed meal can be given in the feed and typically contains 50–100 mg/kg DM iodine.

Iron deficiency

Iron deficiency is not common in cattle and the primary condition is mainly seen in veal calves without access to roughage. The secondary condition usually follows heavy infestation with sucking lice such as *Haematopinus eurysternus* and *Linognathus vituli* or after haemorrhage. The primary condition can occur in veal calves or others fed predominantly raw milk or unsupplemented milk substitute. The calf has only sufficient iron for about three weeks after birth and milk is a poor source of iron. In the case of veal calves there is an attempt to maintain iron levels low to keep the meat white. Over half the iron in the body is in the form of haemoglobin with small amounts present in myoglobin and in enzymes used for oxygen utilization. The normal blood haemoglobin values for adult cattle are 8.0–15.0 g/100 ml. However, the value in a calf at birth is 12.9 g/100 ml, dropping to 10.4 g/100 ml on a diet of milk and solid feed (Holman, 1956). The calf's daily iron requirement is 50 g and as only about 2–4 g are received

from the cow's milk there is a need to supplement with hay, straw and cereals. The only source of iron for veal calves on slats without roughage is the milk substitute and this needs to be supplemented. Levels less than 19 mg soluble iron/kg DM of feed are likely to result in problems.

Signs

The main sign is a reduction in appetite followed by reduced weight gain. The mucous membranes tend to become pale, but death is extremely rare.

Necropsy

Necropsy findings are of pale muscles with the blood thin and watery and clotting slowly. The liver tends to be enlarged and there is moderate anaemia. Diagnosis depends on the history of the diet and signs. It can be confirmed by haematological examination demonstrating a reduced erythrocyte count and low haemoglobin value. The serum iron level is low (normally 30 mol/l, 167 µg/100 ml when born, reducing to 12 µmol/l, 67 µg/100 ml at three weeks). The main differential diagnoses are those of copper and cobalt deficiency but signs additional to the anaemia will be present.

Treatment and prevention

Treatment usually involves the injection of 1 g of iron weekly to each calf as iron dextran or 0.5–1.0 g iron as ferric polygalactofuranose. Vitamin B₁₂ is also often used at levels of 5–10 µg/kg body weight. Prevention is by supplying milk substitute containing an iron concentration of 25–30 mg/kg DM. This will ensure that the animal has a normal appetite and growth and it will help to produce pale meat suitable for veal (Bremner *et al.*, 1976). This is because the level is sufficient to give an acceptable blood haemoglobin without there being enough to produce much myoglobin. Most milk substitutes for calf rearing contain considerably more iron.

Selenium/vitamin E deficiency

(see p. 302)

Vitamin E and/or selenium can be deficient and result in muscular dystrophy, also known as white muscle or fish flesh disease. It can be seen at any age after birth. Selenium deficiency is mainly dependent on the area where crops are produced. Soils derived from granite or pumice are deficient. Alkaline soils encourage selenium absorption by plants. The condition appears to be becoming increasingly important, probably due to the increased cost of bought-in feeds causing farmers to use

more home-produced crops for their animals. The accepted level of selenium in feeds is 0.1mg/kg DM. Selenium is mainly used by the body in the production of the enzyme glutathione peroxidase.

Vitamin E deficiency is much more dependent on the type of crop grown and its storage, etc. Vitamin E levels tend to be high in green pasture, silage, dried grass or kale. Adequate levels of the vitamin are also present in cereal grains, well-cured fresh hay, maize silage and brewers' grains, but deficiencies can occur on poor quality hay, straw or root crops unless there is a suitable supplement provided. Vitamin E tends to deplete with storage. Calf diets high in unsaturated fatty acids, as can occur where cod liver oil, fishmeal, soya bean meal or linseed oil are fed, may become deficient due to their oxidation, resulting in rancidity and the destruction of vitamin E. Storage of grains when wet or with propionic acid can also reduce the vitamin E level. Normal levels for growing cattle are considered to be 150mg of α -tocopherol, and for the calf, milk substitutes should contain antioxidants and 300iu/kg DM α -tocopherol.

The condition affects muscles, particularly cardiac, skeletal and diaphragmatic. Deficiency can occur in suckler calves sucking mothers with low selenium or vitamin E levels or in artificially reared calves on deficient diets. The condition results from unsaturated fatty acids entering the muscle cells where they accumulate. They are oxidized to lipid peroxides, which result in degeneration and calcification. It is believed vitamin E helps prevent lipid peroxide formation within the muscle cells whereas selenium compounds with many unsaturated points are known as polyunsaturated fatty acids and these are particularly common in vegetable oils, which therefore predispose to peroxide formation.

Signs

The signs vary in degree and in the sudden death syndrome the calf appears perfectly healthy but while drinking or normally within 30 minutes of feeding the animal will suddenly collapse. Death is usually within a minute of collapse. Mortality is 100 per cent.

Acute muscular dystrophy is again sudden in origin. The animal becomes dull and lies in lateral recumbency. There is respiratory distress, a heart rate often elevated to 150–200 beats/minute and irregular. The rectal temperature is normal, the calf is fully conscious and has normal eye reflexes. Most calves die within 6–18 hours and the mortality approaches 100 per cent.

The most common form seen is subacute muscular dystrophy and the morbidity is variable between about 10 and 40 per cent of calves. The signs depend on the muscles affected. The animal may stand stiffly; it is reluctant to move and when it does it may have a stiff gait. The calf is often weak and will not stand for long.

However, it is fully conscious with normal appetite, normal temperature and usually normal respiratory rate, but the heart rate may be raised. In many cases the gait is abnormal and it moves by rotation of the hocks. In some cases the affected muscles are swollen and firm on palpation. It has been shown that there is increased susceptibility to infectious diseases such as calf pneumonia due to delayed lymphocytic response.

Necropsy

On necropsy of calves with the sudden death syndrome there are often no macroscopic lesions. Other cases may show congestion of the liver and lungs. The heart shows a slight pallor of the myocardium. Histologically, lesions not otherwise apparent can be detected with a haematoxylin basic fuchsin-picric acid method and these are considered to be peracute myocardial degeneration. In acute muscular dystrophy there are localized streaks in the diaphragm and skeletal muscles. In the latter they tend to be bilaterally symmetrical white or grey areas in the muscles. In the heart there may be cardiac hypertrophy and myocardial degeneration with pulmonary congestion and oedema. Histologically, there is no inflammation but changes vary and include hyaline degeneration and coagulative necrosis. In subacute muscular dystrophy there is usually no cardiac involvement but the skeletal muscles show bilateral grey or white areas.

Diagnosis

Diagnosis depends on the area and diet provided as well as the signs. Decreased glutathione peroxidase levels occur (normal >23iu/ml RBC) and the normal level of selenium in the blood is 0.63 μ mol/l. There are raised plasma creatine phosphokinase and aspartate transaminase levels. The blood vitamin E level normal range is 3.0 to 18.0 μ mol/l and it will be low in deficiency. Otherwise liver and kidney levels of selenium can be examined (normal, 3 and 30 μ mol/kg DM). Response to treatment can be determined as a means of diagnosis.

Treatment

Therapy can involve the use of vitamin E and/or selenium depending on the cause of deficiency. The dose of DL₂- α -tocopherol acetate is about 6iu/kg body weight. Selenium can be injected as 0.1–0.15mg/kg sodium selenite. Long-acting selenium injections are obtainable. The combined injections have become available and produce acceptable results. Selenium can also be given in the form of reticular bullets or in soluble glass. The diet should provide sufficient vitamin E and selenium. Cows with calves at foot or in late pregnancy can

be given a combined vitamin E/selenium injection to supplement their calves.

Prevention

For prevention, growing calves should be given a supplement at the rate 0.1 p.p.m. selenium of the total ration and 150mg/head of α -tocopherol daily. Cows should receive a supplement of vitamin E during the last two months of pregnancy. Injections of selenium and vitamin E can be used; selenium bullets or soluble glass intraruminal boluses are also of value. Pastures can be top-dressed with fertilizer containing sodium selenite 75–150g/ha (1–2oz/acre) or foliage dusting or spraying can be undertaken at 17.5g/ha ($\frac{1}{4}$ oz/acre). Analysis of pasture should be undertaken to determine that toxic levels of selenium are not produced; this can occur at levels of 0.5mg/kg. Selenium can be added to the drinking water.

Zinc deficiency

This can be either primary due to a lack of zinc, or secondary due to impaired uptake. It is usually seen in calves from six to ten weeks old, particularly in the period after weaning, and most commonly they are housed. Usually, calves do not show signs on diets containing 40 ppm zinc, but it is probable that calcium and highly fibrous diets reduce zinc availability and perhaps low copper levels reduce uptake. A congenital skin condition occurs in Friesian calves resulting in an increase in requirement (see p. 181).

Signs

Signs usually occur about two weeks after the deficient diet is introduced. The main signs are of poor growth with possible stunting. There is alopecia and parakeratosis often affecting the limbs, muzzle, vulva, anus and tail head. There are fewer lesions on the main part of the body. In some cases any wounds or abrasions will take longer to heal. Most animals do not die but skin biopsies show increased thickness of all skin components and the stratum corneum contains nucleated epidermal cells.

Diagnosis

Diagnosis is partly on the lesions and a biopsy shows parakeratosis. Normal plasma zinc levels are 9–18 μ mol/l (80–120 μ g/100ml). Serum alkaline phosphatase, albumin and amylase levels fall whereas serum globulin levels rise. The calves usually start to respond to therapy in about a week.

Treatment and prevention

Treatment involves oral medication with zinc sulphate at a level of 2g weekly, or 1g weekly by injection is useful. Any calcium oversupplementation should be corrected and fibrous roughage should be reduced. A diet containing 50 p.p.m. zinc should prevent the condition. Weekly oral medication with 0.5g zinc sulphate can be helpful. Long-term control can be obtained with zinc-containing fertilizer.

Furazolidone poisoning (see p. 941)

Furazolidone was a common form of prophylactic medication in calves, which can result in problems of toxicity. However, its use is now banned in many countries. There are two syndromes, one of which (the acute) involves overdosing at levels of 20–30mg/kg body weight and the classic condition results from long-term feeding of low levels, often 2mg/kg. Both are usually the result of poor mixing, which allows some animals in a group to receive more than the others. Mortality in both cases is high and the chronic form may be seen several days after furazolidone feeding ceases.

Signs

In the acute form there are nervous signs with hyperexcitability, including muscle tremors, arched back and possibly circling, convulsions and death normally within a few days. When the chronic condition occurs there tend to be necrotic lesions and haemorrhages in the mouth and lower gut. This results in melaena or dysentery.

Necropsy

After death few lesions are seen in the acute condition but when chronic there are haemorrhages and necrosis in the alimentary tract. Haemorrhages are present on the peritoneal and pleural surfaces and there is decreased myelopoiesis in the bone marrow.

Diagnosis

Diagnosis depends on the signs and feeding the compound and can be confused with bracken poisoning (see p. 946) or anthrax (see p. 717).

Treatment and prevention

Little therapy can be given in either case but in the acute form furazolidone feeding should be stopped at once. Noise should be kept to a minimum and excite-

ment should be avoided. Sedatives such as acepromazine, xylazine or magnesium sulphate can be helpful. In the chronic form little can be done, except perhaps to give blood transfusions. Prevention, where allowed, involves the correct dosage of furazolidone being offered to calves and it should be thoroughly mixed. If given with milk substitute from a bulk container the milk must be constantly agitated. Furazolidone in the micronized form or combined with diethyl sulphoxide or other nitrofurans will reduce the risk. Therapy with furazolidone in those countries where still allowed, whether medicinal or prophylactic, should not be repeated.

Iodism (see pp. 302, 823)

The overuse of sodium or potassium iodide in therapy for conditions such as actinobacillosis, iodine deficiency or ringworm can lead to iodism. The signs depend partly on the form of administration. If intravenous the animal can show considerable discomfort with dyspnoea, staggering and tachycardia. When given subcutaneously there may be swelling following injection for about two days and local discomfort for about two hours after administration. In the oral form the coat becomes stary, with a scaly skin and often a fine, white dandruff. There is excessive lacrimation and nasal discharge with, in some cases, a degree of inappetance. If problems arise in treatment from the intravenous route then the iodine should be given subcutaneously or orally. When signs occur following oral administration, treatment should be discontinued.

Cerebrocortical necrosis (CCN, polioencephalomalacia)

Aetiology

It is a deficiency of thiamine caused by endogenous thiaminase. Thiaminase has been found to be produced by *Clostridium sporogenes* and certain *Bacillus* spp. which can be found in cases of CCN. However, this does not mean they are the only factors (see p. 903).

Occurrence

It is a sporadic condition which can occasionally occur as outbreaks. Most animals affected are fast-growing, well-nourished animals between 6 and 18 months old. It can occur following deprivation of food followed by good grazing or feeding with concentrate.

Similar syndromes can be produced experimentally by feeding large amounts of bracken or horsetail which

contain high levels of thiaminase. Amprolium is also a specific thiamine antagonist and has also been used experimentally. Molasses toxicity results in a similar problem due to a fall in the propionate levels. Thiamine is naturally synthesized in the rumen. It forms an essential component of several enzymes used in gluconeogenesis in the brain. Deficiency in thiamine results in increased blood pyruvate levels and a decrease in the lactate : pyruvate ratio as well as a depression of the erythrocyte transketolase level. This causes an interference with normal carbohydrate metabolism and the cerebral cortex in particular requires the oxidative metabolism of glucose.

It is possible that thiamine deficiency might have a direct metabolic effect on the neurones, particularly in the calf which is very dependent on the pentose pathway of metabolism in which the transketolase enzyme limits the rate of activity. Thiamine pyrophosphate is a coenzyme for several carbohydrate metabolic reactions and it is associated with transketolase in the pentose pathway of glucose oxidation. There tend to be marked cerebral oedema and cerebral necrosis and the signs are mainly the result of an increase in intracranial pressure.

The morbidity is usually low but occasionally up to 25 per cent. However, mortality can be 25 to 50 per cent if not treated early, with higher levels in young cattle (six to nine months) than older ones.

Signs

In acute cases there is a sudden onset of nervous signs including blindness, muscle tremors, particularly of the head and neck, head pressing, jaw champing and frothy salivation. Animals tend to be hard to handle and in the early stages signs may be intermittent. Although the animal appears blind, and the menace reflex is absent, the palpebral and pupillary reflexes are present. The convulsive signs soon become continuous with the animal becoming recumbent. The signs are then of opisthotonus, nystagmus, optic disc oedema, often strabismus and clonic-tonic convulsions which become worse when the animal is stimulated. The temperature is normal, the ruminal movements are normal but the heart rate is variable. Calves often die in one to two days although older animals show signs for a longer period. Recovery following therapy may well take two to four days or longer.

The signs of the subacute form last for a few hours to several days and include blindness, head pressing and standing. The condition will resolve in some cases. However, in an outbreak of CCN some of the animals show anorexia, partial impairment of eyesight and a mild depression. Almost all of the subacute animals recover within 24 hours of therapy.

Although recovery may occur, some animals may still remain blind. The longer the time between onset of signs and therapy, the less favourable the prognosis. When cattle remain dull and anorexic after three days' treatment they are unlikely to recover and should be slaughtered.

Necropsy

Most of the animals do not show any gross changes in the body other than the brain. There is usually increased intracranial pressure with a yellowing and compression of the dorsal cortical gyri. The cerebellum tends to be compressed into the foramen magnum and recovered animals show decortication of the motor area and occipital lobes. Histologically there is bilateral necrosis of the dorsal occipital and parietal cerebral cortex and also, occasionally, the thalamus, basal ganglia, lateral geniculate bodies and mesencephalic nuclei. Cerebellar lesions also occur.

Diagnosis

Diagnosis can be made from the following:

- (1) History – age of animals, a change in feeding and the condition of the animal.
- (2) Signs – blindness, normal palpebral and pupillary reflexes; normal ruminal movements, normal temperature but otherwise many nervous signs.
- (3) Blood pyruvate and lactate levels are increased.
- (4) Urine pyruvate levels increased.
- (5) Erythrocyte transketolase activity reduced (Table 18.1).
- (6) Pyruvate kinase levels are much increased.
- (7) Thiamine levels in erythrocytes, blood and plasma may be in the normal range.
- (8) Blood creatine phosphokinase (CPK) levels may occur.
- (9) Thiaminase levels increased in rumen liquor and in faeces.

Table 18.1 Differences in thiamine levels within certain tissues of the body in animals with or without cerebrocortical necrosis. (After Edwin *et al.*, 1979.) TPP = total plasma protein.

| | CCN (\pm SEM) | Not CCN (\pm SEM) |
|--|------------------|----------------------|
| Liver dry ($\mu\text{g/g}$) | 2.5 ± 0.43 | 11.1 ± 2.11 |
| Heart dry ($\mu\text{g/g}$) | 2.5 ± 0.56 | 13.2 ± 2.12 |
| Brain dry ($\mu\text{g/g}$) | 1.8 ± 0.37 | 7.7 ± 1.52 |
| Erythrocyte transketolase (% TPP effect) | 172 | 15 |

- (10) Haematology virtually normal although total and differential counts may show a mild stress reaction.
- (11) Increased cerebrospinal fluid pressure, 200–350 mm saline (normal 120–160 mm saline).
- (12) Histology – bilateral necrosis in cerebral cortex (bisect brain longitudinally, put one half in buffered formalin, the other is deep-frozen).
- (13) Green fluorescence of brain when exposed to long-wave ultraviolet light.

Differential diagnoses are shown in Table 18.2.

Treatment

Thiamine hydrochloride should be administered intravenously at a dose of 10 mg/kg (5 mg/lb) BW, and the dosage should be repeated every three hours or so for five treatments. A response will occur in 24 hours if animals are caught in the early stages, otherwise recovery is slowly progressive over several days. Multi-vitamin injections are often used but although they are suitable for follow-up therapy, in the initial stages insufficient thiamine will be administered unless very large doses are given.

Nursing is important and the cattle should be presented with wholesome food including at least 50 per cent good quality roughage. Rumen liquor from cattle on predominantly roughage diets may be helpful. The use of dried brewers' grains can help the conditions as they contain high levels of thiamine and others of the

Table 18.2 Differential diagnoses.

| Disease | Differential diagnoses |
|--------------------------------|--|
| Listeriosis | Unilateral facial paralysis, pyrexia |
| Lead poisoning | Abdominal pain, diarrhoea, no pupillary reflex, no ruminal movements |
| Coenuriasis | Slow onset, circling |
| Molasses poisoning | Similar to cerebrocortical necrosis but history of feeding large quantities and also glucose levels fall whereas thiamine levels remain normal |
| Amprolium poisoning | Similar to cerebrocortical necrosis but history of feeding it |
| Bracken or horsetail poisoning | Similar to cerebrocortical necrosis but highly unlikely to cause such a manifestation other than experimentally |
| <i>Haemophilus somnus</i> | Infection, but usually pyrexia and neutrophilia |

B vitamin group. Levels of 0.5–1.0kg/300kg BW (1–2lb/6cwt) have been suggested.

Control

The precipitating factors for CCN are still not known, which makes it difficult to recommend preventive measures. As the condition is the result of endogenous thiamine activity, provision of extra thiamine is of limited value. Most natural feeds contain thiamine at a level of 2ppm and this, plus the vitamin synthesized in the rumen, is normally sufficient. Provision of adequate amounts of roughage should prevent the condition and a level of 1.5kg roughage per 100kg BW is suggested.

Urolithiasis

Urinary calculi are either organic or inorganic. The organic type are less common and form casts or urinary deposits. The inorganic ones tend to be crystalline and are more common. The condition is usually seen in calves that are housed, with milk substitute as their main source of feed or in weaned growing animals fed high levels of concentrates. Some pastures are problem areas, which can be due to high plant oestrogen, oxalate or silica levels. Most calculi in housed animals contain calcium or magnesium ammonium phosphate although struvite and oxalate deposits occur at times. At pasture, carbonates of calcium, magnesium and phosphorus are most common. Vitamin A deficiency has been suggested as a precipitating factor both indoors and when cattle are grazing. The urinary pH has an influence and phosphate and carbonate calculi form more readily in an alkaline than an acid urine (adult ruminant urine is alkaline with a pH of 7 to 9). Binding of the calculi occurs with mucoprotein in the urine and this is seen more frequently when oestrogens from plants or growth promoters are present, or the ration is pelleted.

Urolithiasis can occur in all animals fed a predisposing diet regardless of sex; however, the condition is mainly seen in the male because signs are not normally observed unless some form of urethral blockage occurs. More cases are found in castrated than entire animals. Calculi can lodge anywhere in the urethra but occur most commonly at the sigmoid flexure of the penis with the region of the ischial arch being the second most common site.

Signs

Most of the signs are associated with partial or complete blockage of the urethra. This is seen as frequent attempts to urinate, which may be accompanied by the

passage of small amounts of urine, often blood-tinged, or the attempts are unproductive. Calculi may be present on the prepucial orifice hairs. There is usually evidence of mild to severe colic with kicking at the belly, paddling movements and tail swishing. In most untreated cases with complete urethral obstruction, there will be perforation of the urethra or bladder rupture. When either takes place there is usually a period of relief from abdominal pain. When bladder rupture has occurred the urine enters the abdomen, which becomes distended and there is a fluid thrill present on percussion. In those with urethral perforation, urine tends to dribble under the skin, causing ventral abdominal distension, which will start to progress anteriorly. In most cases there is some toxæmia and possibly uræmia and this is seen as inappetance, with increasing dullness of the animal, which will ultimately become comatosed and die.

Necropsy

At necropsy there is usually some degree of cystitis, often with urinary deposits present in the bladder. When the bladder ruptures there is much fluid in the abdomen and in those cases of urethral perforation there will be erosion in the area of the calculus and urine, possibly with cellulitis, present subcutaneously. The position of the calculus can be ascertained by the passage of a catheter.

Diagnosis

The diagnosis depends on the history, particularly of the area and feeding as well as the sex of the animal and signs. If there is bladder rupture then the fluid can be aspirated from the abdominal cavity. It is often difficult to determine that urine is present without its odour and appearance. Urinary crystals may be present on prepucial hairs and these should be analysed. The main differential diagnoses are ascites, intussusception and constipation.

Treatment

Treatment of the condition is primarily by surgery. If the animal is nearing slaughter and there is no bladder rupture or urethral perforation then casualty slaughter is best. Otherwise, treatment is usually only successful in the early stages and all treated animals and others in the group must be carefully examined for several days subsequently. It may be possible to perform a urethrotomy and remove the calculi. Provided the stones are distal to the ischial arch then the provision of a urethrotomy in the perineal region may overcome the problem and, if it proves impossible to remove the

calculi, the opening can be made permanent. Medical treatment can include hyoscine butylbromide injected intravenously or intramuscularly at a dose of 20–40 mg/animal, or 5–10 ml of protein-free pancreatic extract possibly repeated once or twice. Acetylprromazine can give useful results acting as a smooth muscle relaxant. Withdrawal of concentrates may assist the condition and the provision of salt water following relief of the blockage is useful.

Prevention

Prevention is partly dependent on feed alteration, and precipitation of phosphate can be avoided by having a correct ratio of calcium to phosphorus, which should be at least 1.2:1, but levels up to 2.5:1 have been suggested. The concentration of magnesium in the diet should be kept low and this means that the maximum amount of magnesium oxide that should be added to the diet is 200 g/t ($\frac{1}{2}$ lb/ton) of feed. In the concentrates, up to 3 per cent salt has been recommended and it is thought to have an ionic effect rather than just causing diuresis. Such diets should only be used where there is always free access to water. The addition to feed of urinary acidifiers such as ammonium chloride or phosphoric acid can be helpful. In animals at pasture the use of salt in the water can reduce the concentration of silicic acid in the urine, thereby preventing silica calculi formation. Adequate water supplies must always be

available at pasture and areas likely to produce urolithiasis are best grazed by female cattle.

Introduction

Although cattle of all ages may become infected with many species of parasites, clinical disease caused by parasitism is mainly observed in groups of animals under 18 months of age, especially when two preconditions coincide:

- (1) The availability of large numbers of the infective stages of the parasite (a variable that is usually dependent on the relationship between the bionomics of the parasite and suitable maturation conditions).
- (2) The presence of susceptible cattle grazing on the contaminated area.

When these two conditions are fulfilled, the resultant simultaneous maturation of large numbers of parasites in a specific host organ produces severe tissue disruption and the consequent signs associated with the parasite involved. The gastrointestinal tract, lungs and liver are the organs most commonly affected. It is prudent, therefore, when considering the diagnosis and treat-

ment of parasitic disease, to inquire whether the two preconditions have existed and to involve their separation as part of the therapeutic and prophylactic advice given.

Nematodes

Parasitic gastroenteritis (PGE)

The term itself is currently specifically associated with the presence of large numbers of nematodes in the abomasum and intestines rather than any other endoparasites. The nematodes in the abomasum are generally considered to be the primary pathogens, with those in the intestines playing a lesser but synergistic role.

In temperate areas the predominant worms in the abomasum are those of the genus *Ostertagia*, with *O. ostertagi* the most important and numerous. In the small intestine *Cooperia oncophora* and *Nematodirus helveticus* are commonest.

There are two common forms of ostertagiosis, type I and type II, and since they are the result of different manifestations of the bionomics of *O. ostertagi* they will be described separately.

TYPE I OSTERTAGIOSIS

This form of the disease is characterized by a profuse watery diarrhoea in calves at grass. The faeces, because of the grass diet, is usually green. There is rapid loss of weight in severe cases, coupled with a slight hypoalbuminaemia due to protein loss and in chronic cases this can eventually result in submandibular oedema. It is most common in late summer and autumn in northern temperate areas.

Aetiology and epidemiology

The direct cause is the ingestion over a relatively short period of large numbers of the infective larvae of *O. ostertagi*. The presence of such large numbers of larvae is a result of several epidemiological interactions, a

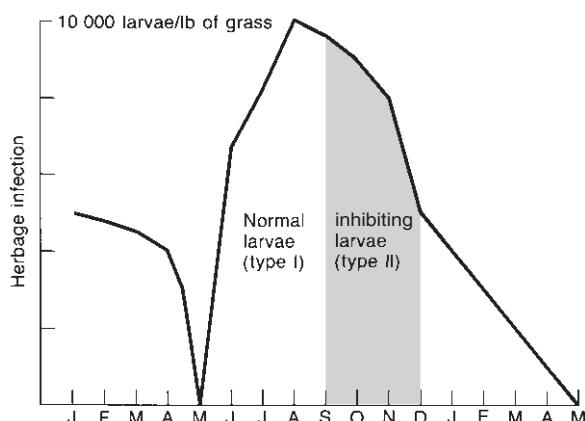

Fig. 19.1 Normal annual pattern of worm larvae on pasture in northern temperate countries.

working knowledge of which is necessary if the best advice on treatment and prophylaxis is to be offered.

The annual pattern of fluctuations of infective larval numbers on calf grazing was described by Michel (1969), and can be seen in Fig. 19.1, which shows that the number of infective larvae in northern temperate areas is lowest in May and June but rises to a peak in late August and September. Summarized, the pattern arises from the following sequence of events. Calves put out to graze in April or May, on grazing that has been used for cattle (and especially calves) during the preceding year, ingest some of the infective larvae remaining on the pasture from the contamination produced in the previous summer. These infective larvae develop into adults in approximately three weeks and egg-laying commences. The rate of hatching of these eggs is influenced by temperature and availability of moisture, and providing the latter is present increases as the temperature rises, reaching a peak in midsummer. The larvae thus hatched in May, June and July migrate or are washed out of faecal pats on to surrounding herbage to await ingestion by the eventual host. Their numbers are maximal in late July, August or early September, the precise timing depending on the climate in the area involved during the year in question. In normal climatic years in the British Isles the maximum number of infective larvae is found in southern England in late July, and in the west of Scotland and Northern Ireland in mid to late August. Wet summers produce an earlier peak but numbers of infective larvae decrease more quickly than normal due to more rapid depletion of the numbers in faecal pats and to dilution due to the more abundant grass growth under these conditions. Conversely, in dry summers the build-up is delayed; release of larvae from faecal pats does not take place under the autumn rainfall and the larval contamination is maximal thereafter.

Parasitic gastroenteritis normally occurs when calves or non-immune older cattle are grazed on pastures on which a large number of infective larvae are present. Typical cases occur in dairy herds where autumn-borne replacement calves are put out to graze for the first time in April or May. The pastures used are frequently close to the farmhouse to enable both ease of inspection and rehousing should weather conditions deteriorate. For these reasons the same fields frequently have the same use each year. The calves remain on the fields until mid-summer, excreting eggs that initiate the midsummer larval increase. At that point, when grass in such paddocks requires resting, the farmer has aftergrass available after conservation for silage or hay. The calves are transferred to the aftergrass with or without anthelmintic treatment. Shortly afterwards, by which time the grass in the original fields has recovered slightly, spring-born calves are put out on to it. If no prophylactic measures are taken, the inevitable result of severe type I ostertagiosis ensues a few weeks later in the latter calves, caused by ingestion of massive numbers of infective larvae by fully susceptible cattle over a relatively short period of time.

Pathogenesis

Ingested infective larvae of *O. ostertagi* develop in the gastric glands in the abomasal mucosa, emerging 18–21 days later as adults. Whilst in the mucosa their presence produces distension of the parasitized acini, which in turn causes several pathological and biochemical lesions. Firstly, the hydrochloric acid-producing parietal cells in the acini are destroyed and replaced by rapidly dividing undifferentiated cells that do not produce acid. If the infection is severe and lesions extensive a thickened hyperplastic gastric mucosa results, little acid is produced and the pH of the abomasum rises from pH 2 to pH 7, and the intercellular junctions are disrupted. The change in pH has several major consequences. Above pH 4.5 pepsin ceases to be active in protein digestion; at pH 6 and above pepsinogen is not converted to pepsin and remains unaltered in excess and is reabsorbed into the bloodstream via the ruptured intercellular connections, raising the blood pepsinogen concentration. At the same time blood proteins such as albumin can leak outwards into the lumen. As a result of the rise in pH the abomasal contents become less bacteriostatic and bacterial overgrowth of the damaged wall results.

Signs

When all the above events occur the intestinal metabolism is also affected and the classical signs of acute diarrhoea, inappetance and weight loss commence.

TYPE II OSTERTAGIOSIS

This form of the disease is usually found in yearlings in the late winter or spring following their first season of grazing. Affected cattle can be housed or outwintered.

Aetiology and epidemiology

As with type I disease the direct cause is the simultaneous maturation of large numbers of *O. ostertagi*. The circumstances surrounding the event require some additional explanation, since the normal time of the disease is not when infective larvae on the pasture are most abundant.

Infective larvae present on pasture after September and ingested from that time until the following spring undergo a change in their normal parasitic development, which results in a period of delayed development at the early fourth larval stage while within the abomasal wall. The behavioural change has been shown to be more common in some strains of *O. ostertagi* than others and to be brought about by either cold or desiccation in their pre-parasitic exposure (Armour *et al.*, 1969). In the late autumn, calves that have not had adequate prophylactic treatment may harbour many thousands of such larvae but relatively few normally developing larvae or adult worms. Type II ostertagiosis results when these inhibited larvae resume their development in the late winter or spring, the emerging larvae producing the same lesions as those causing type I disease.

ATYPICAL FORMS OF PARASITIC GASTROENTERITIS

Parasitic gastroenteritis in beef herds

This is not usually a problem in spring-calving herds, since most of the infective larvae are consumed by the adult cows, which normally have enough immunity to prevent a high percentage of worms establishing and producing eggs. The calves that might transmit the infection are too young to consume much grass in the early part of the season. As a result the peak of infective larval numbers does not develop until September or October when most calves are weaned, treated and housed. Conversely, in autumn-calving herds in which calves are weaned in the following spring and grazed in the same manner as dairy replacements, the same epidemiological picture can result, i.e. type I ostertagiosis will occur in the absence of preventative measures.

Early-season type I ostertagiosis

In areas where climatic conditions allow autumn-born calves to be put out in March or early April, the number

of infective larvae remaining on pasture can be sufficiently high to cause normal type I disease from 4 to 6 weeks after going to grass.

Nematodirosis in calves

Parasitic gastroenteritis due to large infections of the nematode *Nematodirus battus* has recently been observed. Normally recognized as a parasite of sheep, it has recently been observed to be able to be transmitted by cattle, both on farms where annual alternation of sheep and cattle has taken place and even where cattle only are kept, and has caused severe outbreaks of diarrhoea in calves.

Cooperiosis in calves

In the last decade, as a result of the widespread use of suppressive regimes with avermectins and moxidectin that are more effective against *Ostertagia* than *Cooperia* species, the prevalence of *Cooperia oncophora*, the commonest of that genus in northern Europe, has increased in comparison to *Ostertagia* species. In faeces samples taken during the first two-thirds of the grazing season on farms where intermittently applied avermectins have been routinely used for prophylaxis, *Cooperia* species eggs can form up to 90 per cent of the eggs excreted, with *Ostertagia* species forming the majority of the remainder. In such circumstances large *Cooperia oncophora* worm burdens can accumulate in a short time when hatching conditions are favourable. These can result in outbreaks of acute diarrhoea and loss of condition, and are rather similar to *Nematodirus battus* infections in lambs in spring, although in calves they usually occur in July or early August. If left untreated calves normally recover after a few weeks and become immune to *Cooperia oncophora*, but the loss of condition can be prevented by prompt treatment.

Parasitic gastroenteritis in adult cattle

Although uncommon, since most cattle acquire immunity by the age of 18 months, occasional individual cases can occur. Bulls that are grazed on calf paddocks and cows, which due to debilitating intercurrent diseases such as fascioliosis may have some of their normal immune reactions depressed, can both suffer from type II ostertagiosis.

Diagnosis

Affected animals invariably present with diarrhoea, which may be present to a greater or lesser degree in all members of the group. Younger animals are fre-

Table 19.1 Differentiation between type I and type II ostertagiosis.

| | Type I | Type II |
|----------------------------------|---|--|
| Seasonal incidence | Predominantly July–November; occasionally April–May | February–May |
| History | Usually in calves at grass for the first time, heavily stocked (8–10/ha). Occasionally in beef yearlings during the second year's grazing, and in individual cows and bulls transferred from hill herds to more intensive systems | Always in calves that grazed on heavily stocked pasture during the previous autumn, usually in younger members of group. Can also occur in bulls grazing calf paddocks. Occurs usually when housed or within 3 weeks of being put to grass |
| Clinical signs | Profuse green diarrhoea; will only usually recur once approx. 10 days after treatment. Rapid loss of body weight. Morbidity high, mortality low | Intermittent profuse diarrhoea. Recurs every 2 weeks until supply of inhibited fourth stages is exhausted. Morbidity low, mortality high |
| Laboratory findings ^a | Not usually anaemic PCV > 0.3 RBC > $7 \times 10^6/\text{mm}^3$ Hb > 10 g/100 ml Plasma pepsinogen 2–5 iu | Mild anaemia PCV 0.22–0.26 RBC $5.6 \pm 10^6/\text{mm}^3$ Hb $8.4 \pm 0.5\text{ g}/100\text{ ml}$ Plasma pepsinogen 2–8 iu |
| Post mortem | pH abomasal contents >5.0 >50 000 adult <i>O. ostertagi</i> Severe abomasal reaction | pH abomasal contents >5.0 >50 000 adult <i>O. ostertagi</i> plus large numbers of immature fourth stages Severe abomasal reaction |

^a PCV, packed cell volume; RBC, red blood cell; Hb, haemoglobin.

quently the most severely affected. There will be a history that indicates grazing on potentially infected pasture during the preceding four to eight weeks in the case of type I ostertagiosis or during the previous late summer and autumn for type II ostertagiosis.

Specific diagnosis (see Table 19.1) can be assisted by the following tests.

(1) Faecal egg counts. Despite the dilution of faeces caused by diarrhoea, the nematode egg counts will be in excess of 1000 eggs/g. Counts may be higher in less severely affected calves that have not yet become severely diarrhoeic. In older animals and in some individuals in type II cases the faecal egg counts may be low enough to be misleading, and if suspected the results of other tests should be borne in mind.

(2) Plasma pepsinogen. In healthy calves the normal level of plasma pepsinogen is less than 1 international unit (iu) of tyrosine. In affected calves the level will normally be greater than 3 iu, and in very severely diseased individuals up to 4.5 iu. It should be pointed out that in adult cattle the normal pepsinogen level can be 1.5–2 iu, almost that found in calves in the prepatent period of type II ostertagiosis. Plasma pepsinogen levels in adults therefore should be carefully evaluated.

(3) Plasma gastrin. The plasma concentration of the hormone gastrin has been shown to rise at the time of patency in experimental infections and to peak at levels between 500 and 1000 pg/ml. Although still under investigation it may be used as a substitute for plasma pepsinogen in the future.

(4) Post mortem findings. In both type I and type II ostertagiosis the abomasum (providing the animal has remained untreated) will contain large numbers of adult *O. ostertagi*. The number can vary from 50 000 to 1 000 000 in extreme cases. In type II disease pepsin digest of the abomasal mucosa or incubation in luke-warm normal saline will reveal large numbers of inhibited fourth stage worms. The pH of the abomasal contents will be raised to pH 4.5.

Treatment (see Chapter 60)

Type I disease can be treated with almost any of the anthelmintics currently available such as levamisole, benzimidazoles or avermectins. Type II disease requires the use of some of the modern longer acting benzimidazoles or pro-benzimidazoles or avermectins such as ivermectin, doramectin, abamectin, eprinomectin or moxidectin. The avermectins and moxidectin are much

the most effective in removing both adult and inhibited fourth stage parasites as a result of their persistence and slow excretion. Levamisole is much less effective for type II disease, as it has a poor efficiency against inhibited worms due to its rapid excretion (see p. 1021), and the benzimidazoles can vary in efficacy depending on the time of treatment in relation to the onset of inhibition of the worms, i.e. in the early and late stages of inhibition the larvae are thought to have a more active metabolism, and therefore absorb more anthelmintic; in the middle of the inhibition period they absorb less, and it is then that the benzimidazoles do not have the persistence necessary to kill the worms.

Prevention

As for most parasitic diseases, prevention is more cost-effective than treatment. Since there are no vaccines yet available for gastrointestinal nematodes, numerous schemes that combine grazing management and anthelmintic therapy have been developed. The methods fall into three types: (i) evasive; (ii) suppressive; and (iii) dilution.

Evasive strategies: The basis of this category (also called the 'Weybridge' system) was first enunciated by Michel (1968) at the laboratory of the same name. Using the knowledge of the epidemiology of parasitic gastroenteritis that had then become available, Michel pointed out that if susceptible cattle were removed from infected to uninfected grazing just before the summer increase in infective larval numbers, serious parasitism could be avoided. When combined with anthelmintic treatment at the time of movement the system reduces the level of nematode worm egg contamination on the clean grazing. In essence, therefore, the system involves taking no prophylactic action until early July. At that time, pasture which has not been previously used for cattle grazing that year is available, after grass has been taken for silage making or some other form of conservation.

The calves are given anthelmintic treatment before being moved to it. The timing of the treatment can vary with the pharmacokinetics of the anthelmintic used and its effect on nematode eggs if contamination of the aftergrass is to be avoided. For instance, the longer acting benzimidazole anthelmintics (e.g. oxfendazole, albendazole, fenbendazole) are ovicidal within a few hours after treatment and their slow rate of excretion means that cattle are protected from infection with susceptible parasites for approximately 30 hours after treatment. They can therefore be put back safely onto the contaminated grazing for 24 hours after treatment before transfer to the aftergrass. The same technique can be applied with avermectins and moxidectin, which

although not ovicidal have an even longer half-life and will inhibit further infections for at least two weeks. On the other hand, levamisole has a rapid excretion rate and is also not ovicidal. If reduction of contamination as well as nematode removal is intended, cattle treated with levamisole require to be yarded after treatment at least overnight, if not for 24 hours. After this first treatment in early to mid July, and depending on the availability of grass and its previous grazing history, the calves may require no further treatment until housed in late autumn, although in practice many are treated four to six weeks after the first movement. Although highly effective and the most economical method of prophylaxis when carried out carefully, it should be pointed out that although excellent for control of gastrointestinal nematodes it is not completely effective in the prevention of lungworm infection caused by *Dictyocaulus viviparus*.

Suppressive strategies: These have been introduced gradually since the mid 1970s and are also based on knowledge of the epidemiology of the infections. Unlike the evasive systems, which allow natural infection and pasture contamination to take place in spring and early summer, the basis of these methods is to suppress egg production during that period (Fig. 19.2). If pasture contamination is prevented or reduced, the summer increase of infective larvae is of such proportions as to cause a negligible risk of severe parasitism. Suppression is carried out by two different methods: (i) repeated anthelmintic treatments with standard preparations, the interval between which is determined by the pharmacokinetic properties of the chemical used; currently most of the anthelmintics used are avermectins or moxidectin; or (ii) the use of a device, usually an intraruminal bolus, which has a continuous slow release of the active anthelmintic for periods from 60 to 140 days. Such boluses are usually administered by balling-

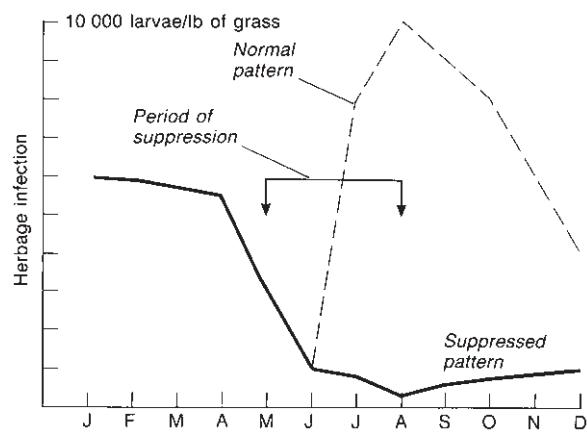

Fig. 19.2 Rationale for anthelmintic suppression.

gun at or just before susceptible calves are put out to grass in the spring, although recent experiments have shown that they can also be effective when given in midsummer to prevent infection in calves grazing previously contaminated fields. The length of prophylactic activity varies between different climatic areas and nematode species, e.g. in south-eastern areas of the UK suppression for eight weeks after being put to pasture in spring may be sufficient, but in wetter western areas it may require to be prolonged for a further five weeks and if lungworm infections are present on the farm for up to 15 weeks.

Dilution strategies: Originally described in New Zealand as the Ruakura method (McMeekin, 1954) and further amended by Leaver (1970), the methods consist of the grazing of paddocks in relays by groups of calves followed by groups of older cattle. The basis of the technique is that the greater consumption of infective larvae by the immune or partially immune adults will delay and reduce the build-up of infective larvae on the paddocks. Initially, no anthelmintic treatments were given, but in modern practice the method is frequently combined with either of the evasive or suppressive techniques.

The advantages and disadvantages of each of the three preventive methods are summarized in Table 19.2.

Parasitic bronchitis (husk, hoose)

Dictyocaulus viviparus is almost the sole cause of severe pulmonary helminth infections in cattle. Occasionally other parasites are found, but rarely in numbers

sufficiently large to cause disease. In general, calves at grass from midsummer to autumn are those most frequently clinically affected, but heavy infections in animals of any age previously uninfected will produce signs. It is most prevalent in dairy-type calves, but is also common in weaned beef calves. The range of signs can vary from occasional coughing to severe respiratory distress, and is a reflection of the number of infective larvae ingested during a relatively short period.

Aetiology and epidemiology

The immediate cause of clinical symptoms is the ingestion two to four weeks previously of large numbers of infective larvae of *D. viviparus* by non-immune cattle. Experimentally, severe infections can be induced by a single administration of larvae at a rate of between 25 and 50 larvae/kg body weight. Typically, an affected calf weighing 300 kg will have ingested between 7500 and 15 000 L3 (third stage larvae). This is a much smaller infection than is required to cause parasitic gastroenteritis by *O. ostertagi*, and is an indication of lesser margin for error involved in ensuring adequate prophylaxis.

The epidemiology is more complex and infections are also much less predictable than are those of gastrointestinal nematodes, principally because at present not all details of larval survival and transmission are known. Infections are more prevalent in wetter areas, especially those in the west of the British Isles. One of the major differences between *D. viviparus* and gastrointestinal nematodes that has an influence on the unpredictability of infections is that the female worm produces eggs

Table 19.2 Advantages and disadvantages of the prophylactic methods for gastrointestinal parasites.

| Method | Advantages | Disadvantages |
|-------------|--|--|
| Evasive | Low labour cost Low anthelmintic cost Not likely to lead to anthelmintic resistance in nematodes | Does not protect against lungworm Reduces the flexibility of pasture usage in the late summer |
| Suppressive | If carried out for long enough will reduce the chances of lungworm infection More likely to lead to anthelmintic resistance in target nematodes | Higher labour or anthelmintic costs especially in the case of slow-release boluses Allows more flexible use of grazing |
| Dilution | Lower anthelmintic costs | Requires excellent fencing and high labour costs and is generally used only in well organized dairy farms Is not effective for prevention of lungworm infection |

containing fully developed larvae, which are passed in the faeces. These become infective within a much shorter time than the eggs of *Ostertagia* species and hence in optimal conditions can produce a rapid increase in their numbers. In addition to rapidity of maturation to infectivity, larvae are also dispersed from faecal pats by some of the following means: (i) ascending the common faecal fungus *Pilobolus* and being propelled into the air on discharge of the sporangium, to be carried by wind to adjacent areas; (ii) although unverified, there is evidence that earthworms or coprophagous beetles may act as transport hosts; (iii) also unverified, it has been reported that the European hare (*Lepus europaeus*) can be infected, although experiments have shown that the smaller blue hare (*L. timidus*), common in Ireland, is refractory to infection. In addition to these means of dispersal it has been shown that infective larvae can remain viable in soil as well as on pasture over the winter, and that small numbers of adult worms and hypobiotic larvae can survive and overwinter in infected animals despite their hosts having some immunity to further infection, only to mature and propagate larvae during the following spring.

Pathogenesis

After ingestion, infective larvae penetrate the intestinal mucosa, moult to the L4 stage of their life cycle and migrate via bloodstream and lymphatic channels to the lungs. This takes place approximately one week after being consumed, and up to this point no clinical effects are observed in the host. After that period, larvae break out of blood vessels into alveoli and small bronchioles, after which they moult to become young adults, and as they increase in size they ascend the bronchiolar tree towards the large bronchioles and bronchi. Larvae are first found in faeces from the 25th day after infection.

Signs

Clinical signs appear during the second week after infection and their severity depends on the number of developing worms. The signs range from occasional to repeated coughing, with a noticeably increased respiration rate in the worst affected. By the third week, severely affected cattle do little else except stand in a characteristic head extended position with rapid shallow breathing and frequent coughing.

Although most calves, if not severely affected, will recover after treatment, a small percentage will suffer a relapse of clinical signs in the absence of fresh infection. The precise aetiology of this is uncertain, but autopsy reveals an oedematous rubbery lung with alveolar epithelialization observed microscopically.

Necropsy

The pathological progression during maturation progresses from alveolitis and bronchiolitis to bronchitis and severe emphysema, sometimes with superimposition of a secondary bacterial pneumonia. If left untreated after patency even moderate infections can progress in severity due to aspiration of eggs and hatched larvae back into previously unaffected alveoli and smaller bronchioles, resulting in bronchitis and pneumonia.

Diagnosis

Affected cattle invariably present with varying degrees of respiratory abnormality, and since similar signs can occur as a result of infection by a variety of pathogens, careful differential diagnosis is advisable. The grazing history and time of the year in northern temperate areas invariably involve cattle grazing established pasture previously used by other cattle plus the appearance of clinical signs between July and October. Since the caudal lobes of the lung are more frequently affected, adventitious lung sounds are usually more apparent from these areas, in contrast to those from viral pneumonias, which usually affect the cranial and medial lobes. Confirmation of the diagnosis by identification of larvae in faeces or sputum samples can only take place after patency, which takes place approximately 25 days after infection, although it should be noted that in adults that are suffering from a re-infection the infection usually does not reach patency.

Treatment (see p. 1027)

In order to kill the worms and larvae present in the lung tissues, anthelmintic treatment is essential. The most effective are the avermectins and moxidectin; levamisole and some of the more recently developed benzimidazoles or pro-benzimidazoles, such as oxfendazole, fenbendazole, albendazole and netobimbin, are also effective, but the incidence of alveolar epithelialization is more common after their use, since they have little persistent efficacy and reinfection can occur if the same grazing is used before and after treatment. Severely affected animals may also require antibiotic therapy to control secondary bacterial pneumonia, and if anorexia has been present rehydration with electrolytes may also be helpful. In most outbreaks a range of severity is observed and it is frequently advisable to house the worst affected cattle, especially if climatic conditions would be stressful even to healthy calves. In addition, because treatment of severe cases can exacerbate signs farmers should be warned of the possibility. In outbreaks involving adult dairy cows care should be

taken that the anthelmintic used does not prevent sale of milk products for a prolonged period until a withholding time long enough to allow excretion of the drug has passed. The most appropriate drug currently available is eprinomectin, the use of which requires no period of milk withdrawal from sale.

Prevention

There are two major methods available, the first relying on inducing immunity and the second on suppression of infections.

Vaccination (see p. 1011): Immunity can be stimulated by the use of a live vaccine, which takes the form of two doses of 1000 infective larvae irradiated by gamma irradiation. Calves should be two months old before vaccination and the doses separated by four weeks and preferably both doses given before going to grass in the spring or before the time of earliest challenge in outdoor calves. Although the vaccine induces excellent protection against clinical disease it does not completely prevent all worms from natural infections completing their life cycle, so that the parasite can be maintained at a very low level on pasture grazed by vaccinated cattle. If the farmer neglects to vaccinate, parasite numbers can quickly increase sufficiently, if weather conditions are favourable, to affect non-immune cattle within their first grazing season.

Suppression: On farms where calves have suffered lung damage due to viral pneumonia, vaccination may be inadvisable because of the possibility of exacerbation of the existing lesions. Under these circumstances it has been found that regular anthelmintic treatments throughout the grazing season can suppress infection sufficiently to minimize the danger of clinical disease and at the same time allow some immunity to be induced by the natural ingestion of infective larvae from pasture which are subsequently killed before completion of their life cycle (see p. 1027). The method has also been successfully applied to normal healthy calves, but it requires to be carried out and monitored carefully, since there are potential problems in its use. Firstly, the length of time during which anthelmintic suppression is required may vary between areas with different climatic patterns and farming practices. In general in the British Isles it is necessary to provide anthelmintic cover until mid August. The methods of application require that the anthelmintic must be extremely effective against all stages of the parasitic life cycle of the nematode. Those anthelmintics used fairly successfully have been avermectins, either as injections or pour-ons administered at intervals after going to grass that are dependent on the particular pharmacokinetics of the drug used and the

time of turn-out to grass, and intraruminal boluses designed to release anthelmintic either intermittently or continuously for periods up to 140 days. The level of immunity stimulated depends on the number of larvae ingested from pasture and, since this can be highly variable, some cattle in a group may have inadequate resistance to future infection should they be exposed to it. As a result, careful monitoring is necessary after cessation of anthelmintic treatment and some thought required to plan cattle husbandry during the subsequent year and then as adults.

Stephanurosis (kidney worm)

Aetiology and epidemiology

This is mainly an infestation of pigs but it can infect calves and is due to *Stephanurus dentatus*. The adult is up to 45 mm in length.

The condition is found in the tropical and subtropical countries of Africa, East and West Indies, Brazil, Hawaii, Philippines, Australia and southern Europe where pigs are kept, but in calves adult worms do not develop. The larvae cause damage to the liver parenchyma during migration and produce thrombosis of the abdominal blood vessels, which may be fatal. Aberrant larvae can encapsulate anywhere in the host but the majority are found in all parts of the kidney. The eggs produced in the pig form hatch to produce first stage larvae. These develop to third stage infective larvae if there is warmth and moisture. The larvae are often ingested by earthworms and these act as a vector for infection. The infective larvae are otherwise susceptible to cold or drying. Transmission is either by ingestion, which may include earthworms, or by skin penetration. In the host they pass to the liver where they remain for a considerable time before going to other parts of the body.

Signs

They are mostly of anaemia, ill thrift and ascites. Many infestations are without signs.

Necropsy

Necrotic lesions with thrombosis in the mesenteric blood vessels and hypertrophy of the mesenteric lymph nodes are likely to be found. In a few cases there may be haemorrhages and abscesses in the lungs and kidneys.

Diagnosis

This will depend on the presence of calves grazing areas with infected pigs. An immunodiffusion test can be used. There is a marked eosinophilia.

Treatment and control

Fenbendazole at high doses may be effective. Calves should not graze pastures recently used by pigs.

Bunostomosis

Bunostomosis in cattle is caused by the hookworm *Bunostomum phlebotomum*. It mainly affects cattle up to one year old and causes a range of signs from unrest and mild abdominal pain to diarrhoea and eventually anaemia depending on the stage of the infection and the number of worms present. It is more prevalent in subtropical and tropical regions than in temperate; this distribution has become especially marked during the last decade as the worm, which does not occur in large numbers, seems especially sensitive to some of the modern anthelmintics and may now be absent from those areas where frequent suppressive anthelmintic treatments have been applied.

Aetiology and epidemiology

Bunostomum phlebotomum parasitizes the small intestine of cattle. Adults can reach 3.0 cm in length and are characterized by a large buccal capsule with lateral cutting teeth and a tooth-like structure in its base, which is the duct of an oesophageal gland. The worms suck blood, which can induce anaemia and in large numbers cause diarrhoea.

The eggs from adult females pass out with faeces. Depending on climatic conditions, a parasitic infective larva, which is susceptible to desiccation, will develop under optimal conditions of adequate moisture and warmth within one week. The infective larvae can infect susceptible cattle in either of two ways.

- By penetration of the skin after which it enters the bloodstream and passes to the lung, emerging into the alveoli and after further moulting up the bronchial tree to the pharynx, where it is then swallowed and passes to the intestine to mature.
- By direct ingestion after which it burrows into the intestinal wall during development to emerge as an adult.

The prepatent period is eight weeks. The worm flourishes in conditions of adequate moisture and warmth and thus is generally a subtropical problem, but disease has been recorded in countries as far north as Scotland, where it has been seen in cattle maintained indoors on damp straw bedding.

Signs

Heavy percutaneous larval infections cause restlessness, stamping and itching. Once in the intestine adults

suck blood and cause haemorrhagic anaemia and hypoalbuminaemia, and small numbers (about 2000) in comparison to other gastrointestinal nematodes, other than *Haemonchus placei*, will cause very severe disease and death.

Diagnosis

It is difficult to diagnose when prepatent and mild anaemia is the main sign. When patent it should be differentiated from other parasites that cause haemorrhagic anaemia, e.g. *H. placei* and *F. hepatica*, and those deficiencies such as cobalt or copper (Chapter 21) that adversely affect erythropoiesis.

Treatment and control

The parasite is sensitive to modern anthelmintics and can be controlled by their suppressive or strategic use. Other measures in housed cattle should be the provision of dry bedding and its replacement when soiled. Once infected and treated, cattle normally develop a strong immunity to the parasite.

Haemonchosis

Haemonchosis is manifested by haemorrhagic anaemia and diarrhoea, and is caused by the presence in the abomasum of *Haemonchus placei* (synonym *H. similis*). As with bunostomosis it is mainly pathogenic in immature cattle, since infection in the first three years of life usually produces a strong immunity to reinfection. It also has a similar distribution, being commonest in subtropical and tropical countries, but present in most temperate countries and able to cause disease during any unusually warm periods of weather.

Aetiology and epidemiology

Adults of *H. placei* suck blood from the surface of the abomasum. They are fairly large in comparison to other abomasal nematodes and measure 3 cm in length when fully grown. In the female the ovaries and intestine are spirally intertwined to give the worm its 'barber-pole' appearance and nickname. The male has large barbed spicules, and both sexes a small lancet in the buccal capsule.

Female *H. placei* are very prolific egg producers and can lay up to 10 000 eggs daily. The eggs are passed in faeces and undergo a typical trichostrongyline development to infective larvae. The time taken to reach this stage varies considerably between temperate and subtropical climatic areas. In the former, it may take several weeks in contrast to four days under suitable conditions. The conditions for development of

Haemonchus spp. have been studied in some detail, and it has been concluded that they require a temperature in excess of 18°C and rainfall of 5.3cm/month for maximum translation, but can develop provided the mean minimum temperature is not less than 10°C. As a result of the combination of fecundity and rapid infective development in favourable conditions, pasture can become quickly contaminated with huge numbers of infective larvae. In the subtropics acute infections can therefore be found in susceptible young cattle, whereas in temperate areas infections are more likely to be chronic. Under adverse conditions in the tropics, e.g. dry seasons, infective larvae can undergo hypobiosis in a similar manner to *Ostertagia* spp., and resume development shortly before the rainy season commences.

Once ingested, larvae undergo two moults before becoming adult in 26–28 days, when infections become patent. After the first moult, the L4 larvae and subsequent adults suck blood, leaving haemorrhagic spots on the abomasal epithelium, and the resultant blood loss is the major pathogenic sequelae. However, in large infections the pH of the abomasal contents may be increased in the same way as in ostertagiosis, with the resultant digestive disturbance, raised plasma pepsinogen, possible bacterial overgrowth and diarrhoea. Once patent, peak egg production from females is normally reached between six and seven weeks after infection and may continue for a further six to eight weeks. Cattle, unlike sheep, develop resistance to the worm and unless immunologically compromised by intercurrent illness or malnutrition the population decreases rapidly thereafter and the animal remains fairly resistant for the remainder of its life.

Signs

There are two types of clinical picture. The first occurs in severe primary infections and presents severely anaemic, weak and sometimes diarrhoeic young cattle. The second is found in chronic lesser infections and typically causes weakness, lethargy, weight loss, a less acute anaemia, hypoproteinaemia, submandibular oedema and anasarca.

Diagnosis

Diagnosis can be confirmed if the infection is patent by the examination of faeces samples, which may reveal very high faecal egg counts. The plasma pepsinogen level may be raised. The grazing and past parasitic history may be helpful in differentiating from other causes of anaemia or diarrhoea such as fasciolosis, bunostomosis, copper or cobalt deficiencies, babesiosis, coccidiosis, bacillary haemoglobinuria and malnutrition.

Treatment and control

Anthelmintic treatment is the primary consideration and *H. placei* is susceptible to levamisole, avermectins, moxidectin and modern benzimidazoles as well as the flukicides rafoxanide, clorsulon and nitroxynil. This should be coupled with movement to uninfected pasture. Prevention can be achieved using similar methods as those described for ostertagiosis.

Trematodes

Fasciolosis

Fasciolosis in cattle is a chronic wasting disease caused by the presence in the liver and bile ducts respectively of immature and adult trematodes of the genus *Fasciola*. The disease is found in vast areas of the world, with the smaller *F. hepatica* (3.5 × 1 cm) in temperate countries and the larger *F. gigantica* (7.5 × 1 cm) in tropical regions the commonest species. Calves and yearlings are most commonly affected but any age of animal may be susceptible. Although it may take place at any time of the year, infection is most prevalent during autumn in temperate areas, with the resultant effects of disease becoming apparent in winter and spring.

Aetiology and epidemiology

F. hepatica: Multiplication of the parasite is partially climatically regulated, since its life cycle involves an intermediate host that requires adequate moisture and a suitable ambient temperature. The intermediate hosts are various species of snail of the genus *Lymnaea*, which are found on wet mud surfaces. In the British Isles, *L. truncatula* is the species involved. It prefers a neutral or slightly alkaline habitat, but can survive in fairly acid conditions such as peaty hills, although under such conditions individual snails remain small and the population low. At its maximum it can have a shell length of 1 cm. The snail population fluctuates, being least in winter and greatest in June and July, especially in years when late spring rainfall has been above average, when large numbers accumulate and are therefore available for transmission of *F. hepatica*.

Briefly summarized the life cycle of *F. hepatica* is as follows. The adult parasite in the bile ducts is a hermaphrodite and can be self- or cross-fertilized. Large numbers of eggs are produced by each parasite, which pass from the ducts to the gall-bladder and are subsequently passed into the intestine on contraction of that organ. Eggs are then passed in the faeces, but will not hatch unless moist and until an ambient temperature of 10°C is reached. Hatching at temperatures between 22 and 26°C takes nine days, but under normal

temperatures in the months of May and June in the British Isles, it can take four weeks. On hatching, the released miracidium must locate and penetrate the foot of *L. truncatula* within three hours. Once in the snail, the parasite undergoes multiplication through stages of sporocyst and rediae and reaches the cercarial stage after a minimum of two months, although in colder temperatures it may take up to 16 weeks or should winter intervene complete development may cease until the following spring. Under natural conditions within the British Isles, cercariae from summer infections are released from snails between late August and October, and in some areas from overwintered infections in April or May. On release from the snail, which must take place in conditions of wetness, the cercariae swim to the nearest plant, encyst on its leaves and become the infective stage, termed metacercariae, several hundred of which can arise from one miracidium. Metacercariae on herbage can survive for several months and therefore maintain the infection from one year to the next.

Cattle become infected by ingestion of grass on which metacercariae are encysted. The metacercariae excyst in the small intestine, the wall of which they penetrate to reach the peritoneal cavity where they move to the liver and invade its capsule. At this point the flukes are very small (about 1 mm) but as they burrow through the liver parenchyma they gradually increase in size and in primary infections in cattle will reach the bile ducts after six to eight weeks, when they mature and become egg-laying adults 10–12 weeks after ingestion. In response to the presence of fluke in the liver parenchyma, the liver of cattle produces a more intense fibrous reaction than that of sheep, and the resultant cirrhosis is much more severe and is longer lasting. The liver cells of cattle do not regenerate as do those of sheep, and the result of even moderate infection in cattle is a more fibrous liver parenchyma than in most other species.

Within the bile ducts, the adult flukes suck blood and the spines on their cuticle cause multiple small haemorrhagic lesions. In cattle, the resultant fibrous reaction within the bile ducts is also more severe than in sheep and the bile duct walls thicken and become gradually calcified thereafter (Fig. 19.3). The result of the fibrous reaction during a primary infection in both bile ducts and parenchyma of cattle shortens the life span of adult flukes in the ducts to a maximum of 1.5 years and reduces the chances of flukes from subsequent infections being able to complete their life cycle. Cattle therefore become largely resistant to further infections, most of which do not become patent, and the few flukes that do so may take much longer than normal to reach patency and survive in bile ducts for a relatively short time.

F. gigantica: Although similar in many respects to *F. hepatica* it is not found in western Europe, but is widespread within tropical and subtropical climatic regions. The intermediate hosts are also snails of the genus *Lymnaea*, but the species are more aquatic than those transmitting *F. hepatica* and thrive in swamps, drainage channels and artificially flooded areas. As a result the epidemiology is closely tied to the periods of maximum rainfall, the snails being infected and development in the snail completed within these periods. Cercariae are shed towards the end of the wet season and encyst on herbage and even on the water surface at the start of the dry season.

The parasitic life cycle is similar to that of *F. hepatica* but each phase takes slightly longer with the result that patency of primary infections take three or four weeks longer than *F. hepatica*, eggs being found in faeces from 13 to 16 weeks after ingestion of metacercariae.

Signs

In severe infections there is a progressive loss of weight with anaemia and occasionally oedema. Subclinical infections cause a reduction in milk yield and reduction in the growth rate of young cattle.

Diagnosis: The disease is characterized by a gradual loss of condition that is exacerbated if the quantity and quality of feeding are suboptimal. A chronic anaemia develops and the packed cell volume (PCV) drops to approximately 20 per cent. Erythrocytes are hypochromic but normocytic, and while the leucocyte count may be slightly raised, the percentage of eosinophils in a differential count is greatly increased and may consist of up to 20 per cent of the total white cell count. In cows the total milk yield and the non-fat solids proportions may be reduced.

Diagnosis can be confirmed by the presence of fluke eggs in faeces samples, but detection is not always as simple as in sheep, especially in adults, since even in patent infections excretion of eggs is intermittent. Examination of plasma shows a hypoalbuminaemia, and during the migration phase the plasma glutamate dehydrogenase (GLDH) is raised. Once the epithelium of the bile duct walls becomes diseased, the plasma concentration of gamma-glutamyl transpeptidase (GT) rises and this is a useful diagnostic indicator.

Treatment (see pp. 1026, 1028)

Affected cattle are treated by administration of a fasciolicide. Of those currently used for cattle the commonest are triclabendazole, oxyclozanide, rafoxanide,

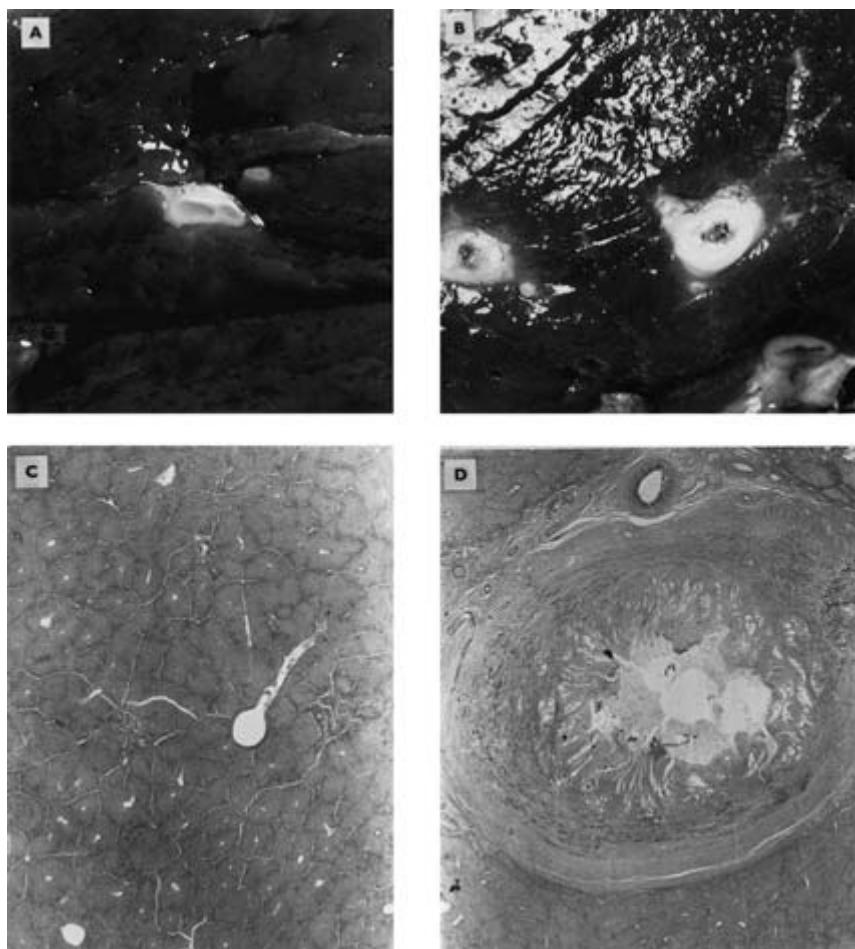

Fig. 19.3 (A) Normal and (B) liver fluke infected bovine liver. (C, D) Microscopic sections of the same stained to show fibrous tissue.

nitroxynil, albendazole, netobimbin and cloresulon. All will remove more than 90 per cent of adult flukes from the bile ducts, but they have variable efficiencies against the immature stages migrating through the liver. The most effective is triclabendazole, which will remove developing flukes from a few days after ingestion. Rafoxanide, nitroxynil and cloresulon are effective against six-week-old flukes at normal dose rates and at increased dose levels affect those four weeks old. Albendazole, netobimbin and oxyclozanide at normal dose rates remove only adult flukes from the bile ducts and are ineffective against immature flukes. All require withholding of meat and milk for human consumption for variable periods dependent on their pharmacokinetics (see p. 1026).

Prevention

There are four methods available that are used individually in suitable circumstances or can be combined

in an attempt to give a more rapid reduction in the prevalence of the parasite.

- Prophylactic use of anthelmintics to reduce both the number of flukes in cattle and the number of eggs excreted. This is by far the commonest practice and involves treatment of cattle once or twice annually. In the British Isles such treatments take place in the autumn and late spring.
- If the areas of snail habitat are delineated and small and they can be drained. This is usually not cost-effective for fluke control alone if the sites are extensive.
- Small snail habitats can be fenced off during the time of greatest infection.
- Snail habitats can be treated with molluscicide. There can be environmental objections since many which were formerly in use were toxic to many species in addition to snails. The most satisfactory is *N*-tritylmorpholine, which although not available in the UK is used in many tropical countries.

Paramphistomosis (stomach fluke disease, intestinal amphistomiosis)

Aetiology and epidemiology

The cause of acute paramphistomosis in Africa is *Paramphistomum microboithrium*. Other *Paramphistomum* spp. and *Cotylophoron* spp. are found in ruminants in Africa and tropical and subtropical regions. In Asia, *Calicophoron* spp. are found and one species occurs in Africa. *Carmyrius* spp. are seen in Africa, India, Pakistan and the Middle East.

It has been recorded in a severe form in Australia, India and the USA. The life cycle is indirect and similar to that of *Fasciola*. It involves aquatic snails that are adapted to a variety of locations. Disease occurs only where there is a massive concentration of the infected planorbid snails. The metacercariae are ingested and the immature flukes develop in the duodenum, where they may be seen in the mucosa. The flukes are 3–4 mm long and 1–2 mm wide. They also develop in the abomasum but are less common. They then migrate through the abomasum to the rumen and reticulum, where again few are found. The prepatent period is very variable, being between one and a half to four months. Most outbreaks occur in the late summer, autumn or early winter when pastures are being contaminated with cercariae. Although all ages of cattle are susceptible, infestation is most commonly seen in yearlings. Fewer infestations occur in the adult, suggesting some degree of immunity.

Signs

Acute paramphistomosis is due to a massive infestation in calves. There is a persistent fetid diarrhoea without blood or mucus, anorexia, weakness, marked loss of condition and then recency. In some cases there is submaxillary oedema and a pallor of the mucosa. Death occurs in about one to two weeks after signs develop.

Chronic: In heavy infestations of adult flukes there is a chronic loss of weight, a dry coat and anaemia.

Necropsy

In the acute case there is severe inflammation of the duodenum and abomasum as the parasite penetrates deeply into the mucosa and sometimes the muscularis layer, and there is haemorrhage. There is muscular atrophy, subcutaneous oedema and fluid accumulation in the body cavities. Large numbers of small, immature, flesh-coloured flukes are present in the lumen. In less acute cases the duodenum is thickened and congested. There is fluid in the abdominal cavity.

Diagnosis

Most disease occurs with immature flukes and so it is not easy to detect in the live animal but it can be missed at post mortem. Often other parasitic infestations are present, which again causes paramphistomosis to be overlooked. However, the history and area where the cattle are grazing can give some indications. There is a reduction in the red and white blood cells and a hypoalbuminaemia. Differential diagnoses include copper and cobalt deficiencies, liver fluke, parasitic gastroenteritis, Johne's disease in the adult and poisoning.

Treatment (see p. 1028)

Few of the modern trematocides have been found to be effective against paramphistomosis. Oxylozanide at 18.7 mg/kg has variable efficacy from approximately 50 to 90 per cent. Niclosamide at 100 mg/kg is highly effective against intestinal paramphistomes but ineffective for adults. Brotianide at 55 mg/kg is effective against adult flukes but less so against the immature stages.

Control

Drainage of low-lying areas and destruction of the soil will considerably reduce infestation. The most susceptible animals, i.e. calves and immature cattle, should be kept away from likely snail habitats. Routine treatment against *Paramphistomum* before they mature and can infect snails is of use.

Schistosomosis (bilharziosis)

Aetiology and epidemiology

There are several parasites in the genus *Schistosoma*. *Schistosoma bovis* is found in African, Asian and southern European cattle. *Schistosoma mattheei* occurs in cattle in central and southern Africa and can infect man. *Schistosoma indicum* is found in India and Pakistan as is also *S. spindale*, which can also occur in south-east Asia and Indonesia. *Schistosoma japonicum* occurs in the Far East. *Schistosoma nasale* is again found in India and Pakistan and is unusual in that the adult occurs in the mucosal veins of the nose. Several minor species occur involving *S. curassoni*.

Various species of the parasite are widespread and the adults live in veins. Unlike most flukes, *Schistosoma* spp. are not hermaphroditic and the longer male carries the long slender female, which is up to 25 mm long, in a gyroctoplasmic canal. Infection can be via the skin or gut. After penetrating the skin the schistosomulae (young flukes) pass via the lymphatic system to the right side of the heart. They then go via the lungs into the circulation and then to the liver. They mature in the portal

Table 19.3 Intermediate snail hosts of *Schistosoma* spp.

| Species | Intermediate snail host genus |
|---------------------|---|
| <i>S. bovis</i> | <i>Bulinus</i> and <i>Physopsis</i> |
| <i>S. indicum</i> | <i>Indoplanorbis</i> |
| <i>S. japonicum</i> | <i>Oncomelania</i> |
| <i>S. mattheei</i> | <i>Bulinus</i> |
| <i>S. nasale</i> | <i>Lymnaea</i> and <i>Indoplanorbis</i> |

veins before migrating to their final area, usually the mesenteric veins, but they are also found in the urinary bladder veins in the case of *S. mattheei* and in the nasal mucosal veins in *S. nasale*. When infection is oral the gut is penetrated and the immature stages pass to the liver via the blood.

Once mature, eggs are produced that can hatch within minutes if conditions are right. The free-swimming miracidiae penetrate snail hosts producing sporocysts, daughter sporocyst and cercariae but there are no redia. The cercariae must infect the final host within one or two days or they die off as there is no metacercarial stage. There are various genera of snails involved depending on the species of *Schistosoma* (Table 19.3). All the snails like mud except for *Oncomelania* spp., which are aquatic.

In many areas of Africa most of the cattle are infected but there are very few signs. Young cattle are more likely to be ill.

Signs

The main signs are of diarrhoea, which may contain blood and mucus and is intermittent. There is a loss of condition and reduced resistance to other diseases. Death occasionally occurs. Infestation with *S. nasale* causes a mucopurulent nasal discharge with dyspnoea. Chronic cases develop nasal granuloma.

Necropsy

In severe infestation there are small grey-white granules in the gastrointestinal tract with petechial haemorrhages and ecchymosis. The ileocaecal body may be enlarged and haemorrhagic. Granulomas may also be scattered through the liver parenchyma as well as the lungs and bladder. In *S. nasale* infestation there may be nasal granulomas.

Diagnosis

The signs and grazing history help but it is difficult to diagnose unless faeces are taken or nasal discharge if *S. nasale* is present. The eggs are large and characteristi-

cally spiral. As the eggs hatch quickly they need to be fixed in 10 per cent formalin.

Differential diagnosis involves coccidiosis, trypanosomosis, poisoning and Johne's disease.

Treatment (see p. 1028)

Trichlorophan, an organophosphorus compound, can be used parenterally, or niridazole or thioxanthane derivatives such as becanthane or hycanthane may be used. Treatment must be performed carefully otherwise a large number of dead schistosomes will produce emboli and lead to hepatic infarction or portal occlusion.

Control

Immunity to the disease occurs but varies with the *Schistosoma* species. Control involves keeping cattle away from areas frequented by the intermediate host. Molluscicides can be of some benefit. Some vaccines are under development, e.g. a recombinant glutathione S-transferase derived from *Schistosoma bovis* has been shown to reduce both egg output and parasitic establishment. Such vaccines can be expected to be available in the next year or two.

Cestodes

Taenia saginata

Taenia saginata is a cyclophyllidean tapeworm, for which man is the final host. It is transmitted to man by the ingestion of the intermediate larval stage in undercooked beef. Although the larval stage can be found in any age of cattle, viable cysts are found mainly in cattle up to two years of age. The presence of the parasite in the muscles of cattle does not cause clinical signs unless the animal is very heavily infected and the myocardium is involved, but because it is a zoonotic infection its presence can cause significant losses to the beef industry, especially in developing countries. In countries where sanitation standards are high it is a decreasing problem that on average is found in 0.5 per cent of bovine carcasses, with occasional heavy infections occurring under unusual circumstances. In those areas of Africa, Asia and parts of Latin America where human sanitation methods are poor or non-existent and local customs favour ingestion of raw or undercooked beef, the prevalence may be up to 20 per cent.

Epidemiology

The adult tapeworm inhabits the intestines of man. Its scolex has no hooks, and apparently moves up or down the intestine depending on whether the host has eaten

recently or not. When the host's stomach is empty the scolex moves back up the intestine towards the duodenum, and these movements produce hunger pains and vague intestinal discomfort. Fully grown the tapeworm may reach a length of 8m. Mature egg-filled (about 25 000) proglottids are shed from its posterior end and are passed in faeces or wriggle out of the host's anus nocturnally. Anal pruritis and occasional diarrhoea are usually the only signs apart from the aesthetic and hygienic conditions involved.

The eggs are resistant to external conditions. They are inactivated within two weeks if desiccated, but are known to survive for 16 days in raw sewage, 71 days in liquid manure, 159 days on pasture and 200 days in sewage sludge. No normal method of handling sewage can inactivate them other than total incineration or extensive heat treatment. Extended periods of sludge digestion with or without heat may affect viability but technical proof is lacking. Chemical disinfectants other than some containing copper at very high pH (11.5) are not ovicidal.

Two-thirds of outbreaks in developed countries have been shown to be associated with the spreading of sewage sludge on agricultural land. The remainder have been presumed to be caused by spread of seagulls feeding at sewage plants and passing viable eggs through them on to grazing land, or by accidental flooding of pasture by contaminated effluent streams from sewage plants. Migrant labour from less developed countries and infected stockmen have been implicated in some isolated local multiple infections.

Once ingested, the egg hatches and the liberated oncosphere travels via the bloodstream to striated muscular tissue, including the myocardium. It develops in the muscle and reaches infectivity three months after ingestion, when it is recognizable as a whitish fluid-filled cyst with a diameter of approximately 1cm, known as a cysticercus. It becomes enclosed in a thin fibrous capsule. Cellular immune reaction around it gradually increases and the capsule becomes thickened, eventually leading to the death of a high proportion of the cysticerci within 18 months and resistance to further infection, although some may survive for several years. After death the contents of the cysts become caseous and finally calcified. The masseter, tongue and heart muscles were generally considered preferential sites and are still examined carefully during meat inspection at abattoirs, in preference to damaging more expensive cuts of meat by the multiple incisions that would otherwise be necessary.

Control (see p. 1028)

There are no drugs suitable for ante-mortem treatment. Carcasses that are found to be infected are normally treated in one of two ways:

- If lightly infected they are frozen to a temperature of -10° for a minimum of 10 days, after which any previously viable cysticerci will have been killed.
- Heavily infected carcasses are usually condemned as unfit for human consumption and rendered after heat treatment into animal feedstuffs in some countries. The thermal death-point of cysticerci is 57°C and meat for human consumption should be raised to at least that temperature if the possibility of infection is to be avoided.

Echinococcus granulosus* and *hydatid cysts

There are two species of the taeniid tapeworm *E. granulosus*. The first is *E. granulosus granulosus*: the adult is found worldwide in the intestine of dogs and many wild Canidae but not the red fox. The intermediate form, the hydatid cyst, is found in domestic and wild ruminants, man and pigs, but not horses and donkeys. The second is *E. granulosus equinus*, which is almost exclusively found in Europe: adults parasitize the dog and the red fox, and horses and donkeys are the exclusive intermediate hosts.

Cattle therefore are affected by hydatid cysts of *E. granulosus granulosus*. The majority of hydatid cysts cause little apparent disease as they are situated in the liver or lung, their presence only becoming disclosed at abattoirs. Occasionally, they develop in sites where their gradually increasing size causes pressure on vital organs., the resultant disease being dependent on the organ and system affected.

Aetiology and epidemiology

The adult worms parasitize the small intestine of the dog. They are small worms, consisting of four segments of length 0.6mm. Large numbers may be present in infected animals, each releasing one gravid segment daily containing many eggs, which are resistant to normal external climatic conditions and remain infective for up to two years. After ingestion by cattle or other hosts the oncosphere penetrates the wall of the intestine and is carried via the bloodstream to the liver or other organs where it lodges and starts to grow to become a hydatid cyst. Growth is relatively slow and may take at least one year to reach a diameter of 20cm. In restricted sites the cyst assumes the shape of the space available, and daughter cysts may be formed and spread to other organs. If growth takes place in the omentum or mesentery, cysts can become very large. There is usually little cellular reaction around cysts in cattle. Since most cattle in developed countries are slaughtered in abattoirs there is little chance of further spread unless casualties are fed to farm dogs or packs

of hounds. In underdeveloped countries or where carcasses are not disposed of, wild Canidae ingesting the offal become infected; the brood capsules from within the hydatid cyst evaginate, the scolex attaches to the intestinal wall and reaches adulthood and patency some six weeks later. Infection in dogs is usually symptomless.

Treatment and control (see p. 1028)

Affected cattle are not treated specifically for hydatidosis, principally because of the difficulty of diagnosis, but also because anthelmintics are only now becoming available for treatment of infected human beings. Activity against larval forms has been claimed for praziquantel and albendazole, although most cysts are excised.

Prevention is directed to ensuring that dogs do not become infected, either by regular treatment, the most effective anthelmintic being praziquantel, or by preventing the ingestion of infected offal.

Protozoa

Coccidiosis

Bovine coccidiosis almost invariably affects groups of cattle less than one year old, although it does occasionally occur in older animals. It is manifested by enteritis, diarrhoea and in severe cases dysentery. Not all members of the group are equally affected and light infections are self-limiting; severe infections can be fatal if untreated. The disease is caused by the ingestion over a short period of large numbers of oocysts of *Eimeria* species by non-immune cattle; the greater the infective dose, the more severe the signs produced. *Eimeria* are species-specific, and although 13 species have been isolated from cattle, *E. zuernii*, *E. bovis* and *E. alabamensis* are much the commonest and most pathogenic. They are found everywhere in the world where cattle are farmed. Cryptosporidiosis is mentioned on pp. 204 and 286.

Aetiology and epidemiology

The presence of large enough accumulations of oocysts to cause disease is the result of farming practices that allow groups of cattle, which frequently have been stressed by transport and by mixing with others, to ingest food or water contaminated by faeces. It can happen either indoors on straw bedding, which is both damp and contaminated with faeces, or outdoors around drinking or feeding troughs. It can take place at any time of the year so long as conditions prevail that produce adequate moisture and temperature for

oocysts to survive and become infective, but frequently occurs three or four weeks after groups of purchased calves are mixed. In North America it has also been associated with the sudden stress of extreme temperature reductions in midwinter.

After ingestion, the oocyst is disrupted, releasing eight sporozoites each of which penetrates an intestinal epithelial cell and develops into a trophozoite. Multiple fission within the trophozoite produces a schizont, which after a few days ruptures the cell to release a large number of merozoites, which in turn invade other epithelial cells. There are up to four generations of schizogony depending on the species involved. The location of the cells invaded is important for the pathogenicity of the species, e.g. *E. zuernii* and *E. bovis* both invade cells in the lower ileum and later schizogony and gametogony (the term used to describe the sexual stages) take place in the epithelial cells of the caecum and colon. The gametocytes are formed deep in the epithelium and their rupture causes severe disruption of the lining of the caecum with resultant haemorrhage into the lumen. After gametogony, oocysts are formed that subsequently are passed in faeces. They are not immediately infective but require to undergo sporulation, in which the sporocysts and sporozoites are formed ready for further infection. The last process requires adequate moisture and warmth and takes 24–72 hours. The total life cycle from ingestion to patency occupies 15–17 days for *E. zuernii* and 15–20 days for *E. bovis*. Oocyst production during infection with a single species lasts for five to twelve days, but may be prolonged in multiple species infections. The oocysts are very resistant to external conditions and will survive for up to two years in suitable environments with adequate moisture. They can resist moderate frosts down to -8°C for two months, but are susceptible to drought, high temperatures and the chemical action of ammonia.

Signs

The presenting signs of diarrhoea or dysentery accompanied sometimes with severe straining in a group of calves leads to suspicion of coccidiosis.

Diagnosis

Examination of faeces samples for the presence of large numbers of oocysts can confirm the diagnosis. Care should be taken in interpretation of oocyst counts since small numbers are present in the faeces of many normal calves, and in severely affected diarrhoeic calves the main oocyst production phase may have passed or their numbers be misjudged due to the dilution factor of liquid faeces. Occasionally, calves may exhibit nervous signs, the reasons for which are as yet obscure, and viral

diseases that have cerebral affects should be considered.

Treatment (see p. 1029)

Two considerations need to be borne in mind. Firstly, severely affected calves will require individual treatment with an anticoccidial and, if deemed advisable, fluid therapy with electrolytes and injections of antibiotics to control secondary bacterial infections. Anticoccidial treatments include injections of sulpha drugs or the oral administration of sulphadimidine at 140 mg/kg body weight daily for three days, or amprolium at 10 mg/kg for four or five days. Amprolium has been withdrawn from sale in many countries because of possible carcinogenesis, and it should be remembered that overdose with amprolium, which is a thiamine antagonist, has also been associated with production of cerebrocortical necrosis (CCN), so care should be taken to give the correct dose in those areas where it is available.

Secondly, prophylactic treatment for other calves in the group should be assessed, depending on the numbers involved. Lasalocid at 1 mg/kg body weight per day, monensin included in the diet at 16.5 ppm of the diet or decoquinate at 100 ppm, either continuously to suppress all infection or for two cycles of medication for a week separated by a week when it is removed, can protect from the infection and allow sufficient immunity to be stimulated. A long-acting intraruminal bolus consisting of 1.6 g baquiloprim plus 14.4 g sulphadimidine is also effective, and sulphadimidine itself can also be used prophylactically at 35 mg/kg, but it should be borne in mind that as light infections are self-limiting such treatments may not be cost-effective.

Other measures should be taken to reduce the chances of infection, i.e. removal of food contaminated with faeces and better siting of feeding and water troughs so that faecal deposition on food and in water is made less likely. If the problem is a recurring event with each batch of calves, thought should be given to a short period of anticoccidial treatment after two weeks of exposure to possible infection so that incipient infections are disrupted but sufficient stimulation of immunity has been allowed to take place. A potent anticoccidial of a novel chemical type, toltrazuril, has been used experimentally in this manner with great success and may constitute a significant future advance in the prophylaxis of the disease.

Neosporosis (see p. 584)

Aetiology

The cause is *Neospora caninum*, a coccidian protozoan discovered within the last decade, and now recognized

as a ubiquitous parasite of cattle and dogs that also affects many other species of animals. Although it is the type species, recently, another species, *N. hughesi*, has been isolated from horses. Currently little is known of its development in animals that are naturally infected. The dog is the intermediate host, and is also a final host in prenatal infections. Infection can be both vertically transmitted from dam to calf *in utero* and lactogenically, naturally by ingestion of food and water contaminated with dog faeces containing *Neospora caninum* oocysts, or from cow to cow. The mechanisms of repeat congenital transmission are unknown at present.

Signs

It is a major cause of abortion in both dairy and beef cattle, and has been observed in almost all countries in the world. Cows of any age can abort from three months of gestation to full term, although most abortions occur at 5–6 months. Foetuses can be born alive or may die *in utero* and be mummified or reabsorbed. Calves that are infected may be born underweight and with neurologic symptoms such as ataxia, decreased reflexes and exophthalmia.

Necropsy

Tachyzoites and tissue cysts are found intracellularly in affected cattle. Tachyzoites measure 6 × 2 microns. Tissue cysts are oval, 102 microns long, and are found in the central nervous system and retina. Although infection can be found in many organs, the commonest site is the brain. The characteristic lesion is a focal encephalitis with necrosis and non-suppurative inflammation. Hepatitis can also be found in epidemic abortions.

Diagnosis

Ante-mortem diagnosis is by serologic methods. Several methods of assay of serum antibody are available, e.g. ELISA and indirect fluorescent antibody. A PCR (polymerase chain reaction) diagnosis of antigens is under development.

Treatment and control

At present treatments are largely experimental. Sulphonamides, pyrimethamine and clindamycin have been used in infected dogs, and decoquinate has been shown to kill *N. caninum* tachyzoites in cultures. Dogs should not be allowed to eat aborted fetuses or fetal membranes, and their faeces should be prevented from contaminating bovine feedstuffs.

Toxoplasmosis

Toxoplasmosis is a protozoan zoonosis that can infect any species of vertebrate. It is mainly recognized as being most pathogenic for sheep, however it occasionally causes human illness, and it can cause significant disease in cattle, although abortion is not as common a result as in sheep (see p. 895).

Aetiology and epidemiology

The parasite involved is *Toxoplasma gondii*. It has a two-host life cycle with both sexual and asexual stages. The definitive hosts are cats, both domestic and wild, which become infected by eating raw infected meat from the intermediate host, which can be any other species of vertebrate but is frequently a rodent. Once ingested the infective cysts are digested, each releasing large numbers of bradyzoites. They penetrate intestinal epithelial cells and undergo a coccidia-like series of schizogonies and finally gametogony in the small intestine to produce oocysts in faeces within one and a half weeks after ingestion of cysts. The cat then excretes oocysts for approximately two weeks. Oocysts remain viable for 17 months on pasture and if they contaminate animal feed any animal consuming it becomes infected.

Within the intermediate host, development is asexual. The oocyst wall is disrupted, releasing eight sporozoites which reach the lymph and blood vessels after penetrating the intestinal epithelium. The tachyzoites, as they are now called, are spread throughout the body to muscles, heart, lungs, liver, uterus and central nervous system, where they penetrate cells and multiply asexually. It is during this phase that the intermediate host becomes ill. After each multiplication the infected cells rupture, releasing 8–16 tachyzoites for further spread. After some days of such divisions the host develops some resistance to the organism and the spread of tachyzoites ceases, but is replaced by the formation of slow-growing cysts, each of which eventually contains large numbers of bradyzoites. Normally these remain until ingested, but should the host's immunity be reduced by other disease the invasive process can recommence. The tissue cysts are susceptible to freezing and cooking to 70°C for 30 seconds and therefore consumption of adequately cooked infected meat is harmless.

The organism is ubiquitous. Blewett (1983) reviewed the serological surveys that have been carried out in domestic animals and came to the estimate that antibody was present in 6.5 per cent of horses, 12.5 per cent of cattle, 23.5 per cent of pigs, 30 per cent of sheep and 40 per cent of cats. He also postulated that different animals vary in susceptibility to infection and in the rate of loss of antibody, and concluded that cattle return to

a seronegative status much more rapidly than do sheep, which are as a result a more reliable indicator of the actual prevalence of the infection.

Diagnosis

At autopsy or in abattoirs the most common findings are multiple necrotic granulomatous foci in internal organs. Histopathological examination is necessary for confirmation. *In vivo*, cattle are presented with vague pyrexic disorders sometimes affecting the central nervous system. If pregnant cows are affected, stillborn or weak calves that die within a few days of birth may result. Such calves frequently manifest nervous signs such as tremors of the head or neck, teeth grinding or convulsions.

Serological diagnosis can be made using a variety of tests such as indirect immunofluorescence or enzyme-linked immunosorbent assay (ELISA), or the Sabin-Feldman dye test. Because of its ease of use, an ELISA using both anti-IgM and anti-IgG for detection of both acute and chronic infection is currently being developed.

Treatment and control

Treatment of acutely infected animals can be attempted by the use of pyrimethamine and sulpha compounds such as sulphadiazine or sulphadimidine. Results in animals have been disappointing compared with those in mice and humans. These drugs affect tachyzoites but not bradyzoites so that total elimination of the parasite is not possible. Recent experiments with the ionophore monensin have shown prophylactic activity in sheep, but there are no reports of its use in cattle (Buxton *et al.*, 1987). Other preventative measures include prevention of cat faecal contamination of animal food and adequate destruction of infected carcasses.

Sarcocystidiosis (sarcocystosis)

Aetiology

The cause is *Sarcocystis*, a coccidian protozoan that has a predator-prey life cycle. The indirect hosts are dogs, cats and man and each may contain several species of sarcocyst, each one specific for a different intermediate host. *Sarcocystis hirsuta* is present in the ox and cat species, *S. cruzi* in the ox and dog and *S. hominis* in the ox and man. In the final host the *Sarcocystis* spp. undergo an enteric cycle with oocysts in the cells producing sporocysts in the faeces. On entry to some intermediate hosts those infected via the dog undergo schizogamy in blood vessel endothelial cells before

passing to the muscle. Those of the cat are not pathogenic and are found in the oesophagus, and throughout the tissues of the intermediate host produce microscopic cysts. If cattle are grazing and ingesting a few oocysts this probably results in a strong immunity. Signs develop about 26 days after infection (see p. 895).

Signs

Usually no signs occur but, following ingestion of massive doses, calves may develop anorexia, fever, emaciation and anaemia. Adults can suffer pyrexia, emaciation and abortion.

Necropsy

There are usually petechial and ecchymotic haemorrhages throughout the body, especially in the heart, brain, liver, lungs, kidneys and muscle. Some animals show emaciation, lymphadenopathy, anaemia and ascites. Death is usually due to necrotizing endocarditis. Histologically, schizonts can be found in the endothelium throughout the body and haemorrhages, lymphatic infiltration and oedema occur in the tissues and organs.

Diagnosis

This is usually based on post-mortem findings.

Treatment

Pyrimethamine at 1 µg/ml and trimethoprim at 5.0 µg/ml alone or in combination with sulphonamides have been shown to inhibit the development of *S. neurona* in cell cultures. Sulphonamides alone were

ineffective. The difficulty with any treatment is the maintenance of sufficient concentrations of the drugs in the cerebrospinal fluid, and relapses are usually ascribed to failure to do so.

Control

This is difficult but involves keeping carnivores away from cattle. Infection in dogs and cats can be avoided by feeding them cooked meat.

| Infectious bovine rhinotracheitis (IBR) | 289 |

Shipping fever (transit fever, pasteurellosis)

Epidemiology

The condition is an important respiratory problem in groups of weaned suckled calves that have been sold, often via a market, hence the terms transit fever or shipping fever. They are usually over six months old and under two years. During part of the sale transactions they will probably have been mixed and grouped with other batches of animals of similar age during transport, at the market or following arrival at the finishing farm. Most cases occur within the first month of their entry to the fattening unit and most cases are seen at least 10 days after arrival (Andrews *et al.*, 1981). The disease is characterized by an illness of sudden onset with dullness, pyrexia and anorexia. It is an acute exudative bronchopneumonia with toxæmia as well as much fibrin present in the exudate and often accompanied by fibrinous pleurisy (Blood & Radostits, 1989). The condition is common in North America, Europe and Britain. It is particularly prevalent in the American cattle feedlot industry and is the largest cause of mortality in that system. In a Colorado survey 75 per cent of all clinical disease in yearling cattle and 64 per cent of all post-mortem diagnoses were due to respiratory disease (Jensen *et al.*, 1976). The morbidity and mortality rates vary considerably but a level of up to 35 per cent and a mortality of 5–10 per cent of those affected or 0.75–1 per cent of the susceptible population is often quoted (Blood & Radostits, 1989). More recently in Britain, morbidity rates of 73–100 per cent with a mortality of 0–8 per cent of those affected and an average mortality of 4 per cent have been reported (Andrews, 2000).

Aetiology

The aetiology of the condition is still open to disagreement. It is considered to be stress or management

induced with the participation of infectious agents. The infection has been thought to be primarily viral, mainly due either to parainfluenza III (PI_3) virus or infectious bovine rhinotracheitis (IBR) virus, followed by secondary infection with either *Pasteurella multocida* or *Mannheimia haemolytica* (Pirie, 1979). *Mannheimia haemolytica* biotype A serotype 1 is considered to be the most common isolate although biotype T strains have also been found. *Mannheimia haemolytica* biotype A produces a heat-labile cytotoxin that is ruminant-specific destroying leucocytes (Sherwen & Wilkie, 1982). *Pasteurella multocida* infection is only isolated occasionally. Recently, it has been proved experimentally that *M. haemolytica* biotype A1 can produce the disease as a primary agent in non-immune calves (Shoo, 1989). Disease does depend on administering the organisms into the lungs either intratracheally (Friend *et al.*, 1977; Gibbs *et al.*, 1983) or intrathoracically (Houghton & Gourlay, 1984; Panciera & Corstvet, 1984). However, the exact mechanism by which the organisms enter the lung and result in lesions is not yet known. Other evidence of *M. haemolytica* involvement is that calves previously exposed naturally to the infection are much more resistant to experimental and natural pneumonic pasteurellosis (Confer *et al.*, 1984).

Although *M. haemolytica* can be isolated from the nasal passages it is only in small numbers when calves are healthy and unstressed. The organisms can be present in low numbers in the tracheal air but are not considered to be normal inhabitants of the lungs (Grey & Thomson, 1971). However, as the calves are transported, move to market and then enter the feedlot, the number of *M. haemolytica* biotype A1 increases in the nasal tract, the tracheal air and then the lungs, where bronchopneumonia can result (Frank & Smith, 1983). Thus management factors are important. The effects of stress are extremely difficult to quantify and have not been successfully undertaken experimentally to produce transit fever. However, transportation of yearling cattle does result in a rise in plasma fibrinogen levels, which is indicative of stress (Phillips, 1984). Increased fibrinogen levels also occur following confinement in unfamiliar surroundings and deprivation of food and water. In addition, it seems that cattle sud-

denly introduced to a diet consisting of large amounts of cereal are more prone to respiratory problems (Wilson *et al.*, 1985).

The environment tends to be important in that disease seems to be related to the season of the year (Andrews, 1978), fluctuations in daily ambient temperature and increased concentration of airborne particles 2.0–3.3 µm in diameter (MacVean *et al.*, 1986). Calves kept at a constant temperature of 16°C (60°F) showed minimum levels of nasopharyngeal bacteria at a relative humidity between 65 and 75 per cent. However, bacterial counts tend to rise at humidities on either side of this range (Jones & Webster, 1981).

The interrelationship of different micro-organisms and transit fever still needs further elucidation. However, cattle entering feedlots with low serological titres to IBR, bovine respiratory syncytial virus (RSV) and *Mycoplasma dispar* were at greater risk of being treated for BRD (Rosendal & Martin, 1986). It has also been shown that IBR, PI₃, bovine virus diarrhoea (BVD) and RSV are all associated with acute respiratory disease (Martin & Bohaz, 1986).

In many outbreaks of transit fever it is likely that the stress of movement plus mixing with other calves, the introduction to housing and a new diet are sufficient to initiate disease. The main organism involved is usually a *Mannheimia* species, especially *M. haemolytica* biotype A1. Spread of infection is optimized by crowded conditions in transport and markets. It is also probable that as animals go down with disease and pass on the infection, the organism increases in virulence. This can be seen in some outbreaks in which disease can be traced from individual animals to other members of the same group and then to other groups (Andrews, 1976).

Signs (see p. 921)

The peracute form is unusual but results in sudden death with no premonitory signs.

In the acute form the animals are dull and inactive with excessive oculo-nasal discharges, which may be mucopurulent. There is usually anorexia although the cattle still drink, and a marked fever (40–41°C, 104–106°F). There is rapid (40+/minute), shallow breathing and a soft, productive cough, which tends to increase with exercise. On auscultation there are bronchial sounds over the anterior and ventral parts of the lungs, which become louder as the condition continues. In some cases squeaks and high-pitched sounds are heard, together with a pleuritic rub. Later signs can include dyspnoea with marked abdominal breathing and an expiratory grunt. Diarrhoea occurs in a few animals. There is usually a favourable response to therapy.

Necropsy

Death is usually the result of anoxia and toxæmia although occasionally in young cattle there is septicaemia. Usually, over one-third of the lung shows marked consolidation and the ventral parts of the apical and cardiac lobes are most involved. Initially, there is lung congestion and then hepatitis with exudate and, in some animals, emphysema. Bronchitis and bronchiolitis are usually catarrhal, often with serofibrinous pleurisy and a fibrinous pericarditis. There is usually much pleural effusion.

Diagnosis

This depends on the history of age, recent movement, weaning or housing. The signs also help with severe respiratory signs involving the anteroventral parts of the lungs and pyrexia. Post-mortem findings of lung consolidation and pleurisy are present, and impression smears show bipolar staining organisms with methylene blue. *Mannheimia haemolytica* or *P. multocida* may be isolated from nasal swabs in live animals or lungs at post-mortem and their antibiotic sensitivity determined. Serology for antibody rise can be undertaken, as also can haematology but often the findings are variable.

Differential diagnosis

Differential diagnosis includes enzootic pneumonia (see p. 242) but this usually occurs in younger calves with a different history. Infectious bovine rhinotracheitis (see p. 289) usually shows mainly upper respiratory signs and a conjunctivitis. Fog fever (see p. 866) is mainly apparent in older cattle at grass after a pasture move in the autumn. Parasitic bronchitis (see p. 272) is present in cattle following grazing. Acute bronchopneumonia would be almost identical except for bacteriological isolation. Contagious bovine pleuropneumonia is severe in all age groups of cattle and the affected animals suffer severe pain and toxæmia with a high mortality (see p. 868).

Treatment

Therapy for shipping fever is given in Table 20.1. Treatment should begin early. Most cattle will usually show some improvement within one to three days of initiating treatment. Complete recovery may take four to seven days. Where severe outbreaks occur it may occasionally be necessary to use mass medication by water as most ill cattle still drink well. Anti-inflammatory agents are often useful in promoting a speedy recovery.

Prevention and control

Although the disease of transit fever is sporadic, many of the conditions that predispose to the problem can be defined. This should mean that methods of prevention should be relatively easy to institute. Ideally, the calves would be weaned at least two weeks prior to leaving the farm of birth (Andrews, 1976). They would be introduced to the type of feed to be provided on the rearing farm. In addition, they would be batched in groups that would go direct from the farm of birth to the rearing farm. In reality this does not happen as the farmer pro-

ducing the calves hopes that by selling them at market he will obtain a better price than by selling direct. In addition, the first farmer will be little concerned about the subsequent disease status of his calves once they have left his farm for sale. This makes the possibility of vaccination prior to movement difficult.

As cattle go through markets, disease prevention tends not to be practised because many of the factors enhancing the likelihood of a disease outbreak are outside the control of the purchasing beef rearers. Thus they cannot control the time before moving, the transport of the animals from the farm of origin, their mixing

Table 20.1 Therapy for shipping fever.

| Drug | Method of administration | Dose | | Duration |
|----------------------------------|--------------------------|------------------|------------------|----------------------------|
| | | (mg/kg) | (mg/lb) | |
| Amoxycillin trihydrate | s.c., i.m. | 7 | 3 | Daily for 3–5 days |
| Ampicillin trihydrate | s.c., i.m. | 5–10 | 2.5–5 | Daily for 3 days |
| Baquiloprim and sulphadimidine | oral | 4–8 | 2–4 | Once or repeat |
| | | 36–72 | 18–36 | after 48 hours |
| Cefquinome | i.m. | 1 | 0.5 | Daily for 3–5 days |
| Ceftiofur | i.m. | 1.1 | 0.5 | Daily for 3–5 days |
| Chloramphenicol (some countries) | i.m. | 10 | 5 | 3–4 times daily for 3 days |
| Danofloxacin | i.v., i.m. | 1.25 | 0.6 | Daily for 3–5 days |
| Enrofloxacin | s.c. | 2.5 | 1.25 | Daily for 3 days |
| | s.c. | 7.5 | 3.75 | Once |
| Erythromycin | i.v., i.m. | 5 | 2.5 | Daily for 3 days |
| Florfenicol | i.m. | 20 | 10 | 2 (48 hours apart) |
| | s.c. | 40 | 20 | Once |
| Marbofloxacin | i.v., s.c., i.m. | 2 | 1 | Daily for 3–5 days |
| Oxytetracycline | i.v., s.c., i.m. | 10 | 5 | Daily for 3 days |
| Oxytetracycline (long-acting) | i.m. | 20 | 10 | Usually once |
| Penicillin/dihydrostreptomycin | i.m. | (20–30 000iu/kg) | (10–15 000iu/lb) | Daily for 3 days |
| | | 20 | 10 | |
| Penicillin (long-acting) | | | | |
| benzathine | i.m. | 5 | 2.5 | Usually once |
| procaine | i.m. | 6 | 3 | Daily for 3–5 days |
| Spectinomycin | i.v., i.m. | 10–20 | 5–10 | Daily for 3–4 days |
| Spiramycin | i.m. | 20 | 10 | Daily for 2–3 days |
| Sulphadimidine | i.v., s.c., oral | 150 | 75 | Daily for 3 days |
| Tilmicosin | s.c. | 10 | 5 | Usually once |
| Trimethoprim and sulphadiazine | i.m. | 4 | 2 | Daily for 3–5 days |
| | | 20 | 10 | |
| Trimethoprim and sulphadoxine | i.v., i.m. | 3 | 1.5 | Daily for 3–5 days |
| | | 12.5 | 6 | |
| Tylosin | i.m. | 4–10 | 2–5 | Daily for 3–5 days |
| Mass medication | | | | |
| Oxytetracycline | oral | 5 | 2.5 | Daily for 5 days |
| Sulphamidine | oral | 100 | 50 | Daily for 5–7 days |
| Trimethoprim and sulphadiazine | oral | 25 | 12.5 | Daily for 5–7 days |
| Tylosin | oral | | | Daily for 5 days |

All animals should be provided with good-quality feed and adequate ventilation. Corticosteroids, e.g. betamethasone, dexamethasone, are often found to help in reducing the level of exudation. NSAIDs may be useful in reducing inflammation, and *Mannheimia* antisera may also be helpful.

with other cattle or the conditions present at market. Likewise they will probably have little direct say as to how the animals are transported or their mixing with other groups before their entry to the rearing farm. It is only once the cattle reach the rearers that control measures can be undertaken. Obviously, they can ensure that the animals are kept in as satisfactory an environment as possible and are only lightly stocked. This is best done by having the animals outside but this is resisted by most farmers because of the inconvenience and extra labour required. The new ration for the cattle can also be introduced slowly.

The problem is worse in North America where calves often travel vast distances. Here various preconditioning programmes are undertaken. It is advised that calves should be fed prior to weaning and kept in the same place once the dams are removed. Following weaning, regular checking of the calves several times a day should be practised. When animals are travelling they should be given adequate periods of rest and offered feed and water. They should also be well bedded during transit. Some farmers inject multivitamin preparations before moving and vaccines can be used, including those against *Mannheimia* and PI₃ virus.

In many countries antibiotics are used following the move. These have given variable results mainly due to predicting when injections should be undertaken. This is because most problems occur about seven to ten days after entry to the feedlot or farm. When used, it is probably best to give long-acting preparations and initiate therapy when the first animals show disease. Use of antibiotic medication in the feed or water is a common practice in North America and while it appears to reduce mortality it has no effect on morbidity.

Vaccination

If it is considered that *M. haemolytica* and at times *P. multocida* form an important part of the disease syndrome of transit fever then it might be possible to obtain some protection by vaccination. Various vaccines are present in Europe but currently only three are available in Britain.

In North America various *Pasteurella* bacterins and viral vaccines have been used to assist with the control of transit fever. Their efficacy appears to be low and literature reviews suggest that at present there is little evidence to show the efficacy of such vaccines under feedlot conditions (Myers, 1984).

Recently in North America several new vaccines have become available. One of these is a *M. haemolytica* vaccine/bacterial extract. This has been shown to be effective to controlled challenge provided two doses of vaccine have been administered prior to challenge (Sherwen & Wilkie, 1988). Response in a field trial has

however shown only a slight decrease in morbidity of disease, with slight improvement in relapse rates and response to treatment (Bateman, 1988; Jim *et al.*, 1988).

Infectious bovine rhinotracheitis (IBR)

Aetiology

Infectious bovine rhinotracheitis (IBR) is a highly infectious and contagious disease of cattle. It is caused by a virus known as bovine herpes virus 1 (BHV 1). It is generally considered that there are several strains of the virus, although often the differences between the strains are not easily shown in the laboratory. The disease is seen in North America, Europe and Africa. It is considered that the outbreak of severe respiratory disease that occurred in Great Britain in the mid-1970s was due to a new strain being imported. Several European countries are undertaking eradication campaigns, many of which are progressing satisfactorily. They often involve initial vaccination with marker vaccines and then blood testing, and movement restrictions until the disease is no longer present.

While the disease is primarily one of cattle, it can also infect deer, goats and pigs. The main sources of infection between animals are nasal discharge (or eye discharge), when it is affecting the respiratory system, and vaginal or preputial discharges, semen, or the fluids and tissues of the fetus when the infection involves the reproductive tract (see p. 579).

Epidemiology

In most cases of respiratory infection disease is spread by aerosol. The genital form of the disease is contracted venereally. As respiratory infection is spread via the air, it can spread by direct contact between the animals or where the cattle are in the same air space, i.e. there is air contact. This can only be avoided by ensuring the walls extend from floor to ceiling and there is no contact with other animals either at the front of the pens or with other groups on either side. However, generally there is a need for close sustained contact between groups. This is why disease is often slow to spread within and between groups. It often takes two to five weeks to spread in a group. However, unexplained outbreaks of IBR do occur on isolated farms.

Latent infection: There is a problem with BHV 1 in that it is able to become a latent infection. Thus once an animal is infected with a strain of the virus or vaccinated with a live viral vaccine, the virus may remain in the animal for the rest of its life without it showing any signs of illness. The site of latency is arguable but the virus

can be found in the trigeminal nerve of clinically normal cattle. However, if the animal is stressed at all, such as when moved or calving, or becomes ill, the virus may be shed. Shedding can also occur in bulls when mating. This shedding may be, but is often not, accompanied by any signs of disease. Corticosteroid injections may promote virus shedding. The level of this latent infection is variable but can be up to 10 per cent of clinically normal animals. In addition, while most of these cattle will show antibody levels to the BHV 1 virus, some do not. Thus all cattle in herds where disease occurs have the capacity to spread disease even when there are no clinical signs of disease present in the herd. The only way of knowing whether or not disease is present is to look at the results of milk or blood tests. If a blood test shows an antibody titre (positive response) to BHV 1 in cattle other than calves it means that the animal(s) have been exposed to infection and could possibly be carriers. If a blood test from an animal is negative it generally means that the animal is unlikely to have been exposed to infection, but it does not completely rule out the possibility that the animal is a latent carrier of disease. Thus tests on individual animals are of limited significance; however, on a herd basis repeated negative tests indicate that it is highly unlikely infection is present. When tests show several animals with antibody levels in the herd then infection is present. The calf that receives colostrum from its infected mother will also show a positive antibody level to the test although not necessarily being infected. The antibody provided from the colostrum will usually remain for one to six months, depending on the amount received from the mother.

Incubation period: The incubation period for the disease is very variable. Experimentally, it usually takes three to seven days. However, in most beef units disease occurs about 10–20 days after introduction of infected or susceptible animals. Longer incubation periods do occur. This is quite likely when it is considered that latent carriers may not be shedding virus at a particular time.

Signs

Respiratory disease: This disease is the most common form. It is usually seen in cattle over six months old but can occur at a younger age. The signs vary considerably but typically they tend to be worst in animals from about six months to two years old.

(1) Mild disease. This is just a conjunctivitis, i.e. slight reddening to the lining of the eye and eyelids with some discharge, usually watery and clear (see p. 921). This often occurs when the disease strain is mild or degree of infection is low, or the animal is resistant.

(2) Subacute disease. This is commonly seen in adult cattle and often is of only short duration. There is a marked rise in temperature lasting only a day or two (40°C , 104°F). Often there is a marked drop in milk yield. Again the lining of the eyes is reddened with discharge and this also involves reddening of the lining of the nose with nasal discharge. The animals will salivate and there may be a short, expressive cough. Breathing is rapid and shallow. The animals recover in 10 to 14 days.

(3) Acute disease. The signs are as in the subacute form but the temperature tends to be higher ($40\text{--}41^{\circ}\text{C}$, $104\text{--}106^{\circ}\text{F}$). These signs are particularly present in growing cattle between six months and two years old. The respiratory signs are more likely to include a cough and there is some respiratory distress. The discharge from eyes and nose tends to become profuse, yellow, thick and purulent. The lining of the nose may show grey areas, which consist of dead tissues that smell and are shed. The signs tend to last a lot longer before recovery occurs.

(4) Peracute disease. The animals develop very high temperatures (42°C , 108°F) with eye and nasal discharge, respiratory distress, cough and then death in about 24 hours.

Some cattle may die owing to complications and this is particularly so in the six month to two year age group. Here mortality may reach 10 per cent or more. However, it is usually only about 1 per cent. Some cattle keep a stertor (snoring breathing) for many months. Some become 'puffers' with bouts of respiratory signs including distress when breathing, loss of appetite and cough. These usually have a secondary bronchopneumonia and die in weeks or months after losing condition. Often they become recumbent before death.

Characteristically, there is a sudden outbreak of disease involving the respiratory tract. This will initially involve the group of cattle to which infection has been introduced. It will then tend to spread round all the other groups and ages of cattle. This can often take a few weeks or many months, dependent on the strain of virus, the level of infection and the degree of exposure to infection of each group. Characteristically, an outbreak in a group reaches a peak at about two or three weeks after its start and is over between the fourth and sixth week.

Reproductive form: In most cases the reproductive and respiratory forms are not seen together.

(1) Infectious pustular vulvovaginitis. This is an infection of the vulva and vagina often lasting several weeks. It results in the discharge of pus from the vulva, usually in small quantities. There is reddening of the lining and

pustule presence. In some cases infection causes irritation in the vagina resulting in frequent urination and possibly increased straining (see p. 628).

(2) Infectious bovine penoposthitis. Bulls show a small amount of purulent discharge from the prepuce. The surface of the penis and prepuce may be reddened with haemorrhages and small necrotic areas.

(3) Endometritis. Infection of the uterus, with discharge, poor conception rates and short returns to oestrus, can occur if semen is infected.

(4) Abortion (see p. 579). This is becoming increasingly common and occurs some weeks or months after the animal is infected. Abortion is usually at six to eight months of pregnancy and often the placenta is retained following abortion. In some cases of infection calves are born weak at the normal time.

Generalized/alimentary form: This is seen in young newborn calves and is recorded mainly in America. It occurs when calves receive little or no immunity in the colostrum and are then subjected to infection. The animals show a severe temperature reaction, they do not eat and they salivate. The lining of the nose is red. The eyes may show a conjunctivitis. In addition, the lining of the mouth and the soft palate (at the back of the throat) are reddened with mucus present. The opening to the trachea, i.e. the pharynx, is also reddened with much discharge present. There is usually severe respiratory distress with a bronchopneumonia. Some calves show severe diarrhoea and dehydration.

Central nervous system/encephalitic form: This is seen in calves under six months old and involves brain signs. The animals show incoordination with bouts of excitement and depression. In other cases there are convulsions, bellowing and blindness with salivation. This nervous form is rare.

Other infections: Reports of infections of the udder and intestinal tract have been made. However, these are rarely the only systems affected.

Necropsy

Respiratory form: In uncomplicated cases, lesions are restricted to the upper respiratory tract terminating at the upper bronchi. Inflammation of the muzzle and the nasal cavities varies from some congestion and petechiation with mucoid exudate, to a fibrinopurulent exudate with necrosis of the nasal mucous membranes. The submandibular and retropharyngeal lymph nodes tend to be swollen and oedematous. There is a laryngotracheobronchitis, which varies from a mild congestion of the

mucous membranes with a mucoid discharge to large areas being covered by a necrotic layer of exudate (Pirie, 1979). In some cases there is pulmonary emphysema and secondary exudative bronchopneumonia, which may be purulent or necrotizing. Histologically, the mucous membranes show acute catarrhal inflammation and in some cases the epithelium and larynx tend to be infiltrated with neutrophils, lymphocytes, plasma cells and macrophages. In naturally occurring infections, inclusion bodies appear to be absent.

Abortion: Aborted fetuses often show marked autolysis and focal necrotic hepatitis.

Alimentary form: Epithelial necrosis of the turbinates, oesophagus, rumen and abomasum. Inclusion bodies are often evident in the surviving epithelium.

Nervous form: A non-suppurative encephalitis occurs particularly affecting the cerebral cortex and internal capsule.

Diagnosis

This will depend on the type but in the alimentary form it will depend on a history of IBR in the herd with virus present in the faeces or nasal swabs and possible necrotic areas on the turbinates. The nervous form is difficult to differentiate except that there is probably an IBR outbreak in the herd. At post-mortem examination the turbinates may show necrotic lesions.

In the respiratory form the history is that a new animal or group has entered the herd. In most cases several animals will be affected and besides varying degrees of respiratory signs there will usually be a conjunctivitis with copious, initially serous, ocular discharge. There may be necrosis of the nasal mucosa but this is absent in the mouth. The virus can be isolated in upper nasal or ocular swabs and is detected by fluorescent antibody staining. Otherwise paired blood samples will show a rise in titre to the enzyme-linked immunosorbent assay (ELISA) test. Other tests used include the serum neutralization test, indirect haemagglutination test, complement fixation test and virus neutralization test. Bulk milk testing will indicate the status of a dairy herd.

Treatment

There is a considerable divergence of opinion as to whether or not to use antibiotic treatment. If the disease appears to be uncomplicated, and this is unusual, then there would appear to be little point in therapy. If, however, as in most cases, there is secondary lung involvement, then therapy is justified. At the

start of an outbreak all cases should be isolated as soon as possible because although it may not stop spread of the disease, the first animals are often clinically the worst affected. If antimicrobial agents are to be used, all ill calves should be treated for three to five days with any one of a number of drugs, including penicillin and streptomycin, oxytetracycline, ampicillin, trimethoprim and sulphadiazine, sulphadimidine, sulphamethoxypyridazine and sulphapyrazole. The animal should be given good, wholesome feed and it should be encouraged to eat and drink. Some farmers have vaccinated their calves with live vaccine after the start of an outbreak, with good results, but to be successful infection must not have become established. It should be remembered that for effective protection, vaccines should be introduced before the onset of infection. Several compounds have been found that are active against herpes viruses. However, many are toxic, but one drug, acyclovir, has been shown to be safe and may in the future be tried in animals.

Control

Management: It is best to keep a closed herd. However, in America, and also Britain, infection has been found in closed herds. Any new animal entering a known uninfected herd should be blood tested prior to entry. If the test is negative the animal should be isolated for a month and then retested. The use of corticosteroids may allow detection of virus in swabs of carrier animals. If the tests are all negative the animal can be allowed to enter the herd. The risks then of the introduction of infection are small. If the animal suffers a respiratory problem while in isolation the second test should not be until two or three weeks after the end of the episode. Some farmers may need to go to these lengths to keep their pedigree herds free from disease, because many European countries will not accept exports unless they are shown to have a negative titre for IBR. The same conditions at present govern the entry of bulls to some artificial insemination (AI) centres.

Vaccination (see p. 1010): An inactivated multicomponent vaccine has been available for a long time. The vaccine could be given as doses two to four weeks apart with a third injection at 10–12 weeks old. Its efficacy has at times been questioned. Subsequently, live IBR vaccines have become available. They are given by intranasal inoculation or injection and should be administered 24–48 hours after entry to the farm. Ideally, calves should be vaccinated 10 days prior to any movement. A gene-depleted live vaccine is available in some countries and allows control of disease. The immunity produced allows differentiation from that produced by the wild strain. This means the vaccination

can be used in an IBR eradication campaign. Live vaccines, as other vaccines, can present a possible danger if contaminated with other pathogens, such as BVDV.

Beef calves can be vaccinated about two weeks or so before they are weaned. One vaccine is temperature sensitive and so only replicates in the upper parts of the respiratory tract. However, the vaccine can still produce circulating antibody levels in some cattle, which will preclude their export or their sale to AI centres. Another vaccine does replicate in organs other than the lungs and produces a good systemic immunity. The vaccines provide effective immunity but they do allow the replication and re-excretion of the IBR virus, which can thus spread infection to non-vaccinated animals.

Several countries within the EU have successfully eradicated BHVI (IBR), including Denmark, Finland and Sweden. An EU-approved national compulsory eradication scheme is being undertaken in Austria. Control programmes are being pursued in the Netherlands, Belgium, France and Germany. A programme for the monitoring, screening, eradication and accreditation of freedom from IBR is being undertaken in the UK by Cattle Health Certification Standards (CHeCS).

| Iodine disorders | 301 |
| Selenium disorders | 302 |
| Manganese and zinc disorders | 305 |

Introduction

The full impact that trace element disorders can have on the health of cattle was seen when Europeans attempted to carry their methods of animal production to the New World and to the Antipodes. The geologically young soils bordering Australia, and forming the Florida peninsula and the interior of New Zealand's North Island, were a graveyard for many an animal until the therapeutic effect of newly discovered essential trace elements became known. Crop and pasture growth was also limited by some of the deficiencies but these were the more easily diagnosed because they produced characteristic foliar abnormalities. The animal's needs were more difficult to delineate because they lacked clinical definition and persisted where the more modest needs of the plant had been met. Since those pioneering days, trace element disorders have been described in many areas of the world and they continue to appear when new methods of production are introduced, but it is important to keep them in perspective.

Differential diagnosis

Trace element disorders carry more than their fair share of blame for poor cattle performance, due to the non-specificity of most clinical signs, the pressures on practitioners to offer a quick diagnosis and the alacrity with which clients accept a diagnosis that may seem to exonerate them from blame. Figure 21.1 presents a scheme for differential diagnosis of some common problems. Of the three main lines of investigation shown, trace elements are only part of the *least probable* explanation, the

most common being malnutrition, which is likely to be a whole herd problem. A preliminary check must be made of the quantity and quality of available feeds (Sinclair & Suttle, 2001). Trace element disorders usually afflict only a minority of the herd but a preliminary 'audit' of the likely mineral inputs and needs may narrow the range of possible culprits (Suttle & Sinclair, 2000). Responses to a broad mix of micronutrients would confirm this line of investigation. Depending on the history of the farm or area, it may be beneficial to attempt an earlier definitive diagnosis by using a specific trace element supplement, but proof of responsiveness amongst an affected minority may require unconventional statistical techniques which take into account initial variation in performance (Suttle, 2000). There may be cross-over between lines of investigation: correction of a gut parasite problem might improve trace element status, while improving the major nutrient supply of a herd (by improving ration digestibility) may lower status and increase the risk of trace element disorders. Seasonal and annual variations in incidence mean that it will always be necessary to review the need for any trace element intervention from time to time. Overall, following such a scheme should improve the precision of diagnoses.

Definitions

Four terms will occur frequently in descriptions of the sequence of events that occur when cattle are deprived of essential trace elements, and these require definition:

- *Depletion*: the reduction of body stores of the element.
- *Deficiency*: the presence of subnormal concentrations of the element in blood or tissues.
- *Disorder*: the malfunction of trace element-dependent body processes (subclinical disorder).
- *Disease*: the presence of visible, clinical abnormalities.

They are particularly useful when describing the trace element status of cattle biochemically, and avoid the confusion caused by using the one word 'deficiency' to describe all four stages, and as a 'tag' for interpret-

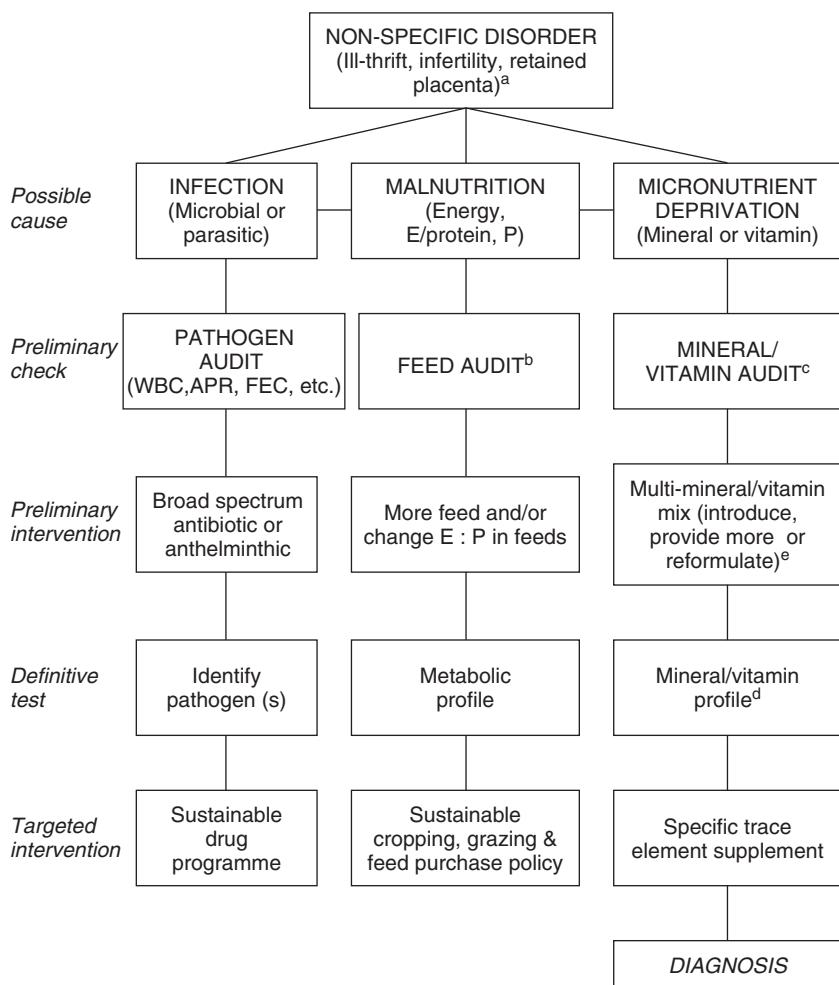

Fig. 21.1 Scheme for the differential diagnosis of trace element disorders with non-specific signs; proceed vertically with a given line of investigation only while test results are positive. WBC = white blood cell count; APR = acute phase proteins; FEC = faecal egg count.

^a Firstly, rule out 'exotic' (e.g. plant, agrochemical or industrial poisons) or common (poor oestrous detection, large calf) factors.

^b See Suttle (2002) for fuller details.

^c See Suttle & Sinclair (2000) for fuller details.

^d See Table 21.1 for best indices of trace element status.

^e Some untreated animals must be left to prove efficacy and allow specific follow-up tests to be made.

ing indices of mineral status which rarely reflect onset of disorder or disease. Throughout this chapter, use will be made of 'marginal bands' for diagnostic criteria (Table 21.1), which reflect the uncertainty of detecting the onset of health-limiting conditions. The following descriptions of specific disorders concentrate on the more commonly encountered deficiencies of cobalt (Co), copper (Cu), iodine (I) and selenium (Se).

Cobalt disorders

Aetiology

The only known functions of Co arise from its place at the centre of the corrin ring of two cobalamin (Cbl)

molecules, methyl-(Me) and adenosyl-(Ado) Cbl, which have contrasting functions in the body. MeCbl acts as a coenzyme to methionine synthetase and is linked to folate metabolism, through the use of methyltetrahydrofolate as the methyl group donor. Deficiencies of this coenzyme can theoretically impair methionine synthesis and the bioavailability of folate and cause formiminoglutamic acid (FIGLU) to appear in urine. AdoCbl enables propionate to be used for gluconeogenesis via succinate and the tricarboxylic acid (TCA) cycle, acting as coenzyme to methylmalonyl-CoA isomerase: insufficiency causes methylmalonic acid (MMA) to accumulate.

The anorexia and anaemia that are successive debilitating consequences of deprivation may reflect the *dysfunction* of AdoCbl and/or MeCbl (Underwood

Table 21.1 Marginal bands for commonly used biochemical indices of micronutrient status in the diet, serum or tissues of cattle: mean values falling within bands indicate a possibility of benefit from trace element supplementation; the more extreme the value and the more parameters affected, the greater the possibility becomes; values below (above for Fe:Cu and thyroid weight) bands indicate a probable benefit.

| | Cu | Co or vit B ₁₂ | I | Mn | Se | Zn |
|----------------------------------|-----------------------|------------------------------|-----------------------------|--------------------|------------------------|-----------------------|
| Diet ^a (mg/kg DM) | 5–15 | 0.04–0.06 | 0.08–0.3 | 10–15 | 0.03–0.06 | 10–20 |
| Serum ^b (μmol/l) | 3–8 | 0.25–0.5 × 10 ^{-3M} | 0.08–0.20 | 0.09–0.11 | 0.13–0.26 ^B | 6–9 |
| Tissue ^c (μmol/kg DM) | 150–300 ^{nL} | 0.2–0.4 ^L | 9.5–15.8 × 10 ^{3T} | 11–13 ^H | 0.6–1.3 ^{nL} | 765–1070 ^R |

^a Higher values are appropriate for: antagonist-containing diets (for Cu, Cu:Mo < 1–3, Fe:Cu > 50–100; Cu:sulphur < 0.0025); for I, with high goitrogen intake); for low agonist intake (e.g. for Se, low vitamin E intakes); for all elements when the digestibility of the ration is high.

^b The ranges are for adults; newborns often have different norms (e.g. 3–9 μmol/l then being adequate for serum Cu).

^c Superscript letters indicate sample origin: B = whole blood, H = heart, L = liver, M = milk, R = rib, T = thyroid; for the latter, an organ weight range of 0.3–0.8 g FW/kg LW is marginal; for the newborn (n), ranges may again differ, L Se being up to 3× that in the adult and L Cu 7–10× higher. Divide values by 3.3 (L) or 4.0 (H,T) for approximate fresh weight basis.

Conversion from μmolar to µg units requires multiplication by: 63.5 for Cu, 58.9 for Co, 126.9 for I, 54.9 for Mn, 79.0 for Se, 65.4 for Zn and 1355 for B₁₂; division by these factors converts mg to mmol units.

& Suttle, 1999). Loss of appetite was initially linked to Adocbl dysfunction and increased blood propionate concentrations, but disturbances of rumen fermentation (McDonald & Suttle, 1986; Kennedy *et al.*, 1991) and the accumulation of other metabolites (e.g. MMA, Rice *et al.*, 1989; succinate, Kennedy *et al.*, 1991; homocysteine, Stangl *et al.*, 2000) may also affect appetite. Loss of appetite would compound the effect of a diminishing supply of the glucose precursor, propionate. The anaemia of Co deficiency may reflect the role of MeCbl in DNA synthesis and red cell maturation.

The basic cause of cobalt-responsive disorders is a simple nutritional deficit that can be traced to impoverished soils in which crops or pastures have grown. Interactions can occur in the soil that leave most of the Co adsorbed in unavailable forms onto manganese oxides, particularly at alkaline soil pH with soil Mn > 1 g/kg (Suttle, 2000). If extraction with 0.43 M acetic acid yields < 0.3 mg Co/kg air-dry soil, deficiencies may develop. The diet should contain > 0.05 mg Co/kg dry matter (DM) (Underwood & Suttle, 1999). Interactions in the animal have been postulated because Co can be incorporated into various analogues of B₁₂ by the rumen microbes. There is thus competition for Co in the rumen between different forms of the vitamin. Cobalamins are selectively absorbed in association with intrinsic factor but if analogues find their way into the bloodstream or tissues, they might complicate the assessment of vitamin B₁₂ status and compromise functions of the vitamin. However, protective mechanisms would probably have evolved, if they are needed, against analogues so copiously produced in the rumen.

Clinical signs

All ruminants require a dietary supply of Co for the synthesis of the essential vitamin B₁₂ by rumen microorganisms. Cattle are less susceptible to a lack of Co than sheep, but when they succumb, they develop essentially the same clinical abnormalities in the same order: anorexia, loss of body condition, muscular wasting and finally an anaemia that is both normochromic and normocytic. In the early stages of the disease, the hair coat can become rough and discoloured (Judson *et al.*, 1982) and may be repeatedly licked. Appetite may become depraved (pica). Eventually, the skin becomes thin and fragile and the mucous membranes pallid. The clinical picture is thus one of a ‘pinning’ or ‘wasting’ disease, indistinguishable from many other causes of ill-thrift. Cobalt-deprived cattle may be more susceptible to infections than normal cattle (MacPherson *et al.*, 1987a).

There is a neurological disease that affects cattle in Australia when they graze *Phalaris tuberosa* pastures called ‘Phalaris staggers’; it can be prevented by Co dosage but not by administration of vitamin B₁₂ and is, therefore, not a classical ‘deficiency’ syndrome. The response to Co may arise through the neutralization of fungal neurotoxins by the element (Underwood & Suttle, 1999).

Necropsy

At necropsy, cattle suffering from Co deprivation show the hallmarks of starvation. There is little body fat except occasionally in the liver, which may be pale and friable due to fatty infiltration; this condition is,

however, far less common in cattle than in lambs or goat kids. In severely affected, anaemic individuals, bone marrow hypoplasia and splenic haemosiderosis will be found.

Diagnosis

Cobalt-responsive *disorders* are best diagnosed through responses in growth or health to Co or B₁₂ supplementation in controlled trials (e.g. Duncan *et al.*, 1986). Biochemical confirmation of subclinical or clinical *disease* from the assay of plasma B₁₂ is more difficult in cattle than in sheep. Plasma B₁₂ concentrations appear to respond feebly to Co supplementation in cattle. Oral doses of Co ten times higher on a body weight basis than those that increase plasma B₁₂ in sheep were apparently ineffective in cattle (N.F. Suttle & J. Brebner, unpublished data). High plasma B₁₂ concentrations (>500 ng/l) are rarely found in cattle yet they are commonplace in sheep and values have often fallen to exceedingly low levels (<100 ng/l, e.g. Reid & McQueen, 1985) before cattle failed to thrive, though there are exceptions (e.g. Duncan *et al.*, 1986). The assay of B₁₂ by the more favoured radioisotope dilution (RID) method is susceptible to interference from non-specific binders (Millar *et al.*, 1984; Schulz, 1987a, b); these include the transport proteins for B₁₂ in bovine plasma (transcobalamins), which show quantitative differences from man (Schulz, 1987a) as well as seasonal anomalies (Millar *et al.*, 1984). Since binding affects the recovery of B₁₂ after deproteinization of plasma or serum, it can impair assay by both microbiological and RID methods. The results of assays of B₁₂ in bovine plasma can vary substantially between laboratories (Schulz, 1987b) and assays of the analogue component by difference, using specific and non-specific binders, are particularly prone to error. Extraction of the vitamin at alkaline pH overcomes the problem and modified assay kits are now available (Stangl *et al.*, 2000).

Assays of vitamin B₁₂ in skimmed milk and liver are far more reliable than those in plasma and values for milk and liver from the same individual correlate reasonably well with each other, particularly at low levels that have diagnostic significance; milk B₁₂ < 0.5 nmol (678 ng/l) indicates a possibility of ill health (Judson *et al.*, 1997b) (Table 21.1). By contrast, the relationship between plasma and liver B₁₂ values is poor, particularly at low levels (Judson *et al.*, 1997a). Diagnostic thresholds for liver B₁₂ in sheep have long been extrapolated to cattle; thus values <0.10 mg/kg fresh liver have been taken to indicate moderate to severe *deficiency* and values >0.19 mg (>140 pmol)/kg have been regarded as normal. There is a curvilinear relationship between Co and vitamin B₁₂ concentrations in bovine liver which

shows better fit at low than at high levels (Mitsiouli *et al.*, 1995; Suttle, 1995); values between 0.06 and 0.08 mg Co/kg DM can be regarded as 'marginal' (Underwood & Suttle, 1999).

The diagnosis of Co disorders from the presence of abnormal metabolites in the blood and urine was developed in sheep and non-ruminants and extended to cattle. Quirk & Norton (1988) found that heifers grazing pastures low in Co (0.036 mg/kg DM) remained healthy and excreted no MMA or FIGLU in urine, despite low plasma B₁₂ concentrations (96 pg/ml). After calving, milk yield was unaffected but very low B₁₂ concentrations in the milk (42–86 ng or 31–63 pmol/l) caused depletion of plasma B₁₂ in their calves (59–74 ng/l) and growth retardation, which was accompanied by increased urinary excretion of FIGLU. They concluded that MMA was less reliable than FIGLU as an index of *dysfunction* but their method for MMA was relatively insensitive (30 µmol/l). Assay of plasma MMA has been advanced as a measure of functional B₁₂ status in sheep, with concentrations >5 µmol/l taken to be abnormal (Rice *et al.*, 1987); as yet plasma MMA has not been tested for the confirmation of Co dysfunction in cattle but a marginal band of 5–15 µmol/l may well prove useful. Increases in plasma homocysteine are found after prolonged Co deprivation (Stangl *et al.*, 2000).

Treatment or prevention

Although there are clearly differences in B₁₂ metabolism between cattle and sheep, there is no evidence that these affect the methods of treating and preventing disorders. The injection of B₁₂ as cyano- or hydroxycobalamin, 2–6 mg/50 kg liveweight, provides protection for several weeks, even though responses in plasma B₁₂ soon dissipate. Slow-release, injectable preparations of B₁₂ are being developed in the Antipodes.

Heavy cobalt oxide pellets given orally, in pairs or singly with a 'grinder', improve the B₁₂ status of growing and adult cattle for several months (Judson *et al.*, 1981; Quirk & Norton, 1988), even when a change in formulation halves their Co content (Judson *et al.*, 1997b); the soluble glass bolus can also give sustained protection (Allen *et al.*, 1985). The effectiveness of infrequent oral doses of Co in anthelmintics has not been tested but weekly doses of 35–70 mg Co without anthelmintic are said to be effective (Underwood & Suttle, 1999). Cobalt supplementation via the drinking water can be practised where there is a piped water supply (MacPherson, 1983). Use of 'protected' or chelated forms for oral use is contraindicated because Co must be given in forms which can be rapidly incorporated into vitamin B₁₂ by rumen microbes. Evidence that volatile fatty acid (VFA) production by rumen microbes is influenced by

Co deficiency (McDonald & Suttle, 1986; Rice *et al.*, 1989; Kennedy *et al.*, 1991) suggests a possible advantage for the oral route over the injection route, since only the former meets the needs of the microbes for B₁₂. Comparisons between methods have rarely been conducted but one at least showed no advantage in calf growth for oral Co versus injected B₁₂ (Judson *et al.*, 1981).

Administration of Co on a group basis via licks containing 0.1 per cent Co or mineral mixes containing up to 0.4 per cent Co may provide an inexpensive means of prevention but could not be guaranteed to protect all individuals. The best long-term strategy on certain soil types will be to apply Co salts, such as hydrated CoSO₄, at 2–3 kg/ha, every three to four years. Responses may, however, be short-lived on sandy soils and negligible on calcareous or recently limed soils containing >1 g Mn/kg DM because most of the Co becomes 'fixed' in the soil.

There is virtually no risk of overdosing with cobalt, but this should not be used as an excuse to overfeed Co to animals whose capacity to synthesize and absorb B₁₂ is strictly limited.

Copper disorders (see also Chapter 18)

Aetiology (see p. 254)

Most Cu-responsive disorders in cattle are induced: they are induced in the rumen where the anaerobic degradation of sulphur(S)-rich, fibrous feeds leaves little of the ingested Cu in a soluble form. After weaning, less than 10 per cent of the total Cu input is absorbed during passage down the gastrointestinal tract and the percentage can be reduced to as little as 1–2 per cent by small increments in dietary Mo (Underwood & Suttle, 1999). Again it is transformations in the rumen that are pivotal: extrapolating from sheep, it appears that the progressive substitution of S²⁻ for O²⁻ in molybdate creates thiomolybdates, which complex Cu and bind it to the solid phase. Surplus trithiomolybdate (MoOS₃) is absorbable and capable of changing the distribution of Cu in the blood and tissues (Underwood & Suttle, 1999). Just how important the systemic effects of thiomolybdates are under normal grazing conditions has yet to be determined. The 'tell-tale' appearance of abnormal plasma fractions, such as TCA-insoluble Cu, has been restricted to experimental situations, involving high levels of dietary Mo (35 mg/kg DM; Wang *et al.*, 1988), and they may serve as slow release pools of Cu in the long term (Underwood & Suttle, 1999).

Most cases of Cu-responsive growth retardation in cattle are associated with abnormally low ratios of Cu:Mo in the herbage (<3.0; Phillippo, 1983) and it has

been suggested that they may reflect direct effects of Mo on the central control of appetite (Phillippo *et al.*, 1987b). It is, however, premature to discount the role of Cu (Suttle, 1988; Underwood & Suttle, 1999) and other factors that influence Cu status should not be ignored. Copper absorption in cattle is as sensitive to Mo inhibition as it is in sheep and the equations derived for grazing sheep to predict Cu absorption (Suttle, 1983b) should give an approximate weighting for cattle. High S intakes from the diet (Suttle, 1983a) or drinking water (Smart *et al.*, 1986) also suppress Cu absorption. Poor Cu absorption, and hence disorders, will therefore be more common on lush, immature, S-rich swards than on brown, mature swards and in wet than in dry seasons. Copper is also absorbed better from hay than from fresh grass of similar S content (Suttle, 1983b). Ensiled grass is a good source of absorbable Cu while S concentrations are low (about 2 g/kg DM), but availability probably falls rapidly as concentrations rise to 3 g/kg DM if cattle share the characteristics of sheep (Suttle, 1983a). High iron (Fe) concentrations also lower Cu status in cattle (Bremner *et al.*, 1987; Phillippo *et al.*, 1987b; Gengelbach *et al.*, 1997), are often raised in spring and autumn pastures and have been implicated in incidents of hypocuprosis (Jarvis & Austin, 1983; McFarlane *et al.*, 1990). There is debate over whether or not the Fe × Cu antagonism requires the presence of moderate amounts of dietary S (Suttle, 1988).

The principal determinants of hypocuprosis in grazing cattle are therefore raised soil Mo, alkaline soil pH (which encourages Mo uptake), sward immaturity, high rainfall (or irrigation), heavy fertilizer N use and high soil ingestion, rather than the Cu content of the soil or herbage, on all but the most impoverished, sandy soils.

Shortage of absorbable Cu leads to (i) rapid depletion of liver stores, (ii) a lowering of caeruloplasmin synthesis and a drop in plasma Cu (i.e. deficiency) and (iii) a reduction in cuproenzyme activities in the erythrocyte and tissues (dysfunction). Although cytochrome oxidase and superoxide dismutase have been the most studied, others such as lysyl oxidase and dopamine hydroxylase will almost certainly follow the non-ruminant pattern in showing disorder (Suttle, 1988). Effects on growth, cardiac function and bone development cannot be attributed to a particular enzyme deficiency with certainty. Even the depigmentation once attributed to diminished tyrosinase activity must be open to other explanations now that it is known to be produced by Co as well as Cu deprivation (Judson *et al.*, 1982). Connective tissue defects, including those in the ligamentum nuchae, are probably due to lysyl oxidase deficiency leading to defective cross-links in elastin. Digestive disturbances may result from disruption of mitochondrial respiration and villous atrophy, but

enhanced inflammatory reactions to gut parasites cannot be ruled out in grazing animals (Underwood & Suttle, 1999).

Clinical signs

The sequence and severity of signs associated with a lack of dietary Cu in cattle (hypocuprosis) depend upon the rate and stage of development at which it occurs. There are no definitive reports of teratogenic or neurological effects, comparable with swayback in sheep (cf. Richards & Edwards, 1986). In the growing calf, loss of hair colour, growth retardation and changes in metatarsal conformation are the earliest signs of abnormality followed by diarrhoea and finally anaemia. Black hair usually turns grey and red/brown hair becomes light brown. The 'foxy brown' discolouration of the Friesian is not attributable to copper deprivation (Mee, 1991). Cardiac hypertrophy has been reported in experimentally depleted calves and this may be an early manifestation of the myocardial degeneration that can cause sudden death after prolonged deficiency in the field (Suttle, 1988). Addition of small amounts of the Cu antagonist, molybdenum (Mo), to the diet (2mg/kg DM) accelerates rather than changes these clinical manifestations of disorder. At much higher Mo concentrations (>10mg/kg DM), animals may develop diarrhoea immediately upon exposure to the antagonist (Suttle, 1988).

Infertility has long been associated with Cu deprivation in cattle but there is little published evidence that deficiency leads to impaired reproduction unless Mo is involved (Phillippo *et al.*, 1982, 1987a). Molybdenum-induced deficiency is associated with delays in the onset of oestrus, impaired conception rate and anoestrus: these abnormalities have yet to be induced experimentally by other antagonists of Cu, such as Fe (Phillippo *et al.*, 1987a). Copper-responsive infertility in cattle given Mo, therefore, may result from the direct or indirect suppression of the release of luteinizing hormone (Phillippo *et al.*, 1987a).

Anaemia is a late sign of Cu dysfunction in growing calves (Suttle, 1988) and may be associated with Heinz body formation in the periparturient cow (Black, 1981). The *in vitro* viability and/or function of neutrophils from Cu-deficient cattle is poorer than that of cells from normal cattle (Suttle, 1988) but exposure to Mo can increase leucocyte counts (Gengelbach *et al.*, 1997); there is no evidence yet for impaired resistance to infections *in vivo* (Arthington *et al.*, 1996).

Necropsy

The pathology of bovine hypocuprosis is largely unhelpful because the histological changes underlying

the clinical signs, like the signs themselves, are non-specific. The earliest and most dramatic lesions are likely to be those affecting the epiphyseal growth plates in the costochondral junctions and metatarsal/metacarpal bones. These can become overgrown to the point that they spill over to leave islets of collagen distal to the plate in various states of irregular calcification and fibrotic replacement (Suttle, 1988). Gross degenerative changes are also seen in connective tissues such as the ligamentum nuchae. In severe cases showing diarrhoea, villous atrophy in the duodenal and jejunal regions is likely to be seen (Suttle, 1988) but is indistinguishable from that caused by gut parasites.

The anaemia of Cu deficiency in the bovine is similar to that of Fe deficiency, i.e. macrocytic and hypochromic. Cardiac lesions including fibrosis of the myocardium have been reported in natural outbreaks only once, over 40 years ago, in Australia. While cardiac hypertrophy was seen in some experimentally depleted calves, which took a long time to develop clinical signs; it was not present in others that were depleted more rapidly (Suttle, 1988).

Attention switched from the lesions that underlie the expected and familiar clinical signs to those which, though less spectacular, occur earlier and may underlie the debilitating effects of the disorder. Fell and his associates (Fell *et al.*, 1985; Fell, 1987) found basement membrane defects in the pancreatic acinar cell, the duodenal enterocyte and kidney tubule, pointing to perhaps a common early failure of proteoglycan organization.

It remains to be seen whether Mo can cause distinctive histological or ultrastructural changes at central sites such as the pineal body which may be crucial to the development of disorder (Phillippo *et al.*, 1987a) and whether or not these are Cu-dependent.

Diagnosis

Since none of the clinical signs of Cu deprivation given above is specific, diagnosis must be supported by biochemical tests showing subnormal tissue Cu status. Because availability has such a major effect on Cu uptake, herbage or dietary Cu concentrations alone are almost worthless and should be accompanied by measures of Mo and S and predictions of available Cu (Suttle, 1983a). In green swards, which contain enough sulphur to potentiate the Mo antagonism, Cu:Mo ratios <3.0 indicate a risk of hypocuprosis. Even then, other factors such as initial Cu reserves, other dietary antagonists (Fe and ingested soil) and the rate of animal production may determine the outcome of events. Genetic variation in bovine Cu metabolism is far less pronounced than that found in sheep (Underwood & Suttle, 1999). Fe:Cu ratios in the range 50–100 indicate the possibility of a Cu-responsive disorder; these and

other guidelines for the biochemical assessment of risk are summarized in Table 21.1.

The conventional criteria of Cu status in the animal, i.e. liver and blood Cu concentrations, are most dependable when herbage Mo concentrations are low (<5 mg/kg DM). Under these circumstances the ranges 150–300 µmol (10–20 mg) Cu/kg DM for liver and 3–9 µmol (0.2–0.6 mg) Cu/l for plasma can be regarded as 'marginal', except for the newborn (Table 21.1): as group means, they indicate that some individuals are likely to benefit from Cu supplementation and that cheap measures to improve Cu status would be prudent. Newborn calves require *higher* marginal ranges for liver (790–3150 µmol Cu/kg DM) and *lower* ranges for plasma (3.0–4.5 µmol Cu/l). At very high dietary Mo concentrations (35 mg/kg DM), changes in the distribution of Cu in the plasma and liver may complicate the assessment of Cu status (Wang *et al.*, 1988). With less extreme though still unusual Mo concentrations (>5 mg/kg DM) in pasture, 'teart'-like conditions may operate for critical periods, with animals responding to Cu while normocupraemic. Low caeruloplasmin:Cu ratios in plasma have been claimed to indicate the antagonistic influence of Mo, but they can be low when the antagonist is Fe (Gengelbach *et al.*, 1997). The relationship between caeruloplasmin and total Cu in bovine plasma is not perturbed in molybdeniferous areas of Scotland (N.F. Suttle & J. Small, unpublished data). It remains to be seen whether supplements that achieve normocupraemia invariably provide a sufficient defence against Mo-induced infertility and whether other parameters such as plasma Mo or plasma Fe concentrations have merit for diagnosing Mo-induced ill health (Phillippo *et al.*, 1987a, b). In establishing Cu as a limiting factor to production in a new area, a response to a specific Cu treatment affords the best assessment, though not necessarily showing Cu deprivation to be the primary cause (see p. 254).

Treatment or prevention

The treatment of Cu deficiency is achieved readily by single oral doses of Cu or parenteral injections of the element. In animals close to market weight the use of chelates of Cu with ethylene diamine, tetra-acetic acid (EDTA), glycine or methionine may result in unacceptable, 'cold' abscesses at the injection site, whether given subcutaneously or intramuscularly. Use of water-soluble complexes such as the hydroxyquinoline sulphonate and heptonate will avoid abscess formation but increase risks of acute toxicity (e.g. Suttle, 1981).

Prevention of deficiency and disorder can be achieved to varying degrees of precision and duration with oral and parenteral supplements. Copper oxide particles are more effective than serial injections, pro-

viding protection for several months (Judson *et al.*, 1985; Rogers & Poole, 1988). Soluble glass boluses are likely in time to give equally sustained protection and are particularly suited to the extensive grazing situation (Allen *et al.*, 1985; Judson *et al.*, 1985; Givens *et al.*, 1988). During periods of supplementary feeding or housing, the use of Cu salts as forage additives or cereal supplements commends itself. Where food supplements are not given, a free-access mineral mixture containing >500 mg Cu/kg is likely to afford protection to the majority of the individuals that take to it in a given herd. If Cu proves to be useful as an antidote to Mo rather than an essential nutrient in some situations by rendering toxic thiomolybdates less available, the provision of Cu by slow rumenal release or steady dietary supplementation may have advantages over other forms of supplementation. The use of chelated forms of copper, such as 'proteinate' or copper lysine, as dietary supplements has given no consistent advantage over simple, cheap inorganic forms and cannot be relied upon to 'protect' copper from molybdenum or other antagonists (Underwood & Suttle, 1999).

Toxicity (see p. 948)

Copper poisoning rarely occurs through the ingestion of excess Cu in weaned cattle because of poor absorption and a well-developed capacity to excrete surplus Cu via the bile. Tolerance of diets containing >250 mg Cu/kg DM for several months has been reported in Friesian steers (Felsman *et al.*, 1973). Much higher absorptive efficiencies prior to weaning mean that calves reared on milk substitutes are relatively vulnerable, but they can tolerate up to 500 mg Cu/kg DM for brief periods (6 weeks; Jenkins & Hidiroglou, 1989). Oral drenching with CuSO₄ solutions can cause haemolytic crises similar to those found in the more vulnerable sheep, but slower rates of exposure via the diet may sometimes cause or contribute to hepatic crises. Rapidly growing bull calves can die suddenly and show biochemical evidence of liver injury, in the form of raised AST activities, and Cu overload, in the form of raised kidney Cu levels, without evidence of haemolysis (no jaundice or increase in kidney iron) and only marginally raised liver Cu (C. Low, pers. comm.). Diagnosis of toxicity becomes possible when 'liver enzyme' values in serum are raised and values for indices of copper status enter the following 'marginal' ranges: serum, 0.018–0.020 mmol Cu/l; liver 6.4–16.0, kidney 0.6–0.8 and diet 1.57–3.14 mmol Cu/kg DM (multiply by 63.5 to obtain mg or ppm units). False 'highs' for plasma Cu during acute infections will be accompanied by Cu:Zn ratios >3–4. Acute Cu poisoning can be caused by overdosage via the parenteral route (Mylrea & Byrne, 1974) and is characterized by haemolytic crises and jaundice.

Iodine disorders (see pp. 257, 586)

Aetiology

Iodine has only one function in the body, as a constituent of the hormone tri-iodothyronine (T_3), which regulates basal metabolic rate. The hormone is formed by the removal of iodine (deiodination) from thyroxine (tetra-iodothyronine, T_4), the physiologically inactive form synthesized in the thyroid gland. Disorders can arise either from a simple lack of iodine in the diet or from the impairment of iodine metabolism by ingested goitrogens. Simple iodine deprivation rarely occurs in coastal regions or on small islands because of the large atmospheric inputs of iodine of marine origin. Diets containing $<0.1\text{ mg I/kg DM}$ are inadequate, those with $0.1\text{--}0.2\text{ mg/kg DM}$ marginal; levels are usually much higher in spring than in summer pasture (Underwood & Suttle, 1999). In areas where winter temperatures are low, iodine requirements probably increase in proportion to energy expenditure/kg LW, making the newborn particularly vulnerable. Selenium deprivation may increase the risk of iodine disorders through its role as an activator of several deiodinase enzymes (see 'Selenium disorders' on p. 302).

Ingestion of inorganic, cyanogenetic goitrogens in certain grasses (e.g. *Paspalum* spp., *Cynodon aethiopicus*), legumes (e.g. *Trifolium repens*, *Medicago sativa*), brassicas (e.g. *B. oleracea*) and by-products (e.g. cassava meal) leads to the formation of thiocyanate in the rumen which impairs iodine uptake by the thyroid. Organic, thiouracil-type goitrogens (e.g. in *B. campestris*, *Leucena leucophala* and rapeseed meals) can impair iodine incorporation into T_4 in the thyroid and its conversion to T_3 in the tissues. Exposure to both types of goitrogen increases risk of disorder and only the former type can be countered by providing more iodine.

Clinical signs

Iodine deprivation is no longer synonymous with goitre. While goitre in the newborn remains the commonest manifestation, lack of iodine also has a specific effect on brain development and non-specific effects on growth, fertility, milk yield and on the skin and its appendages (Underwood & Suttle, 1999).

Necropsy

Thyroid enlargement occurs as an adaptive response to iodine deprivation and undoubtedly provides a simple first measure of the possibility of iodine deficiency. In clinically significant, chronic pre- or postnatal iodine deprivation, enlargement of the thyroid is gross and

there is no need to weigh the gland. Problems of interpretation arise when the degree of iodine deprivation and associated changes are less pronounced. In the UK, the limit of normality for thyroid weight was 0.33 g FW/kg LW , but recent work in Northern Ireland has shown that a higher margin is necessary. Iodine deprivation can cause thyroid weights to reach 0.79 g/kg LW without causing stillbirths (McCoy *et al.*, 1997) and iodine supplementation of beef cows significantly reduced thyroid weight without reducing calf mortality or stillbirths (Smyth *et al.*, 1992). Sound interpretation requires a marginal band of $0.3\text{--}0.8\text{ g/kg LW}$ (Table 21.1). Spurious increases in thyroid weight may occur during the trauma of a difficult calving as part of a generalized oedema.

Diagnosis

Biochemical and histological criteria can contribute to diagnosis in cases of marginal deprivation, but the most commonly used criteria present the greatest problems of interpretation.

Thyroxine: T_4 is transported in plasma bound to proteins, but concentrations in the blood are a poor and unreliable index of functional iodine status. Proper assessment of iodine dysfunction requires measurements of T_3 , $T_3:T_4$ ratios and thyroid-stimulating hormone (TSH), the hormone secreted by the pituitary in response to iodine deprivation. The detection of raised TSH concentrations in the bloodstream indicates that an animal needs more T_3 and is prompting the thyroid gland to increase hormone synthesis. A recent experiment (McCoy *et al.*, 1997) confirms the unreliability of T_4 assays. Pregnant heifers were fed a diet sufficiently low in iodine to cause a 2.5-fold increase in thyroid weight of their newborn calves when compared with an iodine supplemented control group. No significant differences in plasma T_4 concentrations were found between the two groups in either mother or offspring and mean values ($60\text{--}202\text{ nmol/l}$) were in the normal range. There is also a spontaneous fall in plasma T_4 during early lactation to values that are subnormal for other stages ($20\text{--}40\text{ nmol/l}$).

Serum iodine: The element has been measured *in toto* and in protein-precipitable and butanol-extractable forms in serum, but rarely in proven clinical or sub-clinical cases of iodine deprivation, and diagnostic limits can only provisionally be set. Each parameter is a better measure of the degree of excess than of inadequate iodine supply (Table 21.1).

Thyroid iodine: Thyroid iodine concentrations largely reflect the amount of iodine in thyroglobulin which is

lying in store. Since iodine stores can be depleted before cellular changes occur and cellular changes increase the size of the thyroid, tissue iodine concentration alone will be of limited value in determining the total amount of iodine present in the gland. Many authorities use the yardstick proposed in the 1930s that clinical goitre is associated with thyroid $I_2 < 1.2\text{ g/kg DM}$ and $1.2\text{--}2.0\text{ g I}_2/\text{kg DM}$ becomes a marginal range (Puls, 1994; Table 21.1).

Milk iodine: Concentrations of iodine in bovine milk are linearly related to iodine intake (Underwood & Suttle, 1999) and have proven diagnostic value in the ewe. Puls (1994) suggests that values $<25\mu\text{g I/l}$ indicate 'deficiency' in cows, much lower than the corresponding value for ewes (<80), yet this probably overlaps the 'marginal' range.

Histological criteria: A sequence of microscopic cellular changes occur in the thyroid as the organ responds to the stimulus from TSH. Firstly, stores of surplus thyroxine in colloidal form are removed – some pathologists call this 'colloidal goitre', but this does not mean that the abnormality has reached a clinical or life-threatening stage, rather that *depletion* is complete. With stores of thyroglobulin denuded, the epithelial cells which produce thyroxine increase first in number (hyperplasia: 'hyperplastic goitre') and then in size (hypertrophy); it is the latter process which lies behind visible, clinically significant goitre. Hyperplasia can occur in calves which are normal at birth (McCoy *et al.*, 1997) and may be caused by the stress of a prolonged calving. Undue diagnostic significance should not be attached to thyroid abnormalities, although these may be the only post-mortem 'abnormality' to be recorded.

Treatment and prevention

Congenital goitre must be prevented because there is no response to treatment and only the chronic forms of iodine disorders in older animals are amenable to treatment. Simple and thiocyanate-induced deprivation can be prevented by providing inorganic iodine supplements in iodized salt licks or mineral mixes containing c. 0.1 g I/kg . Substantial losses can occur by volatilization in hot climates and the use of less volatile forms such as periodates is then indicated. Slow-release boluses are being developed and a long-lasting form for parenteral administration (iodized poppyseed oil) has long been used, although it is no longer obtainable in some countries due to a failure to update product licences. Problems induced by organic goitrogens can be avoided by using cultivars selected for low glucosinolate content and by-products of such crops (e.g. canola rapeseed meals). Manipulation of the rumen

microflora in isolated populations can limit endogenous goitrogen synthesis from mimosine-containing shrubs such as *L. leucophela* (Jones & Meggarity, 1983).

Toxicity (see pp. 261, 823)

Iodine is a cumulative poison which eventually suppresses thyroid activity. Tolerable exposure is therefore a multiple of daily intake \times length of exposure, rather than a set dietary concentration. The marginally tolerable concentration over three to four months' exposure is $25\text{--}50\text{ mg I/kg DM}$ (Newton *et al.*, 1974) and is rarely encountered under farm conditions unless there is access to seaweed (4–6 g I/kg DM). Iodosis is characterized by poor growth and respiratory disorder in calves (Newton *et al.*, 1974) and by perinatal mortality in offspring of the adult cow (Fish & Swanson, 1983). Once lactation has begun, the cow herself becomes less vulnerable because she is able to secrete much of any excess dietary or therapeutic iodine in milk. Use of iodine in the form of ethylene diamine dihydroiodide (EDDI) for treating foot rot and 'lumpy jaw' in the USA has resulted in many cases of iodosis (see page 261 and Underwood & Suttle, 1999, for further details).

Selenium disorders (see p. 258)

Aetiology

The principal function of Se in animals relates to its intracellular presence in the glutathione peroxidases, a family of antioxidant enzymes (once GSHPx, now GPXn with $n \geq 6$), which use various potentially dangerous peroxides as substrates. Selenium has been linked with iodine metabolism in ways that indicate a separate function, independent of GPX (Arthur *et al.*, 1988). While the basic cause of Se disorders is obviously a shortage of the element in the diet, which in turn can be traced to soil formations also deficient in Se (Underwood & Suttle, 1999), other factors are probably involved in field outbreaks of Se-responsive disease. Calves fed experimental diets of exceedingly low Se content (0.01–0.02 mg/kg DM) indoors can be depleted of Se to the point that they have undetectable activities of GPX1 in their blood and yet do not develop myopathy (Arthur, 1988; Reffett *et al.*, 1988). In one study (Arthur, 1988), the failure to induce myopathy was the more surprising because the diet was also low in vitamin E, which also contributes to antioxidant defence in the tissues.

The importance of dietary sources of oxidant stress was demonstrated by workers in Belfast (Rice & McMurray, 1982), who showed that the addition of polyunsaturated fatty acids (PUFA, progenitors of lipid

peroxides) to diets deficient in vitamin E and Se, simulating the composition of PUFA-rich spring grass, will precipitate myopathy. Other stressors may yet be required to induce myopathy because Arthur (1988) has shown that feeding of PUFA-rich grass indoors to calves deficient in Se and vitamin E did not precipitate the disorder, whereas grazing the same grass produced acute myopathy. He suggested that exercise or some other component of the environmental change at turnout contributed to the development of muscle damage. The excitable behaviour of the calf will of course result in increased activity of muscles involved in locomotion, circulation and respiration: muscular exercise is known to induce oxidant stress and exacerbate the effects of vitamin E deficiency (Jackson, 1987). It is highly likely that the intense and sometimes prolonged muscular activity of the uterus at parturition makes it particularly vulnerable to Se (and vitamin E) deficiency. Adverse weather conditions have been implicated in outbreaks of acute myopathy and the cause of Se-responsive disorders is thus multifactorial (Underwood & Suttle, 1999).

Clinical signs

Selenium deprivation in cattle can impair development throughout life. The suckling calf can develop chronic skeletal and cardiac myopathy if the dam's diet is low in Se (Hidiroglou *et al.*, 1985), while the calf on pastures deficient in Se can suffer growth retardation before (Morris *et al.*, 1984) and after weaning (Gleed *et al.*, 1983). In spring, calves can develop acute myopathy with myoglobinuria when turned out to graze. Selenium supplementation has improved conception rate in cows (McClure *et al.*, 1986) and heifers (MacPherson *et al.*, 1987b). At parturition, cows of low Se status are more likely to retain the placenta than Se-supplemented cows and they are the more susceptible to metritis and cystic ovaries (Harrison *et al.*, 1984). Selenium deprivation also affects the circulatory system: the growing calf can develop a Heinz-body anaemia (Morris *et al.*, 1984) and when calving coincides with turnout, the cow which is both Cu and Se deficient may be vulnerable to haemolysis and haemoglobinuria (Black, 1981).

Despite the variety of clinical signs caused by a lack of Se, it is rare for more than one sign to appear in a single herd. Problems of muscular dystrophy have not been reported in the many studies of retained placenta, which is probably the commonest Se-responsive condition in cattle. Similarly, growth retardation and muscular dystrophy have not been reported in the same outbreak of disorder. Selenium deficiency in cattle has been associated with impaired phagocyte function *in vitro*, prompting speculation that Se deficiency would lead to decreased resistance to disease, but these sug-

gestions have not always been confirmed in experimental studies (Reffett *et al.*, 1988). There are several reports of inverse relationships between blood Se or glutathione peroxidase (GPX) activity with somatic cell counts in bovine milk (e.g. Erskine *et al.*, 1989) and experimental evidence that addition of Se to diets of marginal Se concentration decreases the duration of clinical mastitis (Smith *et al.*, 1984). Similar responses can be obtained with supplements of vitamin E (Weiss *et al.*, 1997), making interpretation of responses to Se combined with vitamin E (the commonest approach) either difficult or impossible. Improvements in calf survival in herds on diets of marginal Se concentration (0.03–0.05 kg Se/kg DM) have been reported, but vitamin E as well as Se was given and the role of Se alone is again unclear (Spears *et al.*, 1986).

Diagnosis

The differential diagnosis of Se-responsive disorders is complicated by the non-specific clinical signs of disease: most can also be attributed to vitamin E deficiency while others, such as retained placenta and growth retardation, have many possible causes of both nutritional and non-nutritional origin. The tolerance of low plasma and blood Se (or GPX) concentrations in the absence of exacerbative factors confirms that measures of Se (or GPX) alone cannot confirm a selenium disorder. Neither is there likely to be a simple relationship between dietary Se concentration and incidence of disease.

In monitoring Se status, the assay of GPX once largely replaced that of whole blood Se because it was easier to assay, yet highly correlated with blood Se concentration. Enzyme activities were converted to blood Se equivalents for comparative purposes. Interpretation of blood GPX activities is, however, complicated by many factors. The measurement of GPX activity is subject to wider interlaboratory variation than most analyses in the clinical context: Blanchflower *et al.* (1986) identified some important variables. The use of an assay kit helped to standardize results, but differences can still arise and each laboratory should determine and quote its own Se equivalence for GPX activity. Results are variously reported per ml blood, per g haemoglobin and per ml cells: while these will be highly correlated with each other within laboratories, the use of common conversion factors for comparative purposes may introduce errors. The slow turnover of erythrocytes ensures that blood GPX activity reflects past rather than present Se supply. The data of Hidiroglou *et al.* (1985) indicate that it may take four months for blood GPX (and Se) fully to reflect an improved Se supply and just as long to reflect a waning supply. It should be noted that the GPX in blood is now

regarded as a dispensable, storage form of the element and indicative of *depletion* rather than *dysfunction*. Plasma Se responds immediately to changes in dietary supply and is a useful adjunct to blood GPX in assessing Se status concentrations of 100–120 nmol (8–10 µg/l) being ‘marginal’ and suggesting possible benefits from Se supplementation (Underwood & Suttle, 1999).

Very small differences in Se status may determine vulnerability. In the study of Hidiroglou *et al.* (1985) for example, myopathy occurred in calves in one year when blood GPX1 declined from 29 to 19 iu/g haemoglobin (Hb) and plasma Se from 11 to 6 µg/l, but not in the next when the respective falls were 51 to 28 iu/g Hb and 16 to 13 µg/l. Pasture Se was consistently low at 0.02–0.04 mg/kg DM. In a survey of the Se status of cattle in north-east Scotland (Arthur *et al.*, 1979), 85 per cent of herds had a blood Se status 50 µg/l, a threshold below which a risk of clinical disease was once suggested, but only 10 per cent had a recent history of myopathy; the winter diets mostly contained <0.05 mg Se/kg DM. In New South Wales, herds of growing cattle with blood Se concentrations usually <20 µg (0.25 µmol)/l rarely benefited from Se supplementation and those that did were not distinguishable from their blood Se levels (Langlands *et al.*, 1981). Studies in New Zealand with dairy cows indicated a critical blood Se concentration as low as 12 µg/l below which milk fat yield fell (Fraser *et al.*, 1987). The latter studies both involved grazing animals with plentiful supplies of vitamin E.

The clinically significant thresholds for dietary and blood Se concentrations probably vary with the Se-responsive condition and the dietary supply of vitamin E. Incidence of retained placenta can be reduced in cows receiving diets of higher Se content (0.04–0.05 mg/kg DM) than those giving freedom from myopathy. Higher thresholds for blood GPX activities and Se concentrations of 50 µg/l may sometimes be needed for normal reproduction (McClure *et al.*, 1986; Underwood & Suttle, 1999), but studies with grazing heifers in New Zealand show possible tolerance of much lower values (Wichtel *et al.*, 1996). Marginal bands must therefore be used (Table 21.1).

The greatest limitation of blood GPX for monitoring disorder is that the target tissue in Se deficiency is often muscle not blood. Furthermore, there are wide variations between muscles in their GPX content and in the lipid composition of their membranes (Rice & Kennedy, 1988). Measurement of blood GPX alone is unlikely to reflect the risk of lipid peroxidation and hence myopathy in crucial muscles. Guidelines for the interpretation of selected indices of Se status are given in Table 21.1. The assay of a peroxidation product in accessible membranes (e.g. malondialdehyde in erythrocytes) may provide an integrated measure of net

oxidative stress but has yet to be tested in ruminants and would not be a specific test for Se (Suttle, 2000). As with other trace elements, the surest diagnosis is often provided by responsiveness to effective Se supplements. By plotting a measure of final performance against performance prior to supplementation (e.g. LWG), it is sometimes possible to identify a small minority of a population which would benefit from additional Se, while mean performance remains unchanged (Suttle, 2000).

Treatment or prevention

The many different methods for administering Se orally and parenterally have been reviewed (Allen, 1983; MacPherson, 1983) and three were compared by MacPherson and Chalmers (1984). Long-term supplementation can be achieved by both routes. By administering heavy metal (iron oxide) (e.g. Hidiroglou *et al.*, 1985; McClure *et al.*, 1986) or soluble glass boluses (Judson *et al.*, 1985) orally and by injecting a relatively insoluble Se salt, barium selenate, in an oily base (MacPherson & Chalmers, 1984; MacPherson *et al.*, 1987b), blood Se concentrations have been increased for at least five months. Supplementing the drinking water (MacPherson & Chalmers, 1984), the pasture (by slow-release fertilizer application; Sanson, 1990; Whelan *et al.*, 1994) or the winter diet (Stowe *et al.*, 1988) with Se can also provide long-term protection. Stowe *et al.* (1988) concluded that a supplement of 2 mg Se/day upon an estimated basal intake of 0.51 mg/day was not sufficient to raise plasma Se in the periparturient cow to ‘acceptable levels’ (>60 µg/l); nevertheless retained placenta and metritis was only half as prevalent in treated as in untreated cows. Oral supplementation prior to calving (13–45.5 mg/day for 15 days) can raise the Se status of offspring substantially and for several months (Enjalbert *et al.*, 1999). Use of organic forms of selenium such as yeasts or selenomethionine can change the partition of the supplement in weaned or adult cattle and increase the transfer of selenium to milk when compared to inorganic sources but is unlikely have any therapeutic, nutritional or economic advantage in the treated animal (Underwood & Suttle, 1999).

It is questionable whether long-term Se supplementation is the most cost-effective way of treating what are usually short-term problems. The Se-responsive diseases associated with parturition and turnout are acute conditions that can be effectively treated or prevented by single injections of Se as selenite or selenate (e.g. Eger *et al.*, 1985; McMurray & McEldowney, 1977). There is considerable variation in dosage practice. For example, for the prevention of retained placenta, Se doses have varied from 2.3 to 50 mg: the highest dose

rate, equivalent to 0.1 mg/kg liveweight, is the most commonly used.

Selenium has generally been given with vitamin E and it is impossible to assess retrospectively whether there was invariably a need for both nutrients. The limited studies in which only one nutrient was given to some animals show that the benefit of providing vitamin E with Se varies from farm to farm. The need for dual supplementation may also depend on the nature of the clinical problem. A combination of oral vitamin E with parenteral Se reduced the incidence of retained placenta in one instance in which the separate treatments were ineffective, but Se alone reduced the prevalence of metritis and cystic ovaries (Harrison *et al.*, 1984). In the treatment of acute myopathy at turnout, McMurray and McElroy (1977) found that vitamin E (2.8 mg/kg liveweight) was less effective than Se (0.0625 mg/kg liveweight) and added nothing when given with Se. In this situation cattle of low vitamin E status were turned onto grass of naturally high vitamin E concentration. The variable responses to vitamin E given with Se will be due largely to the wide variations found in the vitamin E status of housed cattle.

Selenium toxicity (see p. 943)

Disorders occur naturally either when pastures contain plant species (e.g. *Astragalus*) which accumulate selenium avidly from normal soils ('Blind staggers') or when a combination of selenium-rich soil and high pH allows high levels of selenium to accumulate in normal plant species ('Alkali disease') (O'Toole & Raisbeck, 1995). Accidental toxicity can be caused by errors in adding the small amounts of selenium needed to supplement feeds, exposure to multiple supplementary sources and multiple doses (e.g. Se-supplemented anthelmintics) and failure to scale oral drenches or parenteral injections carefully to liveweight. Because selenium is well absorbed, the oral route poses almost as big a threat as the parenteral route. Selenium is a cumulative poison and tolerable daily intakes and dietary concentrations decrease as duration of exposure increases. Lesions occur principally in the hoof, which overgrows to the point where it may be shed, causing a severe, debilitating lameness. The disorder can be distinguished from laminitis (see p. 420) by the fact that the lesions are epidermal rather than dermal (O'Toole & Raisbeck, 1995). The marginal ranges for indices of selenium status within which toxicosis becomes a possible diagnosis are as follows: diet, 50–75; liver, 30–50; hoof, 25–63 and hair 63–126 µmol Se/kg DM (Underwood & Suttle, 1999; multiply by 79 to obtain values in µg): the corresponding range for blood is 25–30 µmol Se/l (McLaughlin *et al.*, 1989). Preventive measures include the removal of 'Se-accumulator'

species from pastures, treatment of soils with fertilizers which lower selenium uptake (ammonium and calcium sulphates) by plants, rotational grazing with less susceptible species such as sheep and improved soil drainage. Oral administration of sulphate-rich mixtures may prevent or alleviate signs (Arora *et al.*, 1975)

Manganese and zinc disorders

(see p. 260)

Cattle deprived of elements such as Mn and Zn under experimental conditions develop diverse clinical symptoms, but the diets used contained far less Mn and Zn than the levels provided by the vast majority of natural diets (Underwood & Suttle, 1999). Field cases of Mn and Zn deprivation would require either an abundance of dietary antagonists which impair the utilization of the element or other factors which massively increase animal needs for Mn and Zn. There is a possibility that 'protection' of protein sources from rumen degradation might allow phytate to escape and lower absorption of both elements and that fine grinding of cereals might have a similar end result (Suttle, 2000). In the field, soil ingestion provides a rich adventitious source of manganese while access to galvanized feed and drinking troughs provides additional Zn, further reducing the risk of disorders. Little attention has therefore been given to reliable assessment of Mn and Zn status in the animal. Serum Mn and Zn concentrations are probably reasonable indices of deficiency (Table 21.1), but marginal concentrations cannot yet be set with certainty for the former; liver values are poor indicators of status for both Mn and Zn (Underwood & Suttle, 1999). Assessment of hypozincæmia is complicated by the fall in values which accompanies the acute phase of microbial infections; this complication can be ruled out by discarding results for samples with raised haptoglobin or fibrinogen levels or high Cu:Zn ratios (>3–4). Intervention with Mn and Zn supplements is rarely necessary and use of expensive chelated sources is unlikely to improve animal status or performance any more than inorganic Mn or Zn sources (Olson *et al.*, 1999; Underwood & Suttle, 1999). Toxicities of Mn or Zn rarely occur.

Anatomy of the udder

Introduction

The mammary gland is essentially a skin gland. It is believed to have evolved by modification of a sweat gland and retains two common features: development by ingrowth of ectoderm; and a bilayered epithelium of inner secretory cells and outer myoepithelial cells, which by contracting promote flow of milk from the peripheral alveoli into the major ducts. Assuming the new function of catering for the immune welfare and nutrition of the neonate, the mammary gland has evolved into a highly branched compound structure with enormous numbers of dilated alveoli. This pattern allows for both synthesis and storage of milk on a large scale. Yet neither function is possible until the cow becomes pregnant, when the rudimentary and inactive gland undergoes massive growth to definitive structure and only then begins to synthesize secretion.

Early development of the udder

The first trace of mammary development appears in bovine embryos of 1.5 cm length as two short lines in the ectoderm running from the umbilicus caudally into the groin. Each line is several cells thick, but intense proliferation of cells in the basal layer at focal points produces an ingrowth, the mammary hillock (Fig. 22.1a). This soon enlarges into an ovoid mammary bud (Fig. 22.1b) invested by a condensation of inductive mesenchymal cells. As the rudiment of the duct system each mammary bud determines the site where a gland will form. By the seventh week of gestation in fetuses 9 cm long, four primary mammary buds are usually present, two on each side, defining the future quarters of the udder. Extra buds occasionally form and develop into supernumerary teats. Active proliferation of mesenchymal cells around the mammary bud lifts the epidermis into a rudimentary teat by the 8-cm stage. Simultaneously, vigorous proliferation of cells near the inner end changes the mammary bud into a solid cellular column, which elongates vertically into the mesenchyme (Fig. 22.1c) as the rudiment of the duct system, the future single galactophore. Meanwhile, division among the epidermal cells below the original bud produces an epidermal cone at the base of the duct primordium.

By the 19-cm stage the growing duct primordium is longer than the teat and slightly swollen at the inner end. Here a cavity or lumen appears and soon spreads proximally towards the teat apex. On reaching the epidermal cone the split remains narrow as the lumen of the future teat canal. Later this will open on the teat apex and both teat canal and superficial epidermis will be lined by a common, thick, stratified squamous, keratinizing epithelium.

By the 35-cm stage (Fig. 22.2) the growing duct rudiment has differentiated into three distinct regions:

- (1) An upper spheroid chamber distended with fluid represents the future gland sinus or milk reservoir.
- (2) A slightly longer mid-portion forms the more slender teat sinus.
- (3) A narrow teat canal within the epidermal cone, but still closed from the exterior by a plug of horny cells.

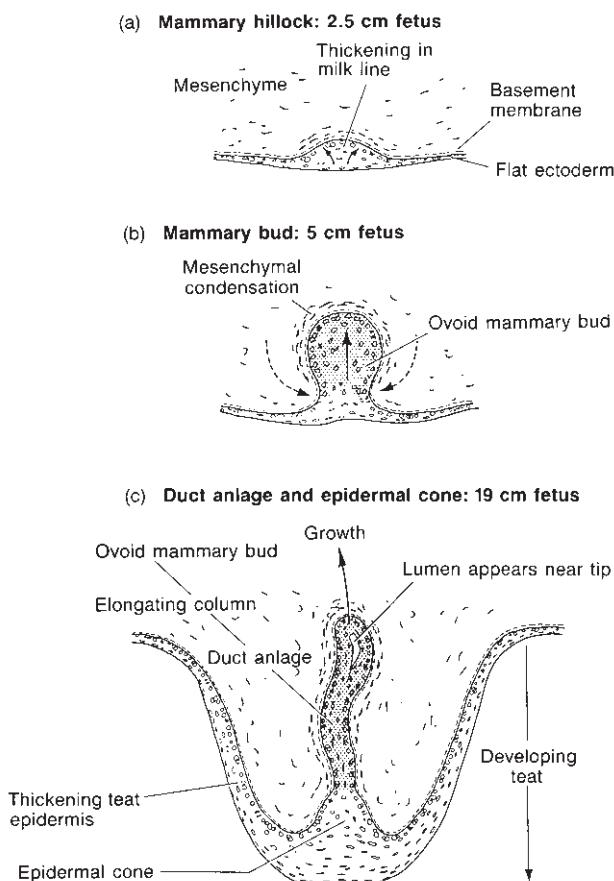

Fig. 22.1 (a) Transverse section of a mammary line at the level of a localized cellular proliferation, which forms a mammary hillock and determines where a gland will develop. (b) Later stage showing an ovoid mammary bud with cells more basophilic (stippled) than in the epidermis. A condensation of mesenchymal cells surrounds the bud. Curved broken arrows indicate growth of mesenchyme, which elevates a rudimentary teat. (c) Sustained proliferation (upper arrow) near the tip converts the mammary bud into a columnar vertical ingrowth, the precursor of the axial duct and storage sinuses. Meanwhile, division among the subjacent epidermal cells produces a cone, which later splits to form the lumen of the teat canal (from Turner, 1952).

From the domed roof of the gland sinus several short solid epithelial cords, the secondary sprouts, project dorsally into the overlying pad of differentiating adipose tissue. When canalized these secondary sprouts represent the bases of the 10 or more major lactiferous ducts, which in the adult deliver milk into the gland sinus for storage. The teat sinus, gland sinus and duct bases are lined by a bilayered cuboidal epithelium. As also in the terminal alveoli, which differentiate later in pregnancy, the inner cells are potentially secretory, while the outer differentiate into myoepithelial elements. In contrast the lowest and narrowest part of the axial lumen, forming the teat canal, is lined by thick,

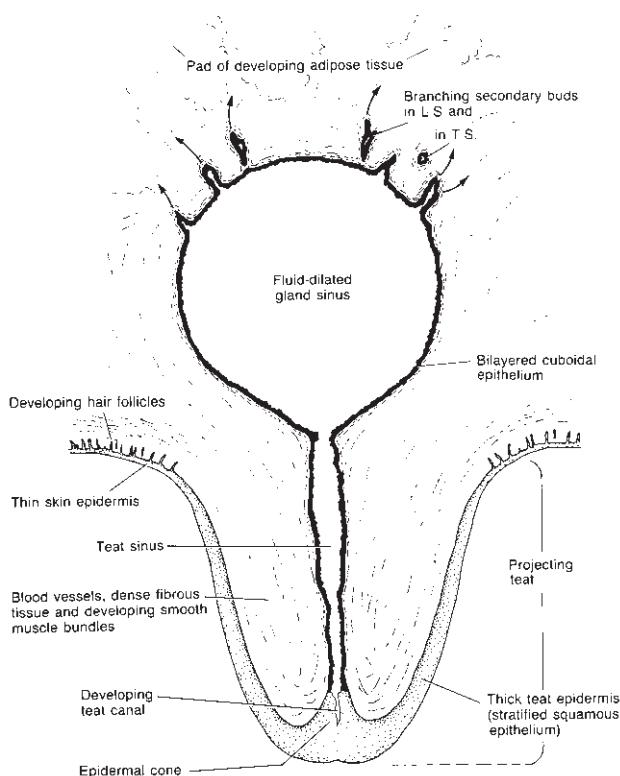

Fig. 22.2 Diagrammatic vertical section of the teat and mammary rudiment in a 35-cm fetus. Stratified epithelium is shown dotted. It appears distinctly thicker in the epidermal cone, where the teat canal lumen is forming, and over the surface of the teat rather than above it where hairy skin is differentiating. Derivatives of the original mammary bud are lined by double cuboidal epithelium (black) and comprise the narrow teat sinus leading from the fluid-distended gland sinus. Up to 10 short secondary buds project from the dome of the sinus and later will branch to form major ducts as they grow into the overlying cushion of fat. LS, longitudinal section; TS, transverse section (from Turner, 1952).

stratified squamous epithelium continuous with and identical to the glabrous epidermis of the teat. The latter is distinctly thicker, even in the fetus, than the epidermis above the teat where hair follicles differentiate from solid cellular ingrowths. The mesenchyme around and between the rudimentary epithelial ducts differentiates to provide blood vessels, lymphatics, small amounts of smooth muscle and an extensive fibroelastic stroma. Tracts of denser white fibrous and elastic tissue form the suspensory ligaments and dorsally numerous lobules form in the pad of adipose tissue.

Just before birth tertiary sprouts develop as short side branches from the secondary ducts, but thereafter the gland remains in an arrested state of development

until puberty. Some extension to the ducts occurs during oestrous cycles, but full structural differentiation of the mammary gland is completed only during pregnancy under the influence of progesterone from the corpus luteum and other hormones. During the first half of pregnancy, intense cell proliferation at the blind ends elongates the ducts, which branch repeatedly establishing an extensive tree. At the peripheral tips of the large number of fine ducts thus formed narrow tubular prospective alveoli then differentiate. In the second half of pregnancy, protein secretion and lipid droplets slowly accumulate, dilating the alveoli into saccular chambers 120 µm across and filled with stored colostrum awaiting release in the first sucking after birth.

The adult bovine mammary gland

The cow's udder comprises four quarters, each an individual gland drained by a teat. The four secretory glands are structurally separate and function independently, without flow of milk between them. Receiving a large flow of blood and laden with stored milk, the lactating udder often weights 50–60kg. Support for this massive weight is provided by dense fibrous suspensory ligaments that insert into the pelvis and tendons of the abdominal wall. The ligaments spread laterally and ventrally over the udder, then converge inwards to join paired median ligaments. These form a double vertical partition separating glands on the left from those on the right. Septa of interlobular connective tissue span between the lateral and medial ligaments and support the heavy lobules of parenchyma. As the medial ligaments contain relatively more elastin than the predominantly collagenous lateral ligaments the full udder drops in the midline and the teats become splayed outwards.

Blood supply

During the production of 20kg of milk each day 9000kg of blood circulate through the udder of the cow. Most of this rich supply arrives through the inguinal canal in the external pudendal arteries derived from the external iliac trunks. The udder also receives a subsidiary supply, cranially through the subcutaneous abdominal artery and caudally via the perineal artery. Numerous small veins leaving the parenchyma anastomose and converge around the base of the udder into a circular vessel that is drained by three trunks: the large subcutaneous abdominal vein, which passes cranially and penetrates the abdominal wall near the xiphoid cartilage; the external pudendal vein, which departs through the inguinal canal; and the perineal vein.

Innervation

The principal nerve supply derives from branches of the third and fourth lumbar nerves, which traverse the inguinal canal. Contributions from the first and second lumbar nerves supply the cranial, and from the perineal nerves the caudal regions respectively. These are mainly sensory nerves, but they carry from the caudal mesenteric plexus sympathetic fibres, which modulate blood flow by direct action on the arterioles. Whereas the skin and particularly the teats receive a rich sensory supply, nerves are sparser in the glandular parenchyma and chiefly, if not entirely, vasoconstrictor: the secretory alveoli lack a nerve supply. After the skin is anaesthetized the deeper mammary tissue may be incised without apparent sensation.

Mammary gland: histological organization

Histologically classified, the lactating udder is a large, lobulated, compound exocrine gland with dilated alveoli storing milk. Each alveolus is a single or bifid sac, slightly longer than wide and distended to an internal diameter of 120–150 µm by milk (Fig. 22.3). The lining epithelium is bilayered. The inner secretory or alveolar cells vary from tall cuboidal (8 µm) in the partially empty gland to stretched squamous (3 µm) in full distension state. Synthesis and release of milk constituents (fluid, casein, lactose and lipid) is continuous, until temporarily arrested by negative feedback. The outer contractile myoepithelial cells are indistinct in routine sections, but staining for alkaline phosphatase reveals their spider shape, with branching processes embracing the curved contour of the alveolar wall (Fig. 22.4). Towards term and during lactation the large alveoli have a rich capillary supply and are packed closely together into polyhedral lobules about 2mm across. The alveoli drain into intralobular ducts which, unlike those in salivary or lacrimal glands, are indistinct, since they resemble the alveoli in size, milk content and secretory lining. The heavy lobules are enclosed and bound together by thin septa of supportive connective tissue. This also carries distributing arteries and veins, lymphatics and the larger interlobular ducts, which converge and unite into major ducts opening into the gland cistern.

The teat

Each teat has a single narrow teat canal, which dorsally opens into a wider teat cistern lined by bilayered epithelium. Normally, the teat canal is kept closed by sphincter action of the surrounding smooth muscle and elastic tissues. Thus in section the lumen is a narrow

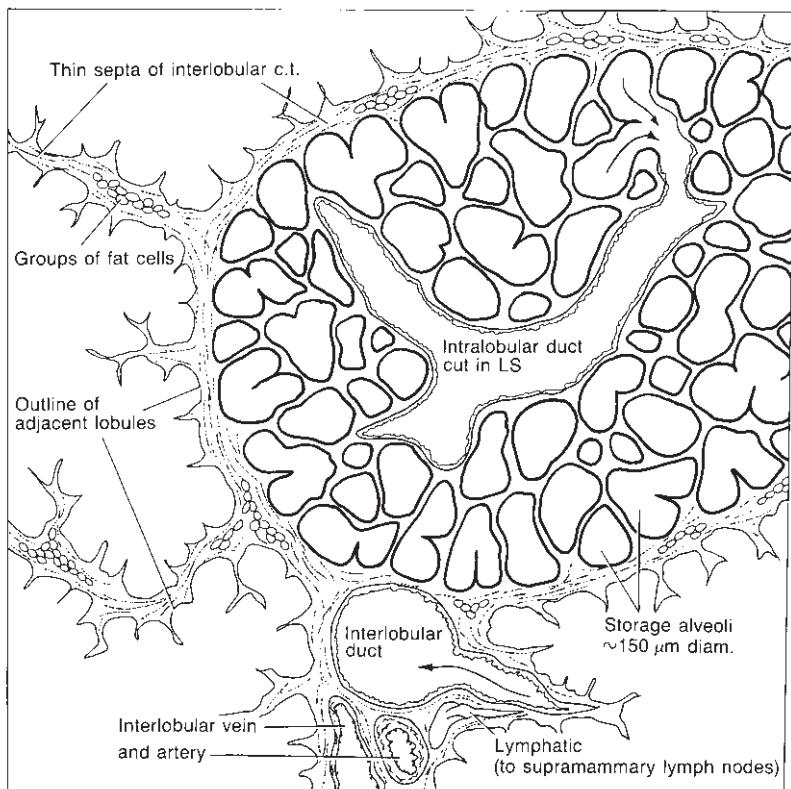

Fig. 22.3 Histological features of the lactating udder, showing large polyhedral lobules supported by thin septa of connective tissue carrying the distributing service vessels: interlobular ducts emerging (at lower right) from lobules, arteries supplying and veins draining the dense networks of perialveolar capillaries. Nearby collecting lymphatics carry a considerable flow of afferent lymph rich in lymphocytes, neutrophils and macrophages and during infections, e.g. mastitis, carrying antigens that induce immune responses in the supramammary lymph nodes.

In each lobule the alveoli tend to be similar in size, but are generally smaller, averaging 60 µm across, with a tall cobble epithelium in lobules that released milk at the previous lactation. When fully distended with milk, as shown, alveoli approach 150 µm in diameter and have a thin stretched lining. Smaller profiles represent alveoli slices in oblique to tangential planes. Intralobular ducts drain milk from alveoli (curved arrows), but unless fortuitously sliced in longitudinal section are almost indistinguishable from the alveoli, being comparable in width and lined by identical secretory epithelium. c.t., connective tissue; LS, longitudinal section (diagram by E.H. Batten).

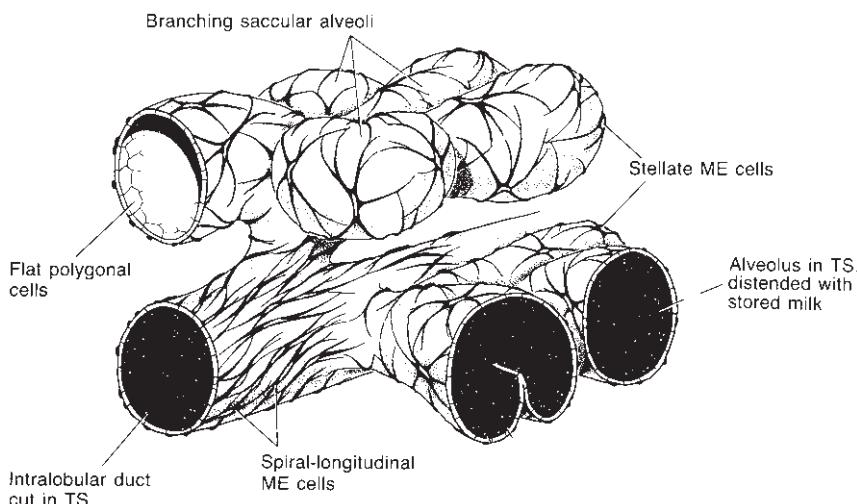

Fig. 22.4 Diagram showing several branching milk-distended alveoli of the lactating udder draining into a relatively wide intralobular duct. In the sectioned profiles fat droplets in the milk are shown white against a black background. Contraction of the network of stellate myoepithelial cells (cytoplasm black, nuclei white) expels milk from the alveoli into the intralobular ducts. In turn these become shortened and compressed by the contraction of the spirally aligned myoepithelial cells, which propel milk towards the larger interlobular ducts. ME, myoepithelial cells; TS, transverse section (after Linzell, 1961).

stellate crevice, with the lining of thick, keratinizing, stratified squamous epithelium thrown into several longitudinal folds that almost meet centrally (Fig. 22.5). The teat is robustly constructed and well adapted to tolerate the shear stresses generated by a suckling calf or milking machine.

Structurally the teat wall comprises five distinct tissue layers: superficial epidermis, then dermis, intermediate layer, fibrous lamina propria and internally the epithe-

rium of the teat canal. The teat is covered by thick, stratified squamous, keratinizing epidermis with neither hair follicles nor sweat and sebaceous glands. Whereas the thinner skin over the udder is relatively loosely attached and can freely be moved over the underlying glandular lobules, the teat skin is immobile and tightly anchored to the deeper fibromuscular core. This firm surface is well suited to withstand mechanical shear forces set up by suckling, hand or machine milking. In

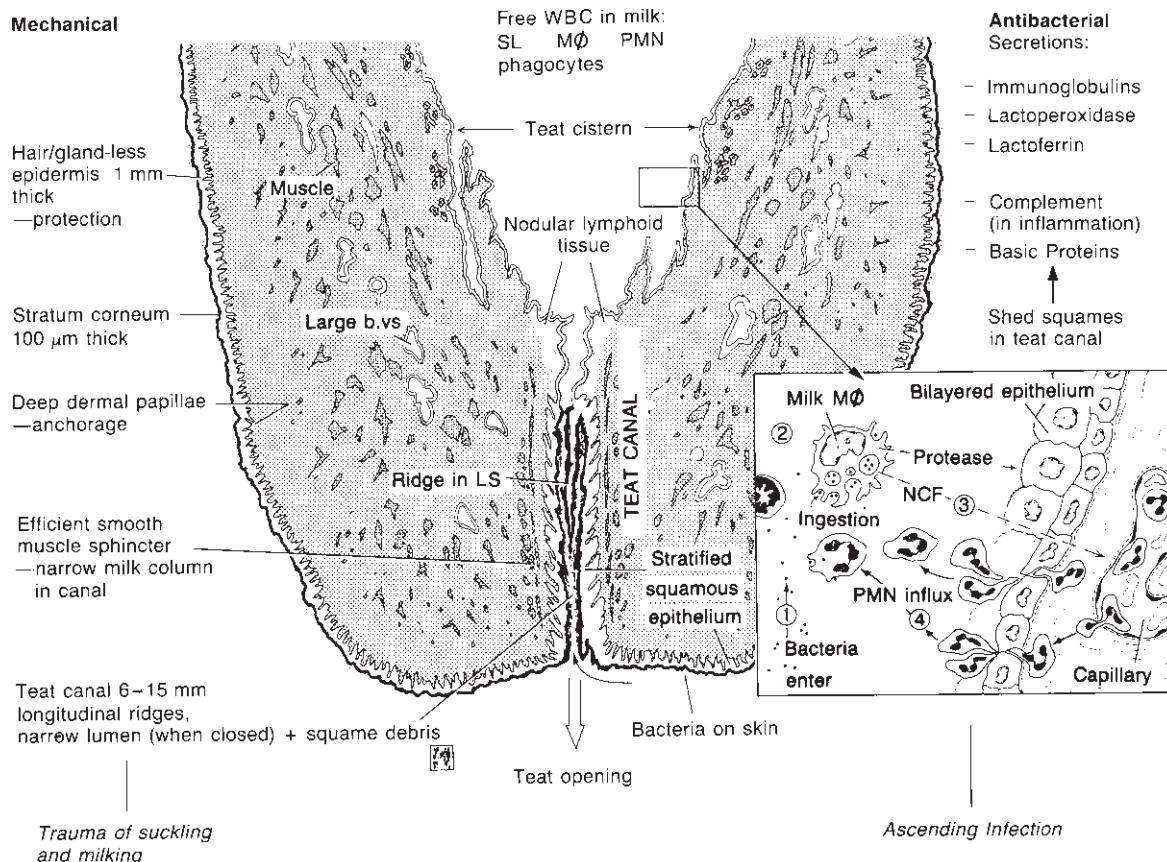

Fig. 22.5 Diagram of a vertical section of a cow's teat, showing on the left factors that protect against mechanical trauma during suckling or milking, and on the right defences against ascending infection by bacteria from the skin surface (curved arrow) entering the teat canal.

Milk normally contains shed epithelial cells, from both alveoli and ducts, squames from the teat canal, small lymphocytes (SL), macrophages ($M\phi$) and neutrophils (PMN). As phagocytes the last two cell types often contain small droplets of fat ingested from the milk. Subepithelial plasma cells occur near the ring of nodular lymphoid tissue that surrounds the rosette or inner end of the teat canal, where the stratified, keratinizing lining gives way to a bilayered cuboidal epithelium of the teat cistern. Insert right summarizes the early response to mastitis-forming bacteria experimentally introduced into the teat canal. Bacteria (1) are ingested by milk macrophages (2), which release enzymes that damage and loosen the inner layer of the epithelium and neutrophil chemotactic factor (NCF), which induces (3) within 4 hours the emigration of large numbers of PMN from the subepithelial capillaries and venules. After insinuating through the cisternal epithelium the PMN (4) join with the macrophages in the ingestion and killing of bacteria. WBC, white blood cells; b.vs, blood vessels; LS, longitudinal section (diagram by E.H. Batten).

In the lactating cow the teat epidermis is remarkable for three features.

- (1) In thickness about 1 mm, it is comparable with muzzle epidermis and some 12 times deeper than epidermis of hair skin (75 µm in frozen sections, which preserve the 30 layers of horny squames only 1 µm thick).
- (2) The protective stratum corneum is a compact layer, 100 µm deep and comprising as many overlapping layers of dead horny squames.
- (3) The underside is deeply papillated: epidermal pegs interdigitate with narrow, deep intrusions of dermal connective tissue.

Over this interface the area of adhesive basement membrane is fivefold greater than in the flat underside of hairy epidermis. This interlocking pattern binds epidermis securely and inseparably into the dermis and dissipates shear stresses from the surface through the deeper tissues. The dermal fibrous mat continues into the dense fibromuscular layer, without the intervening loose superficial fascia typical of thin skin.

Beneath the epidermis the dermis carries a rich capillary network and numerous fine bundles of sensory fibres derived from lumbar nerves 2–4. Despite its thickness as a protection against wear, teat epidermis is highly sensitive, since the penetrating dermal papillae carry sensory nerves and endings to within 200 µm

or less of the surface. This rich innervation receives tactile stimuli and relays to the central nervous system impulses that lead to the release of oxytocin from the pars nervosa into the blood. In turn, circulating oxytocin induces contraction of myoepithelial cells, promoting flow from the terminal alveoli and along the ducts during milk let-down. The deeper regions of the dermis contain dense collagenous tissue surrounding bundles of smooth muscle arranged mainly longitudinally.

The third or intermediate layer contributes much of the strength of the teat wall, as it contains numerous bundles of smooth muscle set in coarse fibroelastic tissue. These muscle bundles are aligned in longitudinal, circular and oblique planes. Major blood vessels are present, including distributing arteries, a complex plexus of anastomosing veins and numerous collecting lymphatics, which drain to the supramammary nodes.

The lamina propria resembles the dermis in its fibroelastic components, but carries more microvessels catering for the nutrition of the adjoining epithelium of the teat canal. During ascending infections with pathogenic bacteria, increased emigration from the local venules creates leucocytic infiltrations beneath regions where epithelial cells have been damaged, as explained in Fig. 22.5.

Both the teat cistern and the gland cistern dorsal to it are lined by a common bilayered cuboidal epithelium. Under scanning electron microscopy the superficial cells fit closely in hexagonal profiles densely covered with microvilli (Fig. 22.6). In the junctional region

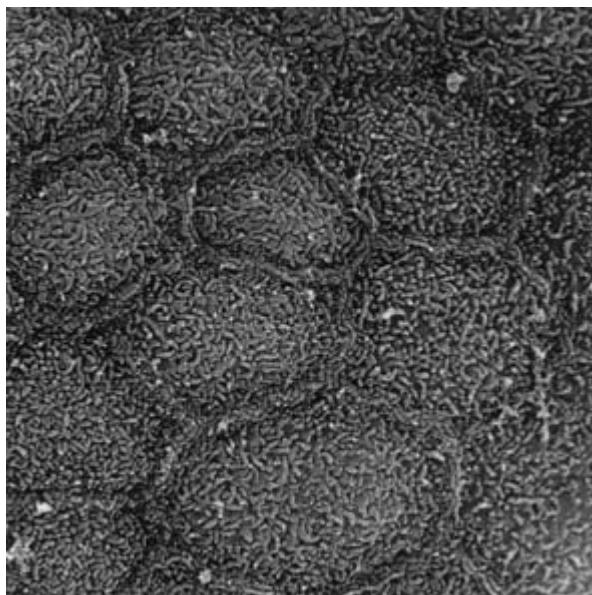

Fig. 22.6 Characteristic outline of teat epithelial cells covered with irregular microvilli ($\times 9000$). From Collins *et al.* (1986).

around the inner opening of the teat canal (earlier termed Furstenberg's rosette from the mucosal creases) the surface cells are more rounded and protruding, with sparser microvilli. In this region just beyond the barrier epithelium of the teat canal the lining may be a lymphoepithelium important in the uptake or penetration of invading antigens. Intraepithelial lymphocytes are profuse and both diffuse and nodular lymphoid tissue are present in the lamina propria. The accumulations of plasma cells and germinal centres (Fig. 22.7) often present there provide evidence of local humoral immune responses.

The physiology of lactation

Introduction

The secretion of milk by specialized mammary glands in the female for the nourishment of the newborn is the essential characteristic that distinguishes mammals from other animals. This feature is epitomized in the dairy cow which, as a result of intensive selection, has a disproportionately high output of energy in milk in relation to body size. Continuing improvements in milk yield and feed efficiency are the result of refinement of the genetic make-up of stock and improvements in management and nutritional practices. This focusing of effort on increasing milk production has prompted the facetious comment that the modern dairy cow should perhaps be regarded as an appendage of the udder rather than vice versa! Indeed, the readjustment of physiological processes that occurs in order to meet the extra metabolic demands of lactation involves not just differentiation and activation of mammary tissue but extends to changes throughout the body. Not the least of these is the hormonal regulation of nutrient utilization and partitioning between the mammary gland and other organs.

Milk is a complex secretion and its production is under complex control. By understanding the underlying physiology, the relevance of correct nutritional and husbandry practices in maintaining health and optimizing performance may be better appreciated.

Mammogenesis

Mammogenesis may be defined as the growth and differentiation of the mammary gland to the stage prior to active secretion. Since milk yield is ultimately dependent on the number of secretory cells and their activity, factors that influence the former during mammogenesis can have lasting implications for subsequent milk production.

Fig. 22.7 A lymphoid nodule with germinal centre beneath the double cuboidal epithelium lining Furstenberg's rosette (HE $\times 32$). From Collins *et al.*, 1986.

From birth to puberty mammary growth is isometric, i.e. in balance with the growth rate of the whole body, but just prior to the onset of ovarian activity mammary growth becomes allometric (i.e. exceeds that of the body surface). Only during the first pregnancy does marked branching of the duct system and lobulo-alveolar development occur, with expanding parenchyma displacing adipose tissue within the mammary fat pad. Lobulo-alveolar proliferation accelerates as pregnancy advances with division of secretory cells continuing at least until the onset of lactation. Balanced mammary development exhibits a crucial dependence on hormonal stimulation. The hormones principally implicated include steroids (oestrogens, progesterone and adrenal corticoids) and protein hormones (prolactin, somatotropin and placental lactogen). Thyroid hormones are possibly also involved. Many of these hormones interact synergistically to promote the different stages of mammogenesis. Oestrogens and somatotropin are responsible for ductal development whereas progesterone and prolactin appear to regulate lobulo-alveolar proliferation. The additional presence of adrenal corticoids maximizes this growth. Placental lactogen may, in some species, also stimulate alveolar formation but in the cow relatively little enters the maternal circulation.

During the period of allometric growth just prior to puberty the administration of exogenous somatotropin to heifers appears to promote an increase in mammary parenchyma. It is known that excess energy consumption during the period of allometric growth in heifers offered a high plane of nutrition results in lower mammary secretory tissue weight and is also associated with low milk production during subsequent lactation. It has been suggested that these effects of overfeeding

during this critical phase of mammary development may in fact be caused by a decrease in endogenous levels of somatotropin, as has been observed during high plane feeding. Thus the interplay between nutritional management and hormonal balance during mammogenesis may have important consequences for subsequent production.

Mammary development is partly reversed during advancing lactation when gradual involution occurs. These effects become more pronounced during the dry period. A period of non-lactation between successive lactations is an essential prerequisite for maximal milk production. Milk yields in the next lactation are definitely impaired if cows are dry for less than six weeks. On the other hand there is little or no advantage to be gained in terms of an increase in subsequent lactation yield by extending the dry period to more than eight weeks.

Lactogenesis

The initiation of milk secretion (lactogenesis) in all mammals is closely coordinated with parturition. Parturition itself involves a complex interplay of endocrine controls with marked differences between species. There are two general concepts as to what constitutes the main lactogenic trigger, the positive stimulus of lactation-promoting hormones and the release from the inhibitory effects of progesterone. A peak in blood prolactin levels coincides with, but is not essential for, parturition. Suppression of prolactin release in cows inhibits the final stages of secretory cell differentiation and results in reduced milk yield. Thus elevation of prolactin (together with adequate amounts of adrenal corticoids) and the permissive effect of progesterone

withdrawal, appear to provide the main lactogenic stimulus in the cow. An additional feature may be the removal near term of a locally produced inhibitory factor (possibly prostaglandin F_{2α}).

Lactogenesis requires the preferential supply and uptake of nutrients by mammary tissue. Nutrient availability is enhanced by the disconnection of the fetal supply at parturition and increases in mammary blood flow and local selective nutrient uptake become evident.

Milk synthesis and secretion

The constituents of milk are synthesized mainly from small molecules absorbed from the blood, specific carrier systems probably assisting their entry into secretory cells. The blood supply provides not only precursors for milk synthesis but also adequate energy-yielding substrates to drive the synthetic processes.

Lactose (milk sugar) is a disaccharide composed of one molecule of glucose and one of galactose. In bovine

milk its concentration, at about 4.8 per cent, is the most consistent of any constituent due largely to its influence in maintaining the osmolality of milk. Blood glucose is the main precursor of lactose but small amounts may also be formed from amino acids, glycerol and acetate. The final enzyme-catalysed step in lactose synthesis from glucose involves an enzyme, 'lactose synthetase', which is unique to mammary tissue. This is composed of two protein components and the availability of the second component, α-lactalbumin (a milk protein), determines the rate of synthesis of lactose, which occurs in the Golgi membranes of secretory cells.

Milk protein synthesis involves the assembly of different amino acids in a specific order along a chain. It takes place in the ribosomes of the rough endoplasmic reticulum (RER in Fig. 22.8) of secretory cells, proteins destined for secretion being released into the lumina of the endoplasmic reticulum. Total amino acid nitrogen uptake by mammary tissue entirely accounts for the output of nitrogen in milk protein. However, the proportions of different amino acids absorbed by the glands are at variance with their appearance in milk

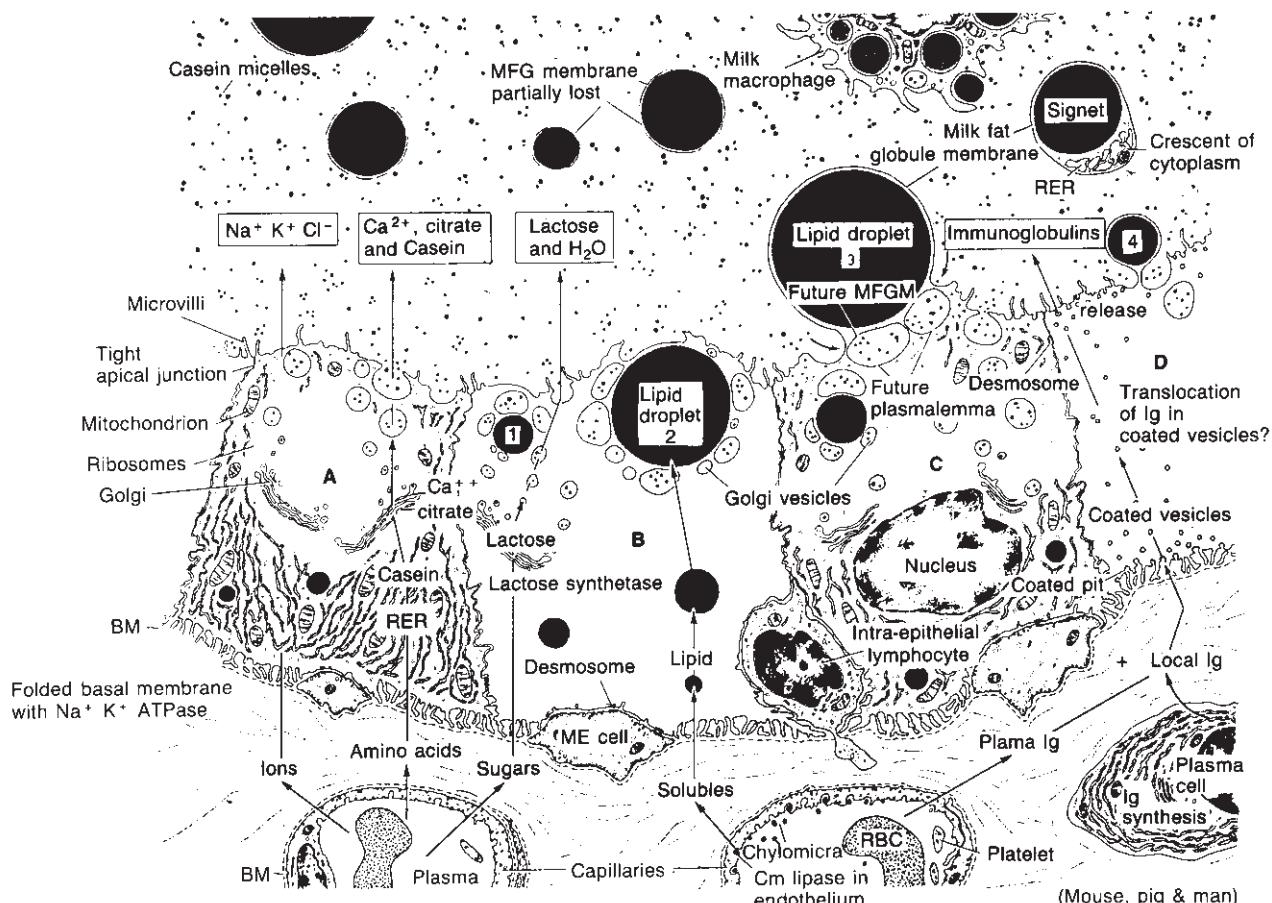

Fig. 22.8 Mammary alveolus secretory pathways. RBC, red blood cell; Ig, immunoglobulin; RER, rough endoplasmic reticulum; BM, basement membrane; MFG, milk fat globule; MFGM, milk fat globule membrane (diagram by E.H. Batten).

protein, indicating that some are metabolized while others are synthesized by mammary tissue. The majority of milk proteins are synthesized locally and are unique to milk (e.g. caseins). However, certain blood proteins and similar proteins synthesized by plasma cells adjacent to secretory epithelia are also transferred into lacteal secretions – in large amounts in colostrum (*see below*).

The fat content of bovine milk varies widely between and within breeds and is influenced by diet and environmental factors. The majority of milk fat is in the form of triglycerides, which are assembled in or near the endoplasmic reticulum of secretory cells using fatty acids and glycerol synthesized in the cytosol. Approximately half of the fatty acids in milk are derived directly from the blood – chiefly those greater than 14 carbons in length. *De novo* synthesis of fatty acids utilizes volatile fatty acids arising from rumen fermentation, fatty acid synthesis from glucose being negligible in ruminants. Acetate and β -hydroxybutyrate are important precursors and contribute mainly to the synthesis of shorter-chain fatty acids. The glycerol required for milk triglycerides is partly derived from hydrolysis of blood lipids and partly by synthesis from glucose. Esterification of fatty acids with glycerol is followed by aggregation of triglycerides to form the characteristic fat droplets of secretory cells.

The mechanisms for cellular release of secretion differ for the various components of milk. Instead of combining into a large exocrine granule typical of zymogenic and serous cells, milk protein remains separate as multiple small granules. These are visible only ultrastructurally and present a large surface area, which facilitates rapid digestion. Non-immune protein, such as casein, is delivered from the rough endoplasmic reticulum to the Golgi complex, where through the agency of lactose synthetase, lactose is added. This causes the vesicles leaving the Golgi to swell osmotically. As they rise through the supranuclear cytoplasm the vesicles become tightly clustered around the sides of the lipid droplets, which lie free in the cytoplasm and may be up to $5\mu\text{m}$ in diameter. Subsequently, membranes of the more superficial vesicles fuse with the apical plasma membrane and their content of protein, lactose, calcium and fluid is emptied into the alveolar lumen by conventional exocytosis. As the vesicles successively discharge, their inner walls remain over the surface of the protruding lipid as the milk fat droplet membrane. Ultimately undercut by the fusion of membranes between the lowest vesicles, the milk fat droplet is liberated into the lumen without damage to the cell and in a manner reminiscent of the shedding from an erythroblast of a pyknotic nucleus of comparable size.

The process of milk fat release is best termed micro-

apocrine, since it does involve some loss of cell components – the membrane investing the lipid and beneath it usually a thin veil of cytoplasm, as illustrated in Fig. 22.8. About 5 per cent of droplets are signet-shaped, with a crescentic fragment of cytoplasm containing a few mitochondria or short profiles of rough ER. Immune proteins, such as various immunoglobulins arriving via the blood or derived from local plasma cells, are taken into the cell base by receptor-mediated endocytosis into coated vesicles, translocated through the cytoplasm and released at the apical membrane.

Mature milk is characterized by a high concentration of potassium and a relatively low sodium concentration similar to the situation within the secretory cells. Milk is 86 per cent water. The amount of water (and hence milk volume) is determined largely by the rate of lactose secretion since lactose is not reabsorbed across epithelial cell membranes and it exerts an important osmotic 'draw' within the milk duct system.

Milk ejection

In the interval between milkings, milk continues to be synthesized and secreted at a more or less constant rate into the alveolar lumina and thence to the large collecting ducts and sinuses. The resistance of the teat sphincter retains the milk in the sinuses but much of the milk remains within alveoli and will not flow out passively even when the teat sphincter is patent. Forcible expulsion is, therefore, required to remove this alveolar milk from the gland. Milk ejection is under neuroendocrine control.

The milk ejection reflex involves stimulation of nerve receptors in the skin of the teat. Mechanical stimulation triggers an impulse in afferent mammary nerves. This impulse is transmitted via the spinal cord and ultimately arrives in the posterior hypothalamus. Specialized neurones in this region synthesize oxytocin (a peptide hormone) and a carrier protein. In addition to receiving the afferent excitatory stimulus originating from the teat, the neurones also receive facilitatory and inhibitory impulses that arise in other parts of the brain. If the net result of these impulses is stimulatory, neurosecretory granules are released into blood capillaries from axons that terminate in the posterior pituitary. Thus following mechanical stimulation of the teats of cows, oxytocin increases rapidly in the blood, reaching a peak within 2 minutes.

In mammary tissue, contractile myoepithelial cells form a basketwork surrounding the alveoli. Oxytocin in mammary blood binds with high affinity to receptor sites on myoepithelial cells (Fig. 22.4), resulting in contraction of the cells and expulsion of the milk from the alveoli.

Although sucking and milking are the most potent and natural stimuli to elicit the milk ejection reflex, udder washing and even visual and auditory cues associated with milking routines can substitute, as the reflex becomes conditioned by experience. Stressful stimuli which involve the release of catecholamines and activity of the sympathetic nervous system can have negative influences on oxytocin release, mammary blood flow and oxytocin binding to myoepithelial cells, thereby inhibiting milk ejection. Myoepithelial cells also contract to an extent in response to direct mechanical stimuli, independently of oxytocin release. Palpation of the udder (or butting by calves) may trigger this local so-called 'tap reflex'.

Galactopoiesis

Frequent milk let-down and its removal from alveolar lumina assists in the maintenance of milk production (galactopoiesis) by preventing 'end product inhibition'. Nevertheless, the continued secretion of milk also depends on a continued hormonal drive, which induces and maintains the synthetic enzyme complement of secretory cells and also ensures an adequate supply of substrates. The chief hormones implicated in the maintenance of lactation are different from those responsible for lactogenesis.

The essential role of the pituitary gland in the maintenance of lactation in all mammals has long been recognized. The roles of the various pituitary hormones have been revealed by studies on hypophysectomized animals with hormonal supplementation or by the use of specific antagonists. In most species (i.e. rabbits, pigs, dogs, humans) prolactin has been identified as the key galactopoietic hormone and suppression of prolactin secretion by bromocriptine has a rapid effect in inhibiting milk secretion. In ruminants, however, suppression of prolactin secretion has only a partial (sheep) or no inhibitory effect (cows, goats) on lactation. In these species, somatotropin (pituitary growth hormone) provides the main galactopoietic stimulus. The dose-dependent stimulation of milk yield in dairy cows that follows administration of somatotropin has been known for many years. With the advent of recombinant DNA technology, commercial exploitation of this effect is now practicable and our knowledge of the role of somatotropin has increased as a result of the considerable recent research on this topic.

The release of somatotropin into circulation from the anterior pituitary is under the influence of various hypothalamic peptides that arrive in the hypophyseal portal blood supply; these include a specific somatotropin releasing hormone and an inhibitory peptide, somatostatin. Thyroid hormone releasing hormone also enhances somatotropin release and synergizes with the

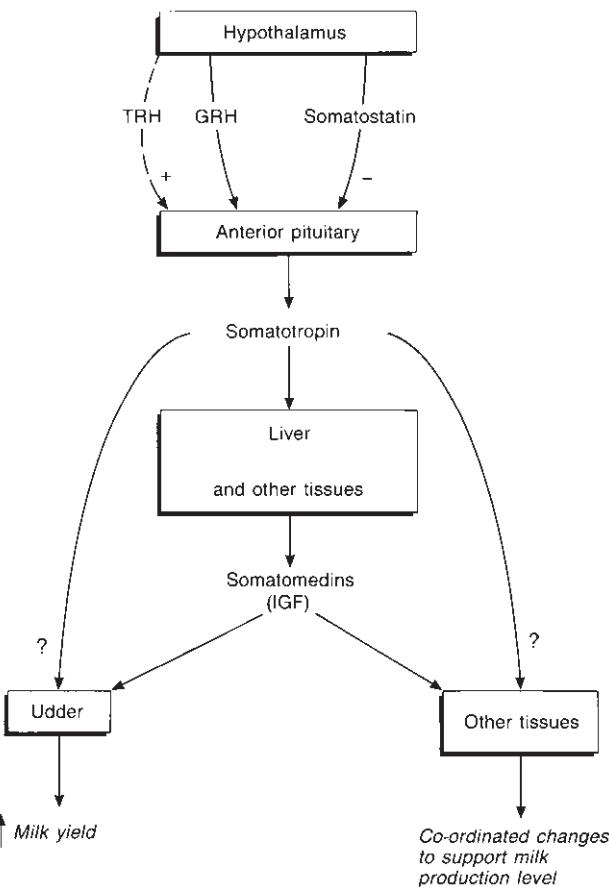

Fig. 22.9 Regulation of somatotropin release and its effects on milk production. TRH, thyroid hormone releasing hormone; GRH, growth hormone releasing hormone; IGF = insulin-like growth factor.

action of the specific releasing hormone. A direct effect of increased levels of somatotropin is the induction in the liver and other organs of the synthesis of other peptides known as somatomedins or insulin-like growth factors (IGFs). IGFs in turn appear responsible for mediating many of the effects attributed to somatotropin (Fig. 22.9).

It seems likely that somatotropin does not exert its galactopoietic effect by direct stimulation of the udder. Rather it acts by partitioning available energy away from body tissues and towards milk production but the increased yield is not merely a passive response to an increased nutrient supply. There is also an increased synthetic activity per secretory cell. Administration of somatotropin also elevates cardiac output and mammary blood flow. It is considered that this increase in blood flow is, at least in part, a consequence rather than a cause of the increased activity of mammary tissue.

The metabolic effects of administering supplementary somatotropin to dairy cows are well documented.

In early short-term studies, acute responses of hyperglycaemia ('diabetogenesis') and elevation of circulating free fatty acids ('lipolysis') were reported. In contrast, there is now substantial evidence from studies where somatotropin has been administered for long periods which indicates that the significant increases in milk yield are perfectly balanced by increased voluntary feed intakes and alterations in metabolism of body tissues such that steady-state concentrations of blood metabolites are maintained. These coordinated changes are consistent with the role of somatotropin as a homeorhetic control, allowing a substantial shift in the partitioning of nutrients to the mammary gland.

The key role of somatotropin in milk production is underscored by the evidence that cows selected for high genetic merit for yield show higher endogenous levels (basal and after stimulation) of somatotropin than low yielders. Furthermore, somatotropin levels decline with advancing lactation in line with milk production. Somatotropin levels are also influenced by nutritional status independently of these genetic effects. Underfed cows have generally higher somatotropin levels than those that are well fed, although this may be offset by a lower somatotropin responsiveness of the underfed animals.

Other hormones with a suggested role in galactopoiesis include adrenal corticoids and thyroid hormones. In most species adrenal corticoids are essential for lactation but there is little evidence that plasma levels are a limiting factor. Thyroxine and triiodothyronine may have a stimulatory effect on milk yield via effects on metabolic rate.

Immediate increases in milk yield can be obtained by commencing three times a day milking, which indicates that the secretory capacity of mammary cells can be increased. Frequency of milking does not appear to affect endogenous somatotropin levels. The mechanisms are not fully understood but may involve the removal of inhibitors.

Manipulation of lactation

The continuing steady increase in annual average milk yields of dairy cows is the result of judicious genetic selection and improvements in management, especially nutritional management. Experts expect these trends to continue for some years to come. However, a growing understanding of the physiological processes of lactation, together with advances in biotechnology, now make possible a variety of new ways to control and manipulate lactation.

Administration of somatotropin to prepubertal heifers has been shown to increase mammary parenchyma but whether this translates into increased milk yields is not yet clear. Nevertheless, optimal nutritional

management during this period is clearly of practical relevance in influencing mammogenesis and subsequent yield.

The hormonal manipulation of galactopoiesis has considerable commercial potential, both in a free market for milk products and for efficient quota management under a milk quota system. Biotechnology-derived somatotropin in prolonged-release formulations is already available for commercial use in some countries (see p. 1073). Endogenous somatotropin production may also be enhanced by administering releasing factors or by immunization of animals against their natural inhibitory peptide, somatostatin. Research into such approaches is under way.

Developments in direct genetic transfers between mammalian cells make possible the insertion of extra somatotropin genes which, if expressed, will enable cows to produce high endogenous levels of somatotropin. The genes might be triggered by an external stimulus such as a dietary factor. Such transgenic 'super cows' could be propagated rapidly using modern reproductive techniques. Transgenic techniques might also be employed to modify the characteristics of the milk constituents produced.

There are also opportunities for optimizing milking procedures to exploit physiological controls of lactation more fully. Further automation of the milking process culminating in robotic milking may permit milking several times a day and, with some sophistication, optimal prestimulation, stripping and individual quarter milking.

Immunology of the udder and teat

Immunity in the mammary gland may be divided into two systems (see Chapter 29). Firstly, a non-specific system that offers a first line of defence when a pathogen invades, and frequently is able to resist the invasion of a number of potentially infectious agents. Secondly, if the non-specific system fails, the tissues of the mammary gland can adapt and produce a specific defence against each infectious agent. Frequently this system, once developed, remembers the invading pathogen, which can be resisted by the specific defence system on a later occasion.

Non-specific immunity

Most infections of the mammary gland of the dairy cow enter through the teat canal so the teat provides a very important barrier to infection, particularly since its exterior surface is frequently exposed to a most contaminated environment. The defences of the mammary gland may be considered under several headings.

The teat canal as a mechanical barrier

The length of the teat canal has no effect on the susceptibility of cows to mastitis but it has been reported in the literature that teat ducts from quarters susceptible to infection had a larger diameter than those from resistant quarters. Differences in teat duct patency might be expected to correlate positively with ease of milking but a relationship between milking characteristics and the incidence of intramammary infection is not universally accepted. Teat ducts with a temporary patency, such that a continuous unbroken column of milk is maintained for some time after milking, may offer a means of entry for micro-organisms and a way in which they may be transported upwards through the duct. In capillary columns of milk at 37°C, micro-organisms are capable of rising rapidly in association with ascending milk fat globules. Any mechanism, therefore, that is likely to break the fat-rich milk column and prevent an upward passage of bacteria is likely to increase the mammary gland defences. Various suggestions have been made on how the teat duct closes, e.g. it may close in a spiral fashion 'wringing out' the last drops of milk, but as the streak canal has ridges arranged longitudinally a spiral wringing would not be effective. Teat canal keratin is a white wax-like material derived from the surface cells of the stratified squamous epithelium and which forms a network in the lumen of the canal, thereby trapping invading bacteria and disrupting the milk column. Another simple mechanical method of preventing organisms from penetrating the teat canal is the flushing action during milking. Organisms not adhering to the teat canal wall or the keratin mesh at the beginning of milking are soon flushed out. The higher infection rate of quarters at drying off has been attributed to the cessation of milking and the consequent failure to flush out pathogens. Later in the dry period, there is an increase in the antimicrobial properties of the canal, which may restrict bacterial multiplication.

Antimicrobial substances within the teat canal

Antimicrobial substances in the teat canal may contribute to the defence of the mammary gland. The antimicrobial role of esterified and non-esterified fatty acids, particularly myristic acid, palmitoleic acid and linoleic acid has been described. These fatty acids are present in the teat canal keratin and it was suggested that the unsaturated fatty acids were the most inhibitory.

Some proteins isolated from the teat canal also play an important role in the defence of the mammary gland. At physiological pH they carry a positive charge and

bind electrostatically to the mastitis pathogens which, at the same pH, carry a negative charge. The inhibiting effect of the various concentrations of these proteins has been demonstrated *in vitro* on the growth of staphylococci and streptococci. This antimicrobial activity of these proteins was not seen when micro-organisms were incubated with whole keratin under *in vitro* conditions. The cationic protein under these conditions would have already bound to other negatively charged molecules in the keratin. In the living animal continuous synthesis of these cationic proteins would overcome such binding. Despite the antimicrobial environment within the teat canal, local colonization by Gram-positive cocci has been reported, but the growth is very feeble with a low percentage viability.

Antimicrobial substances in mammary secretions

Non-specific antimicrobial substances in mammary secretions also contribute to the defences of the mammary gland. Lactoferrin is an iron-chelating protein which, in the presence of bicarbonate, inhibits the growth of micro-organisms having a high iron requirement. The activity of this protein is inhibited by the presence of citrate. Lactoferrin is thought to exert its most protective effects in the mammary secretions during the dry period when its levels are high compared with those in full lactation. These higher concentrations of lactoferrin may also influence the defences of the dry gland through the modulation of leucocyte functions.

Another antibacterial system present in milk involves the enzyme lactoperoxidase. This enzyme, in the presence of thiocyanate and hydrogen peroxide, can produce a short-lived highly oxidative system that is bacteriostatic for Gram-positive and bacteriocidal for Gram-negative organisms. Thiocyanate is present in milk, particularly in animals fed on diets containing legumes or brassicas. Doubt has been expressed in the past over the source of hydrogen peroxide (H_2O_2). Phagocytosing neutrophils are likely to be one source of H_2O_2 and some can be produced by the metabolism of catalase-negative organisms such as streptococci. Another enzyme present in milk, xanthine oxidase, may also contribute by generating H_2O_2 . Recent research has demonstrated that xanthine oxidase is present in the teat duct and secretory tissue of the bovine mammary gland. The action of xanthine oxidase on its substrate leads to a release of hydrogen peroxide, which is then available to the lactoperoxidase system.

In addition to the above, antimicrobial systems that operate locally within the teat canal are likely also to be operative in the milk itself and in deeper parts of the mammary gland. The role of lysozyme in bovine body fluids, including milk, is equivocal. Some authors doubt

its existence and, if present, the concentration would be extremely low, but possibly increasing in mastitis. As yet no defensive role has been ascribed to lysozyme in bovine tissues.

Antimicrobial cationic proteins, as found in the teat canal, may also be present in milk during mild inflammation. These proteins possess similar properties to the cationic proteins in the milk cells and are thought to have left the cells by a process of reverse pinocytosis.

Earlier methods used by many workers attempting to demonstrate haemolytic complement were too insensitive, but more recently a sensitive microassay revealed that low levels of haemolytic complement are present in milk throughout lactation, albeit usually masked by the anticomplement activity of the milk. Complement levels are highest in colostrum, in inflamed glands and in late lactation. A high correlation between the levels of serum albumin and the third component of complement during an inflammatory response suggests that complement components are passively transferred into the milk but this relationship is not seen in normal milk. Although the defensive role of the classical complement pathway remains in doubt it has been established that complement-sensitive organisms, such as some strains of *Escherichia coli*, are killed by the alternative complement pathway. *In vitro* tests, however, do not support this since serum-sensitive strains of *E. coli* can be grown in milk drawn from the udder. It is possible, however, that *in vivo* a very mild inflammatory response is needed to elevate slightly the serum-derived complement in milk.

Specific immunity: lymphocytes (see Chapter 29)

Lymphocytes are present in cows' milk at all stages of lactation and constitute 1–2 per cent of the milk cell population, which is low compared with that of human milk. Lymphocytes consist of T and B cells together with a population of lymphoid cells, which do not consistently carry markers of either T or B cells, the so-called null cells. The ratio of these cells (T:B:null) is similar to that in peripheral blood, but the percentage of B cells is slightly increased in dry gland secretions. Lymphocytes in mammary secretions are functionally competent, responding to mitogens and antigens. However, some responses of the T cells from mammary secretions to mitogens are lower than those of T cells from the systemic circulation. The precise reason for this difference in responsiveness is not clear, although it is known that mammary secretions contain soluble immunosuppressive factors that may be responsible. In addition, the T cell population in the mammary secretion may contain a greater proportion of suppressor cells which would inhibit responses.

Differences in the functional activity of T lymphocytes in blood and those in mammary secretions are evident as differing responses to specific antigens. Much of this work has been carried out using human mammary secretions and supports the view that lymphocytes in the mammary secretion form a distinct subpopulation. They belong to a mucosal immune system in which lymphocytes migrate from secretory surfaces of the body, e.g. the gut, to the mammary gland, but this is not the case in ruminants.

A similar migration occurs with B cells, but in the cow it has been suggested that following intestinal immunization there is a migration of antigen-stimulated IgG lymphoblasts and perhaps of antigen to the spleen and peripheral lymph nodes. This would be consistent with the appearance of serum-derived IgG antibodies in the colostrum and milk. When antigen is infused directly into the udder all classes of antibody, but particularly IgA and IgG₁, are produced locally from antibody-forming cells in the glandular stroma and in the regional supramammary lymph nodes.

Tissues in the terminal inner portion of the teat contain a high proportion of plasma cells, lymphocytes and macrophages, which may be involved in local immunity, and antibody-containing cells have been demonstrated in germinal centres in the distal Furstenberg's rosettes of the teat cistern (Fig. 22.7). Of the plasma cells in this region 88 per cent synthesize IgG₁, 10 per cent IgM while only a few synthesize IgA. The distribution of these cells does not change in relation to the mammary secretory activity.

Although the homing of lymphocytes to the mammary gland appears to be well established in some species, not all migrate into the secretions; in the rat mammary gland some remain in the alveolar and ductal epithelium. These intraepithelial lymphocytes are likely to be the predominating cell types infiltrating bovine mammary tissues and remain in association with the epithelia after a *Staphylococcus aureus* infection. Information from other species may reveal the precise identity and function of these cells. In humans a substantial proportion are T cells. Intraepithelial lymphocytes may form an important defence against infection at mucosal surfaces. Currently, there is a paucity of information on the role or even existence of natural killer (NK) and killer (K) cells in the bovine mammary gland; nevertheless, there is some evidence to suggest that lymphocyte activity in bovine mammary tissues may differ from that of other species.

Immunoglobulins in mammary secretions (see p. 380)

Milk contains most immunoglobulin classes in differing amounts that vary during lactation. IgG₁ is present in

Table 22.1 Immunoglobulin (mg/100 ml) to the blood and mammary secretions of the cow (from Lascelles, 1979).

| | IgG ₁ | IgG ₂ | IgA | IgM |
|----------------|------------------|------------------|-----|-----|
| Blood serum | 1400 | 1300 | 39 | 380 |
| Colostral whey | 1000–9000 | 250 | 470 | 540 |
| Milk whey | 40 | 6 | 11 | 9 |

the largest concentrations and it passes from the blood to the milk by a process of selective transfer. During inflammation of the udder, IgG₂ and other proteins are transferred from the blood. Some immunoglobulins such as IgM and IgA are locally produced and they arise from cells of the lymphoblast-plasma cell series that are located close to glandular epithelium in various parts of the mammary gland. The distribution of immunoglobulin classes in blood, colostrum and milk is shown in Table 22.1.

It will be noted from Table 22.1 that colostrum has a markedly higher concentration of IgG₁ than serum. This concentration is associated with the presence of specific receptor sites for this immunoglobulin on the membranes of bovine mammary epithelial cells. There are suggestions in the literature that the levels of IgA in milk and colostrum have probably been underestimated because much of the IgA is associated with milk fat globule membranes, and some IgM may also be globule bound. The precise origin of IgG₂ and IgA in the mammary gland of the cow remains in doubt. A local synthesis of IgG₂ has been reported in the cow but this was not confirmed in the ewe. There appears to be less disagreement concerning the origin of IgM and IgA, which are thought to be largely derived from local synthesis in the mammary gland of the cow, but in the ewe the synthesis of these immunoglobulins appears to be confined to the period of mammary involution whereas in early and mid-lactation large amounts are transferred from the blood.

Inflammation of the mammary gland leads to a rapid increase in levels of immunoglobulin and other serum proteins, including complement, within the first few hours. In this situation IgM and IgG₁, together with serum-derived complement, control the growth of serum-sensitive coliform organisms. Phagocytosis by neutrophils is more efficient if they are coated with specific IgG₂ antibodies.

The precise role of IgA in the mammary gland of the cow remains in doubt. Some workers believe that it may block IgG- or IgM-mediated complement fixation, in which case it would have detrimental effects on the protection of the mammary gland in early infection. On the other hand, it may activate complement, but this may not be of great importance due to the low levels of com-

plement in milk. There have been some reports that IgA antibodies assist the binding of bacteria to fat-globule membranes. This would hinder the mammary defence system by making the bacteria more difficult to phagocytose.

Phagocytic cell mobilization in the mammary gland and phagocytosis

The most effective system of udder defence against invading pathogens is the phagocytic activity of neutrophils. Normally, these cells are present in milk in very low numbers, the predominating leucocytes in the milk of healthy cows being macrophages and lymphocytes. Neutrophil numbers, however, rapidly increase in the very earliest stages of infection. The value of neutrophils in early infection was seen when unrestricted growth of bacteria occurred in the mammary gland of cows rendered neutropenic by the administration of anti-bovine leucocyte serum.

Neutrophil recruitment within the mammary gland is likely to be triggered by the presence of bacteria and bacterial products, which stimulate the formation of endogenous inflammatory mediators. These mediators lead to a margination of neutrophils in capillary vessels, cause a relaxation of endothelial cell junctions and allow a diapedesis of the neutrophils into the surrounding subepithelial connective tissues. The neutrophils in turn may release other inflammatory agents, further accelerating the process of neutrophil mobilization. The identity of the inflammatory mediators, which has been studied by a number of workers, includes prostaglandins produced by the cyclo-oxygenase pathway, and leukotrienes produced by lipo-oxygenation and interleukins. Prostaglandins have been measured in bovine milk and shown to increase in concentration from 4 hours after the administration of intramammary endotoxin. Prostaglandins are synthesized in bovine mammary tissue and may also be generated by neutrophils.

Pathogens entering the mammary gland and causing mastitis are rarely invasive. Therefore, if an antimicrobial environment is to be produced in the mammary gland neutrophils must be present in the teat and lactiferous sinus regions, the ducts and in the alveolar lumen. Milk collects in the teat and lactiferous sinus regions and it is thought that neutrophils are attracted as far as the luminal surface of the two-cell-thick epithelium by a concentration gradient of chemotactic factors originating from the lumen of the gland. Under these conditions, the neutrophils pass through the basement membrane and between the epithelial cells (Fig. 22.5). In severe staphylococcal infections the surface cells suffer toxic damage and in some cases this leads to large areas of epithelial erosion. Infections with *E. coli*

frequently lead to more localized toxin-induced epithelial lesions and it is from these regions that the neutrophils migrate into the lumen.

A rapid neutrophil migration is essential for the efficient defence of the mammary gland following *E. coli* invasion, but particularly if the response occurs before the bacterial count in the milk exceeds 10^4 /ml. Some cows, however, particularly if recently calved, fail to recruit neutrophils into their milk, and this leads to an unrestricted bacterial growth and severe damage within the mammary gland tissues. This situation may not be observed clinically since there may be a complete lack of inflammatory reaction. Nevertheless, these animals soon become severely ill and death may follow. Frequently, cows respond with a neutrophil recruitment but there is often a delay such that bacterial numbers may increase to a high level. Bacteria and neutrophils may then coexist in the mammary gland resulting in a protracted mastitis.

A rapid neutrophil response is also beneficial for controlling the growth of *Staphylococcus aureus* in mammary tissues, thereby preventing severe disease. A complete elimination of these organisms, however, rarely occurs and frequently a chronic subclinical disease remains in which small numbers of organisms are present in the milk, which has a permanently elevated cell count. These chronic infections may not be immediately obvious to the herdsman due to the very low grade inflammatory response in the tissues.

In any consideration of the immunology of the bovine mammary gland, availability of opsonins to permit the efficient phagocytosis of invading pathogens must be considered. The effector mechanisms of the phagocytes in the mammary gland may be activated by the Fc region of one or more classes of immune globulin and/or by fragments of the complement system bound to particles. Phagocytic cells have receptors for opsonins, where the opsonin is recognized and binds. This is linked with an effector unit that triggers the cell function. Different species of animals have different specificities for their receptors for different classes of immune globulin. Non-ruminant neutrophils have not been shown to bind to cytophilic antibody but cytophilic IgG₂ is active for ovine neutrophils and increases the bacteriocidal activity against *Staphylococcus aureus*. IgG₂ from immune bovine serum or milk whey will opsonize *E. coli*. Furthermore, the major

opsonin for neutrophil phagocytosis of mammary gland pathogens using decomplemented non-immune bovine serum is IgM.

Introduction

Mastitis is the most prevalent infectious disease of adult dairy cattle. Several species of bacteria, fungi, mycoplasmas and algae have been isolated from the natural disease or have been shown to reproduce it experimentally. The predominant species are listed in Table 23.1. Furthermore, many clinical cases of mastitis that are due to infection are negative on bacteriological culture of the mammary gland secretion (Dairy Federation 1987a).

The inflammation, characteristic of mastitis, may be undetectable without the use of diagnostic tests applied to the milk or secretion. This is termed subclinical mastitis. Subclinical mastitis results in raised somatic

cell counts in affected animals. This can result in a raised somatic herd cell count. It is essential to maintain a low cell count in order to comply with statutory milk quality requirements, e.g. the EU requires all milk to be under 400 000 cells/ml, and to ensure that there is no penalty to milk price. In the UK, many farmers with cell counts over 150 000/ml are penalized.

The subclinical stage may be prolonged or proceed rapidly to clinical mastitis in which external signs of disease such as swelling and hardness of the affected gland(s) or clots or discolouration of the secretion are present. Nevertheless, the subclinically infected quarter has a lowered milk yield, altered milk composition and excretes the infecting organism. Subclinical mastitis is a major element in the worldwide economic loss associated with mastitis, which exceeds £ $\frac{1}{2}$ billion annually.

Dynamics of herd infection

Figure 23.1 illustrates the dynamics of udder disease within the herd. The mammary glands can be placed in one of three categories: uninfected, subclinically infected or clinically infected. The relative proportions of animals in these categories vary between herds. Pathogen type also influences the dynamics. For example, coliform infections tend to become rapidly clinical while *Staphylococcus aureus* infections often persist as subclinical infections for weeks or months. Clinical mastitis will usually be treated with antibiotic therapy and the clinical cure rates are variable and will depend on the pathogen. Bacteriological cure rates vary from 90 per cent for most coliform infections to as low as 25 per cent with *Staphylococcus aureus* in older cows.

The mammary gland has a range of defence mechanisms of which phagocytosis of invading organisms by polymorphonuclear leucocytes is probably the most important. Spontaneous elimination of infection by these mechanisms will occur. The rates of spontaneous elimination are low for staphylococcal infections (<20 per cent), high for *Escherichia coli* (>70 per cent) and intermediate for streptococcal infections.

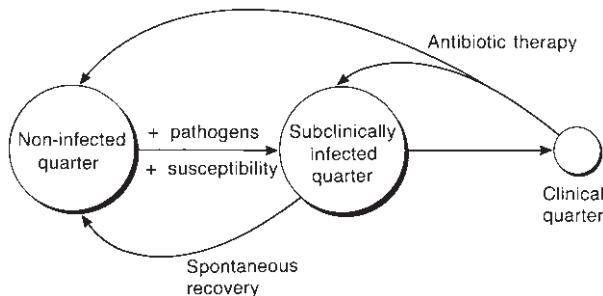

Fig. 23.1 Pattern of intramammary infection and clinical mastitis in a dairy herd.

Effects of lactation age and stage

Udder infection may develop when the cow is lactating or dry. Infection rates are highest in the early dry period although these infections may not persist or develop into clinical mastitis until the next lactation. Clinical mastitis is most common at calving and in the first three months of lactation. The incidence of clinical disease and new infection may increase with lactation number. An example for coliform mastitis incidence by stage of lactation is shown in Table 23.2.

The precise reasons for these effects of age and stage are not known. The high incidence of mastitis around calving is largely a consequence of high new infection rate in the dry period and a periparturient suppression of host defences. Increasing disease with age is probably not due to increased intramammary susceptibility but to increasing ease of penetration of the teat duct by pathogens and accumulated previous infections.

Teat canal

The teat canal is the primary defence mechanism between the semisterile udder and the outside envi-

ronment. The bovine teat canal varies in length from 4 to 18 mm, with a median of 12 mm. It has a heavily keratinized surface and the keratin lining is crucial to the maintenance of its barrier function (Plate 23.1). Keratin traps bacteria as they try to penetrate the teat canal. Excess keratin is removed by shear forces during the milking process and this is a normal event. If there are poor shear forces, excess keratin and bacteria are not removed and may grow up and invade the udder. The barrier function has both physical and chemical elements. Antibacterial lipids and basic proteins have been identified within the keratin lining of the teat duct (Williams & Mein, 1985).

The diameter of the canal and the depth of the keratin layer have been shown to be positively and negatively correlated with infection respectively. Certain defects in machine milking operation can adversely affect the defensive properties of the teat duct, increasing mastitis incidence (see section on machine milking, p. 331 and Chapter 26). Any damage to the teat end or teat canal is likely to increase the likelihood of new infections. This will occur due to a weakened physical barrier and also the increased bacterial colonization on the damaged teat canal.

Colonization or infection of the streak canal, particularly adjacent to the teat orifice, is common with pathogens such as *Staph. aureus* or *Streptococcus dysgalactiae*. Such colonizations may persist for long periods in the absence of intramammary infection but are largely prevented or eliminated by postmilking teat disinfection. Other organisms are often present within the teat duct including *Corynebacterium bovis* and coagulase-negative staphylococci and there are reports of the isolation of anaerobes. The environmental organisms, such as coliforms and *Strep. uberis* rarely colonize the teat duct and this difference is important in the pathogenesis of infection.

Transmission, sources and control of udder pathogens

Broadly, the micro-organisms causing bovine mastitis can be partly classified into two groups: contagious and environmental.

Contagious mastitis: The udder and teats are the reservoir of infection. Transmission occurs during the milking process or udder preparation by contaminated hands, udder cloths and liners. Infection establishes on the surface of the teat and teat canal. Bacteria may then penetrate the mammary gland. Most infections are subclinical and result in raised cell counts. Control measures include postmilking teat disinfection, dry cow therapy and culling. Contagious bacteria include *Staphylococcus aureus*, coagulase negative *Staphs*, *Streptococcus agalactiae* and *Strep. dysgalactiae*. If a herd somatic cell count is over 200 000/ml then this indicates that there is a problem with contagious mastitis. Careful application of control measures based upon teat disinfection and dry-cow antibiotic therapy will eradicate *Strep. agalactiae* over the course of one to two years provided infected animals are not introduced into the herd. *Strep. agalactiae* can also be eliminated through the use of 'blitz' intramammary treatment during lactation and these bacteria are very sensitive to any of the penicillin antibiotics. Levels of *Staph. aureus* and *Strep. dysgalactiae* will also fall to low levels. In some herds, poor elimination rates of staphylococcal infection by therapy will require the heavy culling of chronically infected animals to achieve rapid progress.

Environmental mastitis: The environment is a reservoir of infection. Infections are transmitted onto teats between milkings or during udder preparation. Organisms are forced up through the teat canal during the milking process or after milking if cows are allowed to lie down immediately following milking. Most infections cause clinical mastitis. Sub-clinical infections are less common with *E. coli*, but frequently occur with *Strep. uberis*. Environmental mastitis is controlled by provision of a clean environment, adequate accommodation for cows, milking through correctly functioning machine, good udder preparation and pre-milking teat disinfection. Environmental organisms include *E. coli*, *Streptococcus uberis* (straw bedding), *Klebsiella* spp. (sawdust and shavings) and *Bacillus* spp. Although there is potential for interquarter transfer at milking time it appears not to be the predominant infection mechanism. Postmilking teat disinfection does not prevent infection. Antibiotic therapy has some benefi-

cial effects on coliform mastitis prevention but does reduce the rate of new dry-period infection with *Strep. uberis*.

Environmental mastitis is controlled through good environmental management, a good milking routine, an efficient milking machine, vaccination against coliform mastitis and premilking teat disinfection.

Diagnosis of clinical mastitis

The detection of clinical mastitis depends upon the examination of the mammary gland and its secretion. The affected gland may show swelling, heat, pain and/or hardness. The secretion may be clotted, serous or, occasionally, bloodstained (Plate 23.2a,b). In acute cases systemic signs of disease may also be present including pyrexia, anorexia and occasionally recumbency in toxic *E. coli* and *Staph. aureus* infections. Examples are shown of the clinical changes in Plate 23.2 (c,d).

Clinical disease is most commonly seen in lactating animals, particularly in early lactation, but may develop in the non-lactating gland also. Because the dry animal is rarely closely scrutinized some of these cases remain undetected until calving. 'Summer mastitis' is an acute disease of the non-lactating mammary gland and may affect cows, heifers or young calves. Characteristically, it is caused by mixed infection with *Arcanobacterium pyogenes* and anaerobic bacteria, commonly *Peptococcus indolicus*.

It is important (and in many countries statutory) that dairy cows are examined before each milking for signs of clinical mastitis. This allows abnormal milk to be discarded and the affected animal to be given therapy as rapidly as possible, thereby reducing tissue damage and giving higher cure rates, and minimizing the risks of infection transfer. Discarding mastitic milk also helps to protect the herd somatic cell count and bactoscan or TBC. An alternative to examination of the foremilk for abnormalities during preparation for milking is to use in-line filters, installed in the long milk tube to screen the total milk produced. Disadvantages of this approach are that (i) not all cases of clinical mastitis result in the formation of clots that are trapped in the filters; (ii) the affected quarter(s) have to be identified by an additional examination of the stripplings milk; (iii) the abnormal milk may have passed to the bulk supply prior to detection, particularly in direct-to-pipeline milking systems and (iv) many milkers fail to check the filters. Palpation of the udder after milking also aids clinical mastitis detection but the increase in cows milked per person hour and the provision of automatic cluster removers have precluded this process in many parlour operations. Some milking equipment contains

sensors to aid the detection of abnormal milk and this is likely to become more common.

Diagnosis of subclinical mastitis

A range of tests can be applied to milk to detect sub-clinical mastitis (Schultze, 1985). These tests generally measure the somatic cell count or detect the presence of infecting organisms. These changes are both cytological and biochemical. Most tests are laboratory based although the California Mastitis Test (CMT) and electrical conductivity measurements can be used at the cow side. Tests can be placed in three categories and applied either alone or in combination.

Cytological examination (see p. 323; Chapter 25)

Milk from a healthy, uninfected bovine mammary gland contains somatic cells comprising macrophages, neutrophils and lymphocytes. The number of these is usually <50000 cells/ml milk. When mastitis is present the cell count increases, primarily as a consequence of neutrophil infiltration. Subclinically infected quarters have cell counts in excess of 20000 cells/ml but, because of the dynamic nature of the disease, this value can vary considerably and will sometimes fall below this threshold (Table 23.3).

During clinical episodes the cell count will be elevated, counts in excess of 5000000 cells/ml being commonplace. The cell count is detectable by a microscopic count or by electronic means. Detailed descriptions of the methods employed are available (Dairy Federation, 1984). An indirect estimate of cell counts can be made

Table 23.3 Variation in the cell count of a quarter infected with *Staph. aureus* compared to an uninfected quarter in a Friesian heifer.

| Milking No. | Somatic cell count C × 1000 cells/ml | |
|-------------|--------------------------------------|------------------|
| | Control quarter | Infected quarter |
| 1 | 13 | 424 |
| 2 | 80 | 3943 |
| 3 | 64 | 528 |
| 4 | 84 | 4046 |
| 5 | 44 | 797 |
| 6 | 91 | 4540 |
| 7 | 107 | 1471 |
| 8 | 61 | 1446 |
| 9 | 64 | 528 |
| 10 | 84 | 4046 |

using a variety of tests such as the CMT or Whiteside test. These tests are based upon a gelling reaction between the nucleic acid of the cells and a reagent, either a detergent (CMT) or sodium hydroxide (Whiteside). The reactions are categorized from 0 to 4. Reactions of 3 and 4 have a high probability of infection being present. The advantage of the count is that the results are available immediately, are repeatable, cheap and give an individual quarter result. Many countries employ cell counting of herd bulk milk as an estimate of herd mastitis levels. Individual cow milk cell count services are available in many countries as an intermittent or regular service (e.g. National Milk Records in England and Wales and the Dairy Herd Improvement Association in the USA). A consistently high bulk milk cell count is characteristic of a high level of subclinical infection in the herd. Herds with counts <200000 cells/ml generally have little economic loss associated with subclinical disease. Such herds may however still suffer significant costs due to a high incidence of clinical mastitis, associated with short-duration infections such as coliforms.

Bacteriological examination

The secretion from a normal mammary gland is sterile although it may acquire bacteria from a colonized teat duct during collection. Therefore, the detection of a pathogen in an aseptically collected milk sample is indicative of infection. The number of organisms excreted per millilitre of milk from an infected gland fluctuates widely; hence the recovery of even low numbers of bacteria can be regarded as meaningful if the sample has been taken with adequate care and is not contaminated. Bacteriological examinations have the advantage of being positive or negative, whereas most other tests require the imposition of a threshold value which varies between animals and herds (Dairy Federation, 1987a).

A suitable sample is required for bacteriological examination obtained by an aseptic technique. Samples can be frozen (-20°C) prior to examination although this reduces pathogen numbers (particularly Gram-negatives) and precludes cytological and some biochemical examinations. The bacteria most commonly causing bovine mastitis will grow aerobically on blood agar. The more unusual causes of mastitis such as anaerobes, *Mycoplasma* spp. and *Leptospira* spp. require more specialized techniques not appropriate to the practice laboratory. The inclusion of 0.1 per cent aesculin in the blood agar is useful in the differentiation of *Strep. uberis* from other streptococci. A volume of milk is spread over the surface of the agar plate, which should be incubated for 24–48 hours at 37°C. An

advantage of a bacteriological examination is that the causative organism can be identified and provides a possibility for antimicrobial sensitivity testing. Some organisms such as *Staph. aureus* may be shed intermittently and in small numbers in milk. With these infections, a negative result may indicate that the bacteria have not been isolated due to a dilution effect. Repeat sampling may be necessary in order to confirm a negative result. Disadvantages include cost, complexity and time delay. Detailed methods for the collection and bacteriological examination of milk samples for infection are available (Dairy Federation, 1981).

Biochemical and other tests

Inflammation of the mammary gland leads to a variety of compositional changes in milk either because of local effects or because of an increase of serum components entering the milk. Some of these changes can be used to screen for subclinical mastitis.

Significant changes in ionic composition occur with both Na^+ and Cl^- levels increasing, K^+ decreasing. The individual ions can be directly determined but more commonly the net change in ionic composition is used, measured as an increase in electrical conductivity. Both laboratory and farm-based meters exist and milking equipment incorporating electrodes to measure milk conductivity during milking is marketed in some countries. There are a variety of other factors which may affect electrical conductivity such as oestrus. The majority of electrical conductivity meters work on pooled milk from all quarters and are unlikely to be very accurate due to a dilution effect. However, as for the majority of the milk parameters, the conductivity values of normal and infected quarters overlap and conductivity values vary between herds. These facts make the application of threshold values for diagnosis inaccurate. A fall in lactose concentration is also usual and has been employed diagnostically but has poor discrimination.

Enzymatic changes also occur. Some of the enzyme changes are associated with the increase in cell count (e.g. catalase), others with secretory cell damage (e.g. part of *N*-acetylglucosaminidase (NAG) increase) or with increased permeability (plasmin). The use of NAG has been widely tested and found to correlate well with cell count and infection and offers promise as a cow-side test.

As serum components leak into the mastitic gland they can be employed as indicators of inflammation. The most studied have been antitrypsin and bovine serum albumin (BSA). Automated methods for the detection of antitrypsin have been developed and the test is more sensitive than BSA. Table 23.4 summarizes the major compositional changes in milk due to udder infection and inflammation. For more detail of these

Table 23.4 Changes in milk composition associated with mastitis (examples of 'typical values').

| | Somatic cells (1000) | |
|------------------------|--------------------------------|--------------------------------------|
| | Normal <20 to 75 | Mastitic 100 to >10000 |
| Sodium (mg/100ml) | 57 | 104 |
| Chloride (mg/100ml) | 100 | 200 |
| Potassium (mg/100ml) | 170 | 150 |
| Conductivity (mM NaCl) | <50 | >56 |
| Lactose (mg/ml) | 48 | 44 |
| Catalase | | increased 20-fold |
| NAG | | increased 6-fold |
| BSA (mg/ml) | 0.25 | >0.6 |

NAG, *N*-acetyl glucosaminidase; BSA, bovine serum albumin.

tests and their application the reader is referred to Schultze (1985).

Use of individual cow or quarter sampling in herd investigations

Mastitis control relies upon the application of effective control measures to the herd rather than identification or special treatment of individual animals. It is essential to identify the organisms responsible for the problem and in high cell count herds, the proportion of cows infected. This requires bacteriology and individual cow cell count data which will help to identify the nature of a herd problem or individual animals for segregation or culling. As payment of milk on the basis of cell count becomes more common then the emphasis placed on these systems tends to increase.

If the aetiology of clinical mastitis is to be determined then a microbiological analysis is needed. Such analyses provide information on the patterns of the disease within a herd since there will be delay between sampling and diagnosis during which therapy will usually have begun. Often a broad-spectrum antibiotic is employed to cover the range of possibilities. However, the pattern of disease may be helpful in determining the attention needed to remedy the herd problem. The isolation of *Strep. agalactiae* indicates either that teat disinfection and dry-cow therapy are not being employed effectively or infected animals have been introduced. A pattern of high herd cell count, repeated clinical cases and the frequent isolation of *Staph. aureus* would be typical of poor elimination of infection by lactation or dry-period therapy. This might prompt the use of bacteriological analysis of samples taken after treatment or at drying-off and calving.

Individual cow cell count or other diagnostic tests can be used to identify chronically infected animals for culling, treatment during lactation and other options, although such animals might be identifiable via an examination of clinical records. In the majority of herds the records are unfortunately inadequate for such a purpose. When using individual cow cell counts or other indirect tests the variation in inflammation should be remembered. Confident diagnosis on a single sample is not possible. The changes in these measures due to lactation stage and yield are also relevant. Cell counts in colostrum and in dry-cow secretion are naturally elevated and diagnostically unreliable. As lactation declines and yield falls cell count and electrical conductivity increase slightly. Milk composition and cell count may remain permanently altered or elevated in glands that have suffered severe secretory tissue damage, even if the causative organism has been successfully eliminated (see Chapter 25).

Cattle housing and mastitis

In many countries climatic conditions require that cattle are housed for at least part of the year with consequences for mastitis. In some countries cows are housed all year round. Housing increases the risk of mastitis because the confinement of the animals and the multiplication of micro-organisms in various litters elevate teat challenge, and consequently mastitis. Prominent among these bacteria are the coliforms, *Strep. uberis* and faecal streptococci.

The relationship between housing and mastitis is most clearly established for coliform mastitis. Coliform bacteria have been shown to multiply readily in organic litters, particularly sawdust, reaching counts of >100 million/g. These numbers often exceed those found in bovine faeces and impose a risk of infection. Sawdust has been shown to act as a source of *Klebsiella pneumoniae*, particularly if not kiln-dried, and can lead to severe mastitis problems. Some outbreaks have been controlled by switching from sawdust to sand, which tends to harbour lower numbers of coliforms and reduces the risk of disease.

Streptococcus uberis colonizes the bovine gut and is excreted in faeces and consequently contaminates cattle litter. In straw, multiplication of the organism often occurs leading to high levels of teat challenge and increased infection rates (Bramley, 1982). Since *Strep. uberis* is particularly infectious for the non-lactating or parturient udder this can be a particular problem if dry-cow or calving accommodation is not adequately cleaned and bedded.

Since multiplication in the litter is a crucial factor in increasing challenge to the teat surface, regular removal

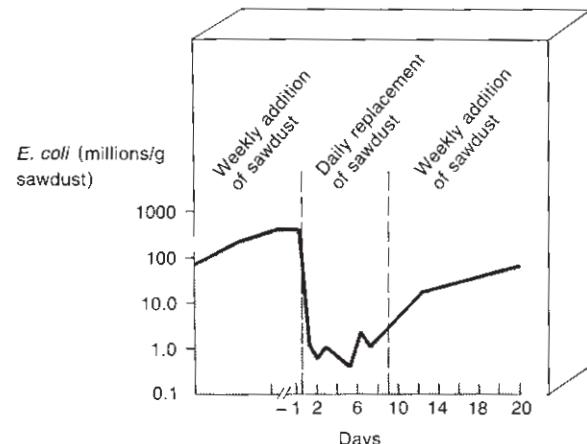

Fig. 23.2 Controlling coliform contamination of sawdust in cubicles by daily removal and replacement.

and replacement of bedding offers the soundest basis for reducing it (Fig. 23.2; Dodd *et al.*, 1984). Herds which house cattle in straw yards should clean these out every 4 to 6 weeks. In mild weather, this may need to be reduced to every 3 to 4 weeks.

The climate within cattle housing is also important since high humidity favours the survival and multiplication of micro-organisms. It has been found that cattle litter generally appearing to be clean and dry can harbour high numbers of micro-organisms and this can pose significant problems when giving advice over herd mastitis problems.

The design and size of yards and cubicles influence cow cleanliness and thus milk bacteriological quality and mastitis. Cubicles that are too short will leave cows' udders lying in the alleyway while those which are too long will lead to dunging on the cubicle surface itself. Obviously, the correct dimensions vary depending upon breed and age. There should be 5 to 10 per cent more cubicles than cows. In loose housing, a lying area of 6 m² for a Holstein cow should be allowed. Overcrowding in loose yards will lead to an increase in environmental infections, in particular *Strep. uberis*. Improper placement of access gates and water troughs in yards will lead to excessively dirty lying areas. Use of dung channels and grids can increase the incidence of damaged teats, etc.

These and other ways in which the environment influences mastitis are the subject of a review by the International Dairy Federation (Dairy Federation, 1987b). Detailed information on suitable dimensions and designs for cattle housing are also available (pp. 42-4).

Machine milking and mastitis

There is unequivocal evidence that the events occurring at milking time influence the incidence of mastitis.

These influences may be via the hygiene practised at milking time or because of effects of the milking machine *per se*. For details on how the milking machine can affect mastitis see Chapter 26.

Milking hygiene

The milk secreted by infected cows contains varying numbers of pathogenic micro-organisms. Herd milking provides opportunities for the transmission of these bacteria between udder quarters and cows via the milking machine itself, the milker's hands or cloths.

Various techniques can be employed at milking time to reduce transmission including:

- (1) Using disinfected water for teat washing.
- (2) Employing individual paper towels or cloths for teat drying.
- (3) Wearing clean rubber gloves.
- (4) Applying a suitable disinfectant to the teat surface after milking.
- (5) Disinfecting or heat treating the cluster between milking cows.
- (6) Premilking teat disinfection.

In addition, segregation of infected animals from the healthy herd can be used although it is impractical in most herds and requires the use of individual cow cell counts or a similar test. The use of measures such as those described above can reduce infection rates by about 50 per cent, effects being greatest against *Staph. aureus*, *Strep. agalactiae* and *Strep. dysgalactiae* (Fig. 23.3). The measures are less effective against coliforms and *Strep. uberis* infection because of their wider distribution in the environment.

Of the various measures to prevent new intramammary infections among milking cows, postmilking teat disinfection is the most valuable. Various disinfectants are used, most commonly iodophors, chlorhexidine and hypochlorite. Emollients are often added to promote good skin condition and rapid healing of lesions. These disinfectants will rapidly destroy bacteria reaching the teat surface during milking and will prevent colonization of the teat duct and the infection of teat lesions. The speed of kill of the postmilking teat disinfectant is not important provided that it is effective. This is contrary to the action of premilking disinfectants which must have a rapid speed of kill. This fast action is required to avoid slowing down the milking procedure.

The importance of premilking hygiene in the production of milk of high bacteriological quality should be emphasized. Data show that effective washing of the teat followed by drying significantly reduces the bacterial content of bulk milk. Washing without drying will result in bacteria being put in suspension. This solution will be sucked in with the milk and increase the bac-

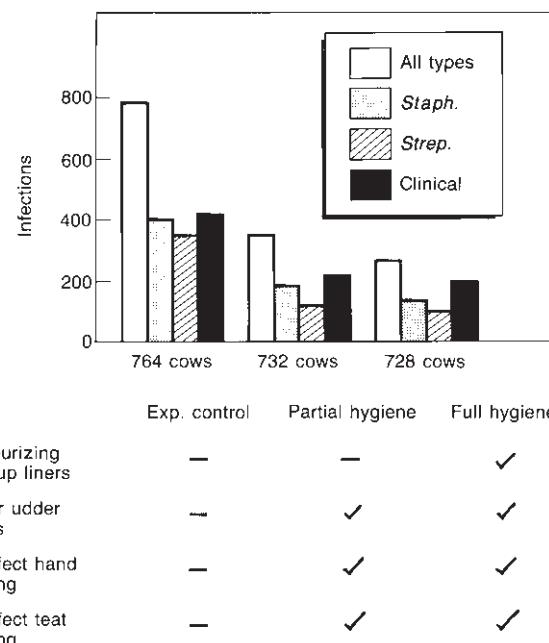

Fig. 23.3 Effect of milking time hygiene on new udder infections.

toscan or TBC. There will be an increased risk of liner slip and impact forces at the teat end. These factors will increase the risk of environmental infections. Ideally, a suitable concentration of an approved disinfectant (usually iodine or chlorine) should be included in the wash water supply. There have been examples of coliform and *Pseudomonas* mastitis problems associated with contaminated udder wash water supplies. These are unlikely where mains water is in use although uncovered water storage tanks may become contaminated with faeces or carcasses of small animals and provide a source of infection. For a review of this subject see Bramley & McKinnon (1990)

Aetiology of mastitis

It has already been stated that mastitis is a consequence of intramammary infection with one or more microorganisms of many different genera. The following section provides information on the most common or important of the different mammary infections.

Staphylococcus aureus (see p. 385)

In many countries this organism is the predominant cause of subclinical mastitis but is also isolated from clinical disease. The important sources of infection are infected udders, teat ducts or teat lesions. Extramammary sources do exist, notably the vagina and tonsils but do not appear important in the pathogenesis of

infection. It has proved possible to eradicate *Staph. aureus* mastitis from individual herds by the application of hygiene at milking time and culling. The major limitation to more effective control of *Staph. aureus* mastitis remains its poor response to antibiotic therapy. Cure rates are highest in first and second lactation animals. In older cows cure rates during lactation may be as low as 25 per cent following intramammary antibiotic therapy. Even following the use of dry-cow therapy, cure rates of 33 per cent in older cows are common. There are a variety of reasons for this of which antibiotic resistance plays only a minor role. *In vitro* demonstration of sensitivity of *Staph. aureus* to an antibiotic is no guarantee of therapeutic success. The ability of the bacteria to survive inside polymorphonucleocytes (PMN), macrophages and epithelial cells, protected from antibiotic action, may significantly contribute to their therapy resistance. Additionally, the pathological changes, notably granulomata and fibrosis, induced in chronic *Staph. aureus* infections renders chronically infected cows essentially incurable. Most commonly *Staph. aureus* udder infection is chronic, acute mastitis being less common than with other bacteria. However, acute gangrenous *Staph. aureus* infections can arise in which uncontrolled growth of the organism occurs elaborating large quantities of α toxin. Such infections are probably not due to strains of increased virulence but rather to a failure by the host to mount an effective defence. Workers in California showed the critical role of the PMN in this defence since subclinically infected cows, made neutropenic, rapidly developed acute gangrenous *Staph. aureus* mastitis (Schalm *et al.*, 1976) (for therapy see p. 396)

***Streptococcus agalactiae* (see p. 387)**

The sources of *Strep. agalactiae* are similar to those of *Staph. aureus*, namely the teats and udder. Consequently, milking time hygiene is an effective means of preventing infection during lactation. The presence of *Strep. agalactiae* in a herd suggests that there are defects in milking hygiene, postmilking teat disinfection and/or dry-cow therapy. Since *Strep. agalactiae* is easily eliminated by intramammary antibiotic therapy it is eliminated from herds employing teat disinfection and dry-cow therapy effectively and routinely. It is possible to include the elimination of infection by blitz therapy during lactation. Blitz therapy is where all quarters of infected cows are treated with intramammary antibiotics. The whole herd may be treated or selected animals. The level of infection relates well to individual cow cell counts. It is important to confirm that *Strep. agalactiae* is the cause of the high cell count before embarking on blitz therapy. The disease may exist as an acute clinical mastitis or persist as a subclinical infec-

tion. The duration of infection is shorter than staphylococci, primarily because of the better response to therapy. More rapid elimination of *Strep. agalactiae* can be achieved by diagnosis and treatment of infected animals although the economic basis for this is doubtful (for therapy see p. 396).

***Streptococcus dysgalactiae* (see p. 387)**

This organism has both contagious and environmental characteristics often associated with poor teat skin condition. Very good control of lactation infections can be achieved by teat disinfection indicating that cow-to-cow transfer is an important mechanism. However, infection in the dry period and in heifers is commonplace, particularly among animals not protected by dry-cow therapy. Outbreaks of clinical mastitis with *Strep. dysgalactiae* frequently follow a breakdown in herd hygiene practices or increases in teat lesions. The incidence of teat lesions can increase rapidly following failures in pulsation, excessive milking vacuum or adverse housing or climatic conditions. In such outbreaks the machine should be given a thorough examination by an expert and the teats closely inspected for damage. The inclusion of a high level of a suitable emollient in the teat dip can promote rapid healing of lesions and prevent their colonization.

Clinical *Strep. dysgalactiae* mastitis can be acute with anorexia and pyrexia in addition to the local signs. However, the response to therapy is usually rapid and elimination rates with penicillins are similarly high to *Strep. agalactiae*. *Streptococcus dysgalactiae* is also encountered in mixed culture with other organisms, notably *A. pyogenes* and *P. indolicus* in summer mastitis. The bacteria can be isolated from bovine tonsils and the bovine genital tract and these sources, allied to the ability of the organism to infect and colonize lesions, may be important in the pathogenesis of dry-period infections.

***Streptococcus uberis and other aesculin-hydrolysing streptococci* (see p. 387)**

These organisms are an important cause of bovine mastitis and, in some herds, are the major cause of clinical disease. Several species can be involved but the predominant one (>70 per cent) is *Strep. uberis*. Others include *Strep. bovis*, *Strep. faecalis* and *Strep. faecium*. Infection with these organisms is not controlled by postmilking teat disinfection although dry-cow antibiotic therapy reduces infection rates by about 50 per cent. However, *Strep. uberis* remains the commonest cause of infection in the dry period and susceptibility to infection has been shown to increase following drying-off (Marshall *et al.*, 1986). In untreated dry cows the

highest rates of infection occur in the initial two weeks following drying-off while in animals given antibiotic therapy at drying-off infection tends to be periparturient. The high infection rates in the dry period and the failure of post milking teat disinfection to control disease emphasize the independence of milking and transmission. The bacteria are widely disseminated on the cow, are present in low numbers in cattle faeces and multiply in bedding materials, particularly straw, to reach high levels. Deep straw yards for housing dry cows seem to pose a particular risk factor. Not all strains are virulent for the lactating gland and a capsular layer is often elaborated conferring resistance to phagocytosis. Susceptibility of the lactating gland to infection may be influenced by the lactoperoxidase system, which in turn can be affected by feeding regimens altering milk thiocyanate levels. Although *Strep. uberis* is sensitive *in vitro* to a range of antibiotics, intramammary therapy often is ineffective and chronic infections are common in some herds. Under these circumstances cow-to-cow transmission may become more important (for therapy see p. 396)

Coliforms (see pp. 383, 1016)

The coliform species most commonly implicated in mastitis are *E. coli*, although other species including *Enterobacter aerogenes*, *Pseudomonas aeruginosa*, *Ent. oxytoca*, *K. pneumoniae* and *Citrobacter* spp. are also encountered. Infection is more common among housed cows and occurs particularly around calving. Subclinical infection is less common and peracute mastitis occurs frequently around calving. About 50 per cent of these peracute infections die. Treatment involves frequent stripping to remove endotoxin, antibiotic, supportive therapy including hypertonic saline and oxytocin, etc. The use of anti-inflammatory drugs, particularly non-steroidal anti-inflammatories, may also be helpful. Many new *E. coli* infections occur during the dry period but do not manifest as a clinical disease until into the next lactation. The incidence of coliform mastitis has increased despite the adoption of the National Institute for Research in Dairying (NIRD) five-point plan, improved milking machines and better hygiene. Transmission between cows is unimportant in pathogenesis and the use of postmilking teat disinfection and dry-cow therapy does not reduce infection rates. The primary source of infection is bovine faeces although secondary multiplication of the bacteria to high numbers in cattle litter is often a factor (see section on cattle housing and mastitis, p. 331).

Infection with coliform bacteria leads to a rapid development of inflammation and often the influx of neutrophils eliminates the infection (Hill *et al.*, 1979). In some animals, particularly in early lactation and in

high-yielding cows, this is not effective, possibly because the rate of neutrophil diapedesis is poor. Recent research indicates that low levels of selenium may be implicated in the process (Erskine *et al.*, 1989) (for therapy see p. 396)

Arcanobacterium (Actinomyces, Corynebacterium) pyogenes (see Chapter 24)

This bacterium is often involved in suppurative conditions in cattle, including mastitis. It is most frequently encountered as one of the mixture of pathogens responsible for 'summer mastitis' in northern Europe. This acute clinical disease of the non-lactating animal has been described in the section on diagnosis (see p. 328). *Arcanobacterium pyogenes* may also infect the lactating cow, or infection may be carried over from the dry period. Infection in the lactating cow is usually associated with teat damage.

The epidemiology of summer mastitis has been much studied because of its epidemic and destructive nature. The disease has been associated with fly-borne transmission and the sheep head fly *Hydrotaea irritans* has been shown able to carry *A. pyogenes*, *Strep. dysgalactiae* and the anaerobic peptococci responsible for the disease. With one exception transmission experiments with infected flies have proved unsuccessful but data do reveal that the use of insecticides or barriers (surgical tape, Stockholm tar, etc.) reduces the disease incidence. The most effective control measure is the prophylactic use of dry-cow therapy. A review of the epidemiology, transmission and pathogenesis has been published (Thomas *et al.*, 1987).

Mycoplasmas (see p. 385)

In recent years several species of *Mycoplasma* have been recognized as important causes of bovine mastitis. The most common cause is *Mycoplasma bovis* but other species implicated include *M. bovigenitalium*, *M. canadense*, *M. californicum* and *M. alkalescens*.

Characteristically, infection with *Mycoplasma* spp. leads to a mastitis, often involving multiple quarters, which is refractory to antibiotic treatment. The secretion may remain normal at the onset although a granular or flaky deposit is recognized on standing. In the later stages a purulent or thick secretion, without offensive smell is often reported. Swelling and firmness is common but after a few days the mammary gland may reduce in size. Milk secretion is severely reduced. Swelling of the supramammary lymph nodes occurs and there may be pyrexia, transient malaise and arthritis. Secretion of mycoplasmas in the milk frequently lasts for two months and often for longer. Intermittent shedding is common. Clearly, such cows constitute an infec-

tion risk for the herd. Most reports relate to infection in lactating cows but outbreaks among dry cows, notably with *M. californicum*, do occur (Jasper, 1982).

Diagnosis requires the application of specific microbiological and serological tests in specialist veterinary diagnostic laboratories. These involve culture from milk onto selective media and a range of serological tests, often growth inhibition, to identify the species.

The most severe problems with this disease have occurred in large dairy herds in California and Florida. It should be considered as highly infectious and affected animals either removed or isolated within the herd. Examination of bulk milk has proved a useful screening method for affected herds. If a herd is suspected of having a problem with *Mycoplasma* mastitis then specialist advice should be rapidly sought. For further information the reader is referred to detailed reviews (Boughton, 1979; Jasper, 1982) (for therapy see p. 396)

Leptospira infection (see also p. 737)

Increasing concern has arisen over leptospirosis for a variety of reasons. Most importantly organisms of the hebdomadis subgroup are pathogenic for man. The organism most involved is *Leptospira hardjo* and this is responsible for the so-called 'milk drop syndrome' and is also associated with abortion in affected herds. The characteristic milk drop appears initially as a mastitis, usually with the milk yield of all four quarters falling to zero within 24 hours. Pyrexia is common and the udder secretion is thickened or clotted and occasionally bloody. The udder remains flaccid and the condition usually resolves within seven to fourteen days. Cases may be restricted to a few animals or up to 50 per cent of animals may become affected over a period of two to three months (Jackson & Bramley, 1983). Antibiotic therapy with tetracyclines or streptomycin may aid the resolution of the clinical phase and reduce carriers although immunity develops following infection. A vaccine is available, which requires an annual booster to ensure adequate protection. Infection of human beings may occur via infected urine droplets, particularly in herringbone milking parlours and leads to a febrile illness characterized by severe headaches. In a proportion of cases this can lead to complications including meningitis and encephalitis.

Coagulase-negative staphylococci and *Corynebacterium bovis*

The incidence of coagulase-negative staphylococci has increased as herd cell counts have decreased. Several species of coagulase-negative staphylococci are commonly isolated from aseptically collected milk samples.

These include *Staph. epidermidis*, *Staph. simulans* and *Staph. xylosus*. Most of these organisms are of low virulence although some isolations are associated with clinical disease. These organisms generally produce a slight elevation of somatic cell count, which may increase resistance to infection with major pathogens.

Similarly, *Corynebacterium bovis* is not usually associated with clinical disease and primarily colonizes the distal teat duct. It is associated with suboptimal teat disinfection. It is rapidly eliminated by antibiotic therapy and its spread is prevented by effective teat disinfection. In the absence of such measures it may be isolated from >70 per cent of aseptically collected milk samples. Growth on blood agar may require incubation for 48 hours, preferably at 30°C, and stimulation by fatty acids supplied either by the milk or by additions to the media such as Tween 80.

Recommendations for control of mastitis

In the USA, UK and Australasia and many other parts of the world there is a recommended mastitis control scheme based upon the '5-point plan'. The elements in the scheme are as follows:

- (1) Apply an approved teat disinfectant after every milking.
- (2) Treat clinical cases of mastitis.
- (3) Infuse long-acting antibiotic into all quarters at drying-off.
- (4) An annual milking machine test and appropriate maintenance.
- (5) Cull cows showing repeated cases of clinical mastitis.

These measures were the basis of controlled experimentation in many countries and have been widely employed since the 1970s. Teat disinfection is to reduce

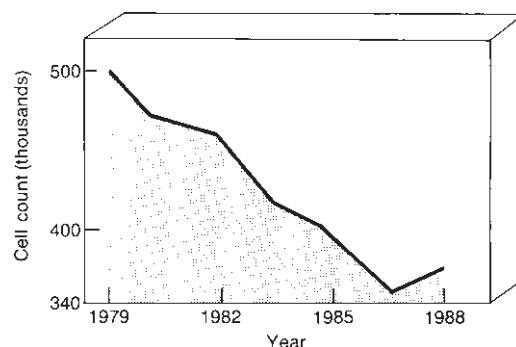

Fig. 23.4 Reduction in bulk milk cell count in England and Wales between 1979 and 1988.

rates of new infection during lactation; the dry-cow therapy serves to eliminate a high proportion of sub-clinical infections present at the end of lactation and to prevent many new dry-period infections. Treatment of clinical mastitis assists the elimination of infection and in the resolution of clinical signs of disease and culling is employed to remove chronically affected cows. Finally, the milking machine maintenance is intended to ensure efficient milking and prevent machine-induced infections as described above (therapy for mastitis is dealt with in Chapter 30).

A review of the progress in mastitis control following the introduction of these techniques has been described by Booth (1988). This shows major reductions in clinical mastitis incidence and in the reduction of bulk milk cell count (Fig. 23.4). The present status of improving mammary gland immunity is described in Chapter 29.

| Clinical disease | 338 |
| Treatment | 339 |
| Control | 339 |

Summer mastitis is an acute or peracute multifactorial infection of the non-lactating bovine mammary gland although clinical signs are often not obvious until parturition. The disease is reported from all four continents where dairy cattle are herded. It is, however, most prevalent in northern Europe and particularly common in some European cattle such as the Friesian/Holstein breeds, being rare in the Zebu.

Aetiology (see p. 334)

Bacteriological analysis of summer mastitis secretion shows a complex infection. Usually *Arcanobacterium (Corynebacterium) pyogenes* predominates and the severity of the infection is related to toxin production from synergistic growth with other bacteria that are anaerobic (see p. 338). *Peptococcus indolicus* is the most common anaerobe but *Bacteroides melaninogenicus* and *Fusobacterium necrophorum* are often found. An undescribed microaerophilic coccus, the Stuart-Schwann coccus is also found. It rarely grows in pure subculture. *Streptococcus dysgalactiae* is also common and believed by some to be a primary agent predisposing to *A. pyogenes* infection.

Much of the reported variation in bacterial culture, and especially isolation of anaerobes, probably results from suboptimal collection and transport of samples, allowing anaerobes to die out.

Epidemiology

Summer mastitis is considered to be epidemiologically most severe in northern Europe. It is also prevalent in

Japan, and parts of the USA, as well as being reported from Greece, Australia, Zimbabwe and Brazil. The incidence varies greatly from country to country, as does the severity of the infection. Most cases in North America are recognized when heifers calve with a non-functional quarter from which the causative bacteria can be recovered, whilst in Japan systemic illness is more common.

The incidence of summer mastitis varies locally. It is greater in the more intensive dairy areas but does not just depend on the density of cattle. It is only in the dairy industry that the importance of the disease is well recognized. It can be prevalent in beef cattle but loss of function of one-quarter is not so important economically in the suckler cow. The Dutch, Germans and Danes believe that summer mastitis is associated with sandy soils, but these correlate well with the best grassland. The high humus content, open structure and free-draining of sandy soils are particularly suitable for foraging, soil-dwelling insect larvae.

The disease is most common in summer and early autumn but can also occur in spring. As well as season, it is particularly associated with calving pattern. In Ireland, with many spring-calving herds, the spring incidence is marked. The black and white dairy breeds seem most susceptible and in the absence of preventive measures the incidence is greatest in older cows.

Transmission

It is a long and widely held belief that flies are involved in the transmission of summer mastitis.

The peak incidence of disease in northern Europe occurs in July, August and September when flies are most abundant on cattle. The sheep headfly (or plantation fly), *Hydrotaea irritans*, is the most frequent visitor to the teats of dry cows and heifers. Flies around pastured cattle have been shown to carry the summer mastitis pathogens even in the absence of disease in the herd. The disease prevalence is coincident with the geographical distribution of the fly in most of Europe. Control of flies on cattle reduces the incidence of summer mastitis. Some 60 per cent of infections occur

in the front quarters, which, it has been suggested, flies can reach more easily.

Various studies using *Hydrotaea irritans* to transmit summer mastitis have given incomplete results. The flies have been shown to carry the various bacteria and to be able to regurgitate the bacteria on to teat skin several days after a previous meal. Contaminated teats have been demonstrated to be one precursor to disease. Recently a study in Sweden confirmed a much earlier, anecdotal, UK report that contaminated *H. irritans* could transmit summer mastitis experimentally.

Summer mastitis also occurs frequently outside the fly season and in areas where the sheep headfly is not found. No other obvious vectors have been suggested in these situations. Cases of clinical mastitis, especially in newly calved cows, involving the same complex of bacteria, have been reported throughout the year. There are likely to be several risk factors to these infections including appropriate exposure to the bacteria and teat damage.

Initial cases of summer mastitis in an outbreak probably occur by chance. Increased incidence will depend on the density of animals at risk; hence there is a peak incidence in late summer-calving herds simply because more animals are challenged when they are most susceptible. Probably the role of the fly is to increase the challenge. It therefore is involved in secondary transmission. The fly may also contribute by stressing animals. Fly pestering can reduce milk yields by inducing gross behavioural changes. Susceptibility to infection during late gestation when there are other environmental and husbandry stressors, especially poor forage and heat, may increase with fly challenge.

Pathogenesis

Damage to secretory tissue is caused primarily by a toxin from *A. pyogenes*, with other virulence factors including a haemolysin, a coagulase and a hyaluronidase. The activity and quantity of these appears to be enhanced in mixed culture with *P. indolicus*.

The route of invasion of the udder by a mixture of bacteria is unknown but it seems unlikely that simultaneous invasion by up to five species of bacteria occurs. It is possible to isolate one or more of these pathogens from the udder of the lactating or dry cow in the absence of overt clinical signs so it is likely that some predisposing factor(s) is needed to cause clinical disease.

Evidence for the teat route of invasion in natural infections comes from the frequency of summer mastitis following teat-end damage. It has been possible to produce infections following surface contamination of

the teat with *A. pyogenes* alone. There is, however, no unequivocally accepted mechanism. Possibilities, each with proponents, include colonization of the teat skin or orifice spreading through the teat duct into the gland, bacteria entering the gland by draining via a supra-mammary lymph node from another site and invasion by haematogenous spread. All of the pathogens are ubiquitous on cattle, easily recoverable from mucous membranes and various lesions, and so a number of routes of invasion may occur naturally.

Clinical disease

Diagnosis of the later pathogenic stages of summer mastitis is relatively easy and requires little experience. Early stages are more difficult to distinguish from other infections.

The infection is most probably ascending so the primary sites are in the teat or in lactiferous tissue near the base of the teat. Initially, there is local inflammation and oedema. Expression of udder secretion may reveal a foul smell indicative of anaerobic bacteria. In summer months the teat may be attractive to flies and if the animal is housed the hind legs attract biting flies. Slightly later, behavioural changes in the animal related to toxæmia become apparent. The animal may be lethargic, inappetant, stop cudding and will become detached from the herd. These signs are easy to recognize at pasture. In newly calved and housed animals the first signs are often tenderness in the quarter, which can be confused with excessive intramammary pressure, and local temperature. The secretion will be discoloured, thick and creamy, rather than colostral, perhaps very clotted in a serous fluid, and frequently foul smelling.

In addition to the extreme mastitis, in later stages pyrexia and lethargy develop. If the infection remains local there may be rupture of mammary abscesses to the exterior. More commonly, the animal becomes systemically ill with progressive lameness from the hind legs, swelling of joints and an elevated temperature. The bacteraemia/toxæmia may be fatal in a few per cent of cases; similarly there may be abortion. Perinatal death is substantially increased and many calves, often born prematurely, fail to thrive.

The infection develops rapidly after the initial recognizable signs so confirmation of summer mastitis by bacteriology is rarely quick enough. Attempts have been made to develop cow-side diagnosis of anaerobic involvement based on specific metabolites but no practical technique is available. The time delay for confirmation is impractical. Evidence shows that 80 per cent of preliminary diagnoses of summer mastitis are correct (Hillerton *et al.*, 1987). The other infections would also

respond readily to the same therapy so unless drastic action, such as teat amputation or immediate culling, is indicated misdiagnosis in favour of summer mastitis has no economic or welfare disadvantages.

Treatment

A number of different approaches to treatment can be taken. The one selected should depend on the anticipated outcome of the case, which in turn depends on the clinical severity of the infection. In a small number of cases the only recommendation is for immediate culling. Less drastic is to treat the infection purely as an abscess; to amputate the teat and drain. This is practised commonly in northern Europe with non-pregnant younger animals, which are often then reared for beef.

In cows and heifers near to or at parturition the prognosis depends on the speed of diagnosis. In most cases in dry cows the infection is sufficiently well developed that destruction of secretory function is virtually complete. A clinical cure can sometimes be achieved but rarely a bacteriological cure. The prognosis is much better if the infection is diagnosed early, and therapy started immediately.

The pathogens are susceptible to a wide range of antibiotics including penicillin/streptomycin preparations. However, there is a poor cure rate when the only therapy is infusion into the udder. This is because the tissue destruction is extensive locally and so diffusion of the antibiotic is limited. A greater success has been claimed for erythromycin, which diffuses more readily. Success has also been claimed for anti-anaerobe preparations containing metronidazole. Chlortetracycline can be useful in the lactating animal but should not be used in the dry gland as all secretory function will be destroyed.

Claims have been made for a variety of other preparations including proteolytic enzymes mixed with antibiotics but controlled studies are rare. Usually, the most successful outcome follows a coordinated effort: frequent stripping of the quarter combined with parenteral intramuscular antibiotics and an intramammary infusion. This conventional approach, although labour intensive, affords the best prognosis for the udder. If systemic involvement is established then treatment of clinical signs to secure the health of the animal is all that can be achieved as the function of the infected quarter has been lost.

The patient should be quarantined as it is a source of further infection.

Control

Summer mastitis is so destructive and expensive that considerable investment in time and materials to

control the disease is made by the 40–45 per cent of farmers who regularly experience losses. Preventive measures are neither simple nor foolproof and usually are damage-limiting rather than totally preventive. The basic aims are to limit exposure to infection from the herd, to prevent colonization of lesions and to prevent spread of bacteria to the mammary tissue.

Assuming that summer mastitis infections will arise anyway it is important to recognize these early and segregate an infected animal to limit direct transfer of bacteria via, for example, bedding systems and indirect transfer by flies. *Hydrotaea irritans* do not pester housed cattle, so separate housing of infected animals is good practice.

The epidemiological spread of infection is related to the density of susceptible animals and the abundance of vectors. Reducing the density of late gestation cattle by spreading the calving pattern and completely avoiding the fly season of July, August and September in northern Europe are likely to be highly effective strategies.

Considerable effort is spent on fly control but this is the least effective method of disease control as persistent presence of insecticide on teats is hard to achieve. The synthetic pyrethroids now in common use are applied in ear-tags or as pour-ons to the back and probably spread by diffusion in sebum. However, the teats lack hair and sebaceous glands are sebum deficient, so limiting spread. Effective fly control on teats is only achieved by direct application or frequent reapplication of insecticide, or by the use of two ear-tags per animal.

There has been a gradual decline in the proportion of dry cows suffering summer mastitis, and in the number of herds affected, in England and Wales since 1988. This has been coincident with the control of flies by use of ear tags and later by pour-on formulations.

Frequently, summer mastitis follows infected lesions on or near the teats. These can be prevented or limited by use of surgical tapes, ensuring that the teats are cleaned first and not bandaged too tightly, or by frequent application of teat disinfectant. Many farmers teat-dip dry cows and heifers daily. This allows frequent inspection, trains the heifers to the milking parlour and ensures good teat condition. Prevention of teat lesions may reduce greatly the attractiveness for flies.

The best tested and most effective means of reducing the incidence of summer mastitis is the general application of prophylactic antibiotic infused into the teat at drying-off. Following administration of synthetic penicillins in a long-acting base, summer mastitis rarely occurs within three weeks. Longer effects are achievable with some preparations. Where the incidence of disease warrants extra investment it is advisable to repeat the application of antibiotic after three weeks. The main problem is avoiding milk contamination after an early calving. All the evidence available

shows a significant reduction of summer mastitis following use of dry-cow therapy. It can also be applied to heifers if the antibiotic is introduced gently into the teat duct.

Attempts to produce a vaccine against summer mastitis have met with little success. This remains a long-term goal and will become more likely as multi-valent vaccines are developed.

Cell counts

What is a somatic cell count?

The majority of somatic cells found in milk are white blood cells, with the remainder mainly epithelial cells shed by the secretory tissue of the udder. White blood cells are found throughout the body and their main function is to protect against disease. When large numbers accumulate they are visible as pus. The measurement of the number of somatic cells in milk is known as a somatic cell count.

Factors affecting the somatic cell count

Mastitis

Inflammation in the udder is in no way different from inflammation in other tissues. The cardinal signs of inflammation, namely swelling, redness, heat, pain and loss of function may not always be of recognizable intensity in mastitis. Signs of clinical mastitis are grossly visible but subclinical mastitis may go unnoticed. The majority of mastitis cases are bacterial in origin. One of the basic host responses to a bacterial infection is the infiltration of white blood cells from the blood into the udder. This is accomplished through the processes of diapedesis and chemotaxis. The degree and nature of the cellular response are likely to be proportional to the severity of the infection. In addition to bacterial

infections, there are certain other factors, some of which are physiological, that affect the cellular content of milk.

Stage of lactation

The somatic cell count is high during the first week of lactation, then soon decreases and remains low for several weeks after which a gradual increase occurs until the end of lactation. As the milk volume decreases in the latter part of lactation, an apparent increase in cell numbers occurs from mere concentration of cells in a smaller volume of milk. The presence of high cell numbers in colostrum may be due to an excessive desquamation of epithelial cells in a small volume of milk in a gland resuming functional activity after a dormant period (Schalm *et al.*, 1971).

Lactation age

The somatic cell count increases with the lactation age of the cow (Fig. 25.1) (Blackburn, 1966). On the basis of histopathological examination of the udders, the increase in the average number of polymorphonuclear leucocytes with advancing lactation age was attributed to an increase in the extent of subacute inflammation of the ducts as well as an increase in the severity of lobular lesions.

Stress

A sudden upset in the cows' routine, for example a herd blood test or coming indoors in the autumn, can cause a raised cell count for a day or two.

Oestrus

Bulling cows tend to have increased cell counts that are probably stress related.

Milking interval

Irregular milking intervals will influence the somatic cell counts in milk. Comparisons of somatic cell counts in milk have generally shown higher counts for shorter

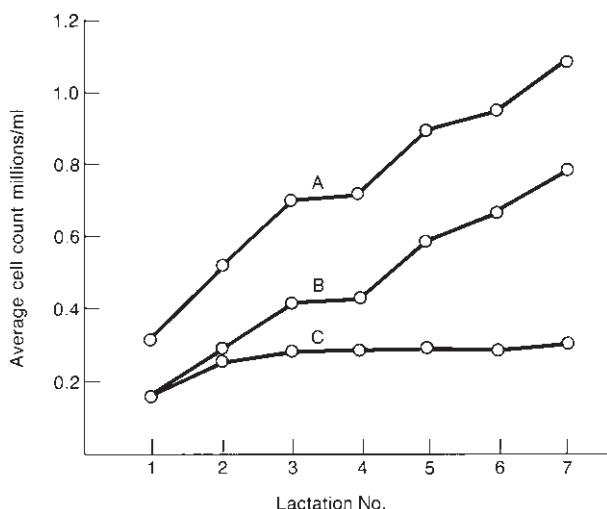

Fig. 25.1 Average cell count for each of seven lactations. A, total cell count; B, polymorphonuclear leucocyte count; C, count of cells other than polymorphonuclear leucocytes. Source: Blackburn (1966), reproduced with permission of Cambridge University Press.

milking intervals. This variation in cell numbers is explained on the basis of total volume of milk secreted leading to a greater dilution of somatic cells during the longer milking interval (Schalm *et al.*, 1971).

Milking machine

A significant correlation between cell counts and milking machine reserve air was observed by Nyhan and Cowhig (1967) in a survey of milking machine efficiency and mastitis in a random sample of 26 dairy farms (Fig. 25.2). Six of the herds were milked with machines that had a vacuum reserve of more than 0.11 m³/min free air (4 ft³/min free air) and these were the only herds with a mean bulk milk cell count of <300 000 cells/ml. However, later work in Australia (Olney *et al.*, 1983) concluded that in the absence of mastitis infections vacuum fluctuations, vacuum level, overmilking or varying pulsator rates will not cause stress or irritation that will lead to an increase in somatic cell counts.

Determination of the cell content of milk

Reference method: microscopic counting (Heeschen, 1975)

The method of microscopic counting of cells in a dry stained smear has been available for many years now although it has some possible errors. The optical and manual operations involved are tedious, especially in the case of serial tests, and the following sources of error must not be overlooked.

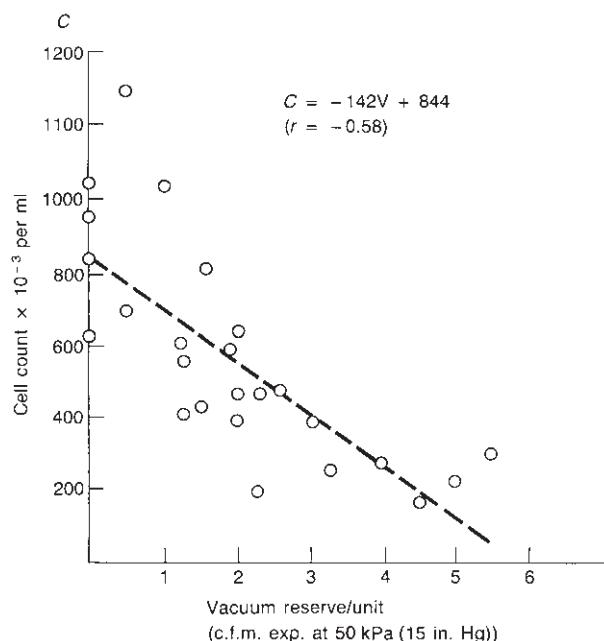

Fig. 25.2 Relationship between mean cell count of herd bulk milk (C) and vacuum reserve per unit (V). Source: Nyhan & Cowhig (1967).

- (1) Distribution of cells in the smears may not be homogeneous. The decision as to whether the stained structures observed are actually cells may be difficult in some cases and must be made subjectively.
- (2) To estimate the cell content every microscopic field examined must be multiplied by a relatively large factor, and this can be a source of considerable error.

Consequently, the primary object of microscopic counting is the screening of other counting techniques.

Electronic particle counting

This can be carried out by the following methods.

Coulter counter (International Dairy Federation (IDF, 1981)): With the aid of the Coulter counter it is possible to determine rapidly and accurately the number of particles over a certain size in a suspension. Prior to the determination of the number of cells, the milk is treated as follows.

- (1) Cells are stabilized to make them resistant to further treatments.
- (2) The milk to be examined is diluted with an electrolyte.
- (3) The fat globules are dispersed to well below the Coulter counter threshold.

The treated milk is passed through a 100 µm aperture located between two electrodes. When a particle passes through the aperture, a small quantity of highly conductive liquid in the circuit is displaced by a particle of lower conductivity. The increased resistance raises the voltage, producing a voltage pulse proportional to the volume of the particle. The number of pulses indicates the number of particles passing through the aperture. The pulses are fed into a threshold circuit so that only those exceeding a particular threshold value (T) are counted.

Fossamatic (IDF, 1981): This instrument is an automatic microscope for counting cells in liquids. Cells are stained with ethidium bromide and are then excited with a high-energy lamp, causing them to emit light at a characteristic wavelength. The emitted light energy is detected electronically, the result being displayed and printed out for each successive sample.

Accuracy of these methods

The precision obtained in the Fossamatic instrument is comparatively high. However, it is not essentially different from that obtained in the Coulter counter. In practical operation, the Fossamatic instrument has proved to be superior to other methods tested. This applies to the rate of samples as well as the handling of the instrument (Heeschen, 1975).

In an International Dairy Federation (IDF) questionnaire in 1983 on the cell counting methods 20 countries indicated they used Fossamatic, 17 used Coulter counter and two used the microscope method.

Interpretation of somatic cell counts

Somatic cell counts can be carried out both on herd bulk milk and individual cow's milk.

Herd bulk milk

Monthly cell counting has been shown to provide a fair estimate of the subclinical mastitis status of a herd; furthermore, the annual mean can be updated on a rolling basis by substituting the current month's count of the same month of the previous year (Booth, 1985).

A herd of cows with physiologically normal quarters could expect a bulk milk cell count (BMCC) of <200 000 thousand cells/ml. Herds with cell counts below this figure do exist (26 per cent of herds in England & Wales; Booth, 1997) but evidence shows that even in these herds there is some subclinical infection (Tables 25.1 and 25.2). A BMCC of 200 000 cells/ml is considered to be a realistic upper limit for herds with mastitis under control (Table 25.3).

Table 25.1 Distribution of cow and quarter infections shown against cell count ranges. Source: Pearson & Greer (1974).

| Cell count ranges ($\times 10^3$ cells/ml) | No. of herds | Infections | |
|--|-----------------|--------------------|----------------|
| | | In quarters (%) | In cows (%) |
| 219–490 | 12 | 9.61 | 25.8 |
| 535–789 | 12 | 17.76 | 42 |
| 1005–1700 | 5 | 29.54 | 54.4 |

Table 25.2 Estimated infection prevalence and losses in milk production associated with elevated BMCC. Source: Eberhart *et al.* (1982), reproduced with permission of the International Association for Food Protection.

| BMCC ($\times 10^3$ cells/ml) | Quarters infected (%) | Production loss ^a (%) |
|-----------------------------------|--------------------------|-------------------------------------|
| 200 | 6 | 0 |
| 500 | 16 | 6 |
| 1000 | 32 | 18 |
| 1500 | 48 | 29 |

^a Production loss calculated as a percentage of production expected at 200 000 cells/ml.

Table 25.3 Guidelines for interpretation of bulk milk cell counts.

| Bulk milk cell count ($\times 10^3$ cells/ml) | Estimate of mastitis problem |
|---|---------------------------------|
| <200 | Slight |
| 200–400 | Average |
| 400–700 | Bad |
| >700 | Very bad |

The prevalence of quarters infected clinically, and perhaps more importantly subclinically, with major pathogens such as *Staphylococcus aureus* or *Streptococcus agalactiae* and *Strep. uberis*, and to a lesser extent *Strep. dysgalactiae*, is the most important factor affecting the BMCC. Fenlon *et al.* (1995) confirmed this in a survey of 30 dairy herds, where they found a good correlation between the number of mastitis streptococci (*Strep. agalactiae*, *Strep. dysgalactiae* and *Strep. uberis*) found in bulk tank milk and BMCC. Gram-negative organisms such as *Escherichia coli* are usually rapidly eliminated from the udder and do not tend to cause many subclinical infections. Unless milk from clinical cases reaches the bulk tank, infections of this type do not tend to influence the BMCC significantly; BMCC,

therefore, is a poor indicator of Gram-negative infections (David & Jackson, 1984).

Both monthly and annual rolling mean figures must be examined to detect trends over a period of time rather than figures for a single month. Where subclinical infections with major pathogens like *Staph. aureus* are not well controlled it is possible to see a gradual increase in BMCC over a period of time, rather than a sudden explosive increase. A sudden spectacular rise in the BMCC where the levels have been consistently <250000 cells/ml could indicate an outbreak, with mastitic milk reaching the bulk milk supply due to faulty detection.

Fifteen countries reported a decrease in national mean cell in an IDF survey (Booth, 1995) (Table 25.4).

Table 25.4 National mean cell counts in 1990 and 1993. Source: Booth (1995). Reproduced with permission of the International Dairy Federation.

| Country | Cell count ($\times 10^6/\text{ml}$) | | Change (%) 1990–93 | Mean ^a |

^a A, arithmetic; G, geometric; W, weighted.

Can the BMCC be too low? There is a perception that too low a cell count can lead to an increase in susceptibility to mastitis. However, BMCC is not a measure of resistance to mastitis. Resistance against mastitis depends on the teat barrier being intact and the ability of the cow to mobilize large numbers of efficient neutrophils in a short period of time. Timms (1990) confirmed this when he showed that cows with a low somatic cell count (SCC) were not at greater risk of mastitis infections when compared to cows with a high SCC. In a survey of 125 herds with a low BMCC (<150000 cells/ml) in the Netherlands the rate of clinical mastitis was significantly related to certain variables that increased the exposure of environmental microorganisms: poor cubicle cleanliness, rubber mats in cubicles and drinking water from sources other than public water all increased the rate of clinical mastitis (Schukken *et al.*, 1990). Berry (1992) found that it is possible to have a low cell count and achieve a low incidence of mastitis in a survey of 35 herds in England and Wales with a BMCC of less than 70000 cells/ml.

Why is the BMCC important? Within the dairy industry, BMCC has become the single most important test used to measure milk quality, to regulate whether milk can be sold and to determine the price paid for raw milk (Bennett, 1993; Wells & Ott, 1995; Leslie *et al.*, 1996). Reasons to include BMCC as a pricing component include: (i) domestic consumer demands for quality, (ii) processor need for high-quality raw milk for further processing, (iii) to help improve udder health and (iv) pressure from international markets for documented high-quality dairy products (Wells & Ott, 1995). EC Directive 92/46 states that all milk (liquid milk or milk for manufacture) must have a BMCC of less than 400000 cells/ml.

Buyers are offering incentives for low BMCCs (Table 25.5), but some may question whether they, the buyers, need low cell counts in milk. Badinand (1994) indicates that the quality of milk is reduced once the number of cells is greater than 70000 to 100000/ml. Inflammatory

p/l, pence/litre.

Table 25.6 Effects of mastitis on milk and milk products. Source: Munro *et al.* (1984), reproduced with permission of the Australian Journal of Dairy Technology.

| Substrate | Alterations |
|------------------------------|--|
| Raw milk | Development of a rancid flavour; lower heat stability of whey proteins |
| Pasteurized milk | Reduction of flavour and quality |
| Recombined concentrated milk | Less stable proteins |
| Cheese | Reduced starter activity; changed clotting time; reduction of curd firmness; losses of fat and casein with the whey; lower yield |
| Butter | Impairment of flavour; less flavour; oxidative taste; longer churning time; inhibition of diacetyl production |

changes in the mammary gland influence the process of milk synthesis both quantitatively and qualitatively. The changes in constituents of milk affect the major components (lactose, fat and proteins) as well as fatty acids, protein fractions, caesins, whey proteins, anions and cations, conductivity enzymes, etc. With increasing numbers of somatic cells the growth of starter cultures in milk may be adversely influenced (Table 25.6). Renetting time and heat stability of the milk can be impaired (Heesch & Reichmuth, 1995).

Individual cow's milk

The normal somatic cell count in milk in various parts of the same udder varies widely from near zero in uninfected areas to something in the order of three hundred million cells per litre in the worst infected areas. A cow can have <200 000 somatic cells/ml with some small area of the gland badly infected.

Many farmers have monthly somatic cell counts (SCC) carried out on the milk samples taken from cows for milk recording purposes. These can provide a rather more detailed monitor of the herd mastitis situation than that provided by the monthly BMCC. The cost of monthly SCC testing for one year is very low and can be recovered in mid-sized herds by preventing one or two clinical cases of mastitis. The recovery of the cost is many times the out-of-pocket expense because of the many uses of SCC data and the number of cows at risk in a year's time. SCC reach the highest level in milk within the first several hours after milking and reach a low point just prior to milking (Schalm *et al.*, 1971). Anything less than a daily composite has reduced reliability and repeatability. Repeated samples over days or months add perspective to the cow's udder health history and improve the interpretation of SCC. Monthly SCC data accumulated over a year for a cow or herd describe more completely the mastitis history of the herd for the previous year. Greater confidence is gained as more samples are represented.

Table 25.7 Interpretation of individual cow milk cell count.

| Count (thousand cells/ml) | Interpretation |
|---------------------------|--|
| Less than 200 | Probably uninfected |
| 200 to 500 | Suspicious: possibly infected in one quarter |
| Over 500 | Infected in at least one quarter |

Individual cow cell counts (Table 25.7) can be of value to farmers and their veterinary surgeons for the following reasons:

- To estimate the proportion of cows in a herd that are infected;
- To screen the herd in order to identify cows for bacteriological examination;
- To identify cows for possible culling (at least two samples at monthly intervals are required);
- As a guide to the effectiveness of dry-cow therapy;
- In a herd with a high total bacterial count (TBC) where the equipment has already been checked, as the first step in identifying the cows that may be the cause of the high TBCs.

Stage of lactation can have some effect; counts are high in the first week after calving and tend to rise slightly in the last few weeks of lactation. First calves that have never been infected will normally have counts of 100 000 cells/ml or less.

Total bacterial counts

Although by no means a new technique, there has been a recent increase in interest in the use of quantitative and semi-quantitative bacterial counts in bulk milk as an aid in the monitoring and investigation of mastitis and milk hygiene problems. The majority of samples submitted

are for the investigation of herd problems with milk hygiene, rising cell counts and/or a high incidence of clinical mastitis. With the majority of countries now basing payment on both the cell count and bacterial count of milk, the results also have economic importance. It is vital that any sample taken is kept refrigerated during transit from the bulk milk tank to the processing laboratory, and this can produce practical difficulties.

EC Directive 92/46 states that all milk (liquid milk or milk for manufacture) must have a total bacterial count (TBC) of less than 100 000 bacteria/ml. Consequently, milk supplies are subject to testing for TBC as a measure of milk quality and bonus/penalty payments are applied according to the level. The bacterial count obtained refers to all bacteria which includes saprophytic bacteria, faecal organisms such as *E. coli* as well as other major udder pathogens.

Sources of bacteria

Bacteria in milk comes from three main sources:

- From within the udder
- External contamination of cows' teats
- The milking plant

If there is a problem with cooling and refrigeration of milk all three sources may contribute to an increased TBC.

From within the udder

The milk from a healthy uninfected quarter contains virtually no bacteria. Neave (1975) found counts of up to 28 million bacteria/ml in a quarter with subclinical *Strep. uberis* infection. However, the majority of quarters with subclinical infections (*Staph. aureus*, *Strep. dysgalactiae* and *Strep. uberis*) had counts of around 10 000 bacteria/ml. Bacterial counts from quarters with coliform infections were slightly lower.

Milk from cows with clinical mastitis should always be withheld. Neave (1975) found counts of up to 680 million bacteria/ml, and several quarters with counts greater than 100 million bacteria/ml (although 10^5 or 10^6 /ml is more usual). Two litres of such mastitic milk added to 2000 litres of bulk milk may raise the TBC by 100 000 bacteria/ml (Cousins, 1978).

Herds with satisfactory average TBC sometimes experience occasional wild fluctuations. This may indicate that mastitis cases are not being detected promptly and mastitic milk is entering the bulk tank. It is therefore essential for mastitis detection to be as thorough as possible especially where milking is direct to pipeline (David & Jackson, 1984).

TBC levels can provide some information regarding the mastitis situation in a herd. However, it must be

borne in mind that a considerable number of bacteria come from other sources, such as soiling on teats and the milking apparatus (Bramley *et al.*, 1984).

External contamination of cows' teats

Attention to udder hygiene and housing, especially cubicle beds and passage ways, is important in reducing contamination from the udder skin. The handling of cows' teats before milking must always result in the risk of transfer of bacteria between teats and from one cow to another. Herds where teats were dry wiped with paper towels had the lowest BMCC and TBC in both the summer and winter period, followed by those herds where only dirty teats were washed and dried with paper towels (O'Rourke, 1987).

Contamination from the milking equipment

Contamination of the milking equipment is generally found to be the most frequent cause of high bacterial counts. Probably the two major causes are cracked and perished rubberware and inefficient cleaning of the plant (see Blowey & Edmondson, 2000a).

Bulk tank analysis

The organisms counted and the standards currently in use by one processing laboratory (Blowey & Edmondson, 2000a) are shown in Table 25.8. Other laboratories may use different criteria. In addition, a semi-quantitative screen is carried out for all other bacteria isolated from that sample. The target values have been reduced in line with the increasingly strict standards being imposed by the milk purchasing companies (Blowey *et al.*, 2000).

TBC vs Bactoscan

Typically TBC is the number of viable bacteria per ml of milk when cultured on milk agar medium at 37°C for

Table 25.8 Target values for different bacterial types in bulk milk. LPC, laboratory pasteurised count.

| Organism | Target value (cfu/ml) |
|----------------------|-----------------------|
| Thermoduric/LPC | <175 |
| Coliforms | <20 |
| <i>Pseudomonas</i> | <500 |
| Total staphylococci | <200 |
| <i>Staph. aureus</i> | <10 |
| <i>Strep. uberis</i> | <2200 |
| Total bacteria count | <5000 |

48 hours. It therefore measures the number of bacteria which grow at a specific temperature on a specific culture medium. Most bacterial counts are now measured automatically by Bactoscan. This counts all viable organisms, irrespective of their favoured growth temperature or cultural requirements. Bactoscan levels are therefore higher than TBCs, by a factor of approximately four- to five-fold. However, there is no direct relationship between the two, as this will depend on the type of bacteria present in any particular sample (Blowey & Edmondson, 2000b).

Thermoduric count

The number of thermoduric organisms present in the sample (i.e. organisms which are not killed by heating to 64°C for 35 minutes) is taken as an indicator of poor milking plant cleaning. This may be caused by inadequate quantities of hot water (less than 18 litres per cluster), inadequate water temperatures, a lack of swirling and jetting during the washing routine, inadequate amounts of dairy chemical used or particularly hard water leading to inactivation of the circulation cleaner. Many farms are now able to achieve a thermoduric count of 10cfu/ml or lower, although with problem herds the count may rise to above 600cfu/ml.

Coliform count

Coliform counts or, more precisely, enterobacteriaceae, are taken as an indication of the amount of faecal contamination on teats. This could therefore indicate a problem with poor housing, or poor premilking teat preparation or both. High coliform counts could also arise from cows clinically or subclinically affected by *E. coli* mastitis, with the milk entering the bulk tank. This could occur, for example, where foremilking is not practised and where mastitis detection is poor. Fluctuating cell count and Bactoscan values are often associated with increased levels of clinical mastitis, especially *E. coli*, *Strep. agalactiae* and *Strep. uberis*.

Pseudomonas count

Pseudomonads are non-enteric coliforms, sometimes referred to as non-lactose-fermenting coliforms or NLFs. An increasing number of NLFs were found in milk samples from clinical samples and high cell count cows (Blowey *et al.*, 2000), and subsequent testing showed that these were primarily *Pseudomonas* species. The pseudomonad count is taken as an indicator of non-enteric, non-faecal environmental contamination, and raised levels are likely to be found in herds with poor premilking teat preparation and/or poor environmental hygiene.

Staphylococcus aureus count

High *Staph. aureus* counts are commonly found in herds with high cell counts and indicate that additional attention to hygiene is needed during the milking process and careful postmilking teat disinfection, to prevent the spread of infection. Spread of infection is by hands, teat wipes and especially the teat liners (inflations). In a proportion of herds the *Staph. aureus* levels in bulk milk are quite high and yet cell counts are acceptable. Advice given in these circumstances is that the herd is at risk from a rising cell count, and that there are probably a number of carrier cows present in the herd.

Total staphylococcal count

The total staphylococcal count was introduced because, with the elimination of *Staph. aureus*, there has been an increasing number of herds with high cell counts caused by coagulase negative staphylococci (CNS). This range of organisms includes *Staph. epidermidis* and *Staph. haemolyticus*.

Differential screen

The differential screen is a semi-quantitative assessment of other bacteria present in the milk sample. The bacteria commonly found include:

- *Streptococcus uberis*. Herds with high levels of *Strep. uberis* in bulk milk samples tend to have more clinical mastitis and may have widely fluctuating Bactoscans. *Strep. uberis* can sometimes be associated with somatic cell count problems, even when staphylococcal levels are low.
- *Streptococcus dysgalactiae* has been associated with poor teat skin condition, particularly in heifers. High levels of total staphylococci or *Staph. aureus* may also be present, as both organisms are associated with poor teat skin condition.
- *Streptococcus agalactiae* is sometimes identified from herds that did not even know that the cows were infected. *Strep. agalactiae* can be the cause of increased bulk milk tank somatic cell counts and high and fluctuating Bactoscans.
- *Corynebacterium bovis* has been associated with suboptimal postmilking teat disinfection. If staphylococcal levels are rising and *C. bovis* is identified in significant numbers in bulk milk samples, then it would suggest that additional attention needs to be paid to postmilking teat disinfection.
- Other organisms include *Strep. faecalis*, *Bacillus* species, yeasts and moulds. The presence of a wide range of these environmental organisms is often associated with high coliform and *Pseudomonas*

counts and with an increased incidence of clinical environmental mastitis. Poor housing and/or poor premilking teat preparation could be involved.

Mastitis monitoring

Introduction

There are few conditions in dairy cows that lend themselves to such a detailed objective numerical monitoring as mastitis. Mastitis is still a significant problem in dairy herds in all countries and many of the factors leading to a high incidence are associated with hygiene and husbandry, i.e. they are under the direct control of the farmer or stockman. It is therefore vital that there is a constant monitoring to ensure that all parties involved are made aware immediately a problem starts to develop.

One of the largest British surveys, starting with 45 000 cows in 378 herds, was completed in 1983 (Wilesmith *et al.*, 1986). Defining a 'case' of mastitis as one quarter affected and with a separate case commencing if seven days had elapsed since the disappearance of clinical signs, they found an incidence of 54.6 cases per 100 cows in 1980, declining to 41.2 cases per 100 cows by 1982. This is in broad agreement with the data of Blowey (1986), reporting a much smaller survey of 22 herds monitored by a veterinary practice, where the incidence of mastitis fell from 51.0 cases in 1979 to 31.8 cases per 100 cows in 1985 (Table 25.9). More recently Kossaibati *et al.* (1998), in a study of 144 well-recorded

Holstein/Friesian herds in England (average herd size 132 cows) over three years, recorded an incidence of 43.4 quarter cases per 100 cows per year. The disease affected 25.9 per cent of the cows in the herd each year, with 1.6 quarter cases per affected cow, giving an overall recurrence rate of 19.4 per cent. This would suggest that some cows are more susceptible to clinical mastitis than others. Although there has been little improvement over the past 10 to 15 years, these figures represent a marked reduction in incidence compared with the 1960s, when Kingwell *et al.* (1970) recorded an incidence of 120 cases per 100 cows per year. The marked reduction in incidence since this period has been associated with the implementation of the 'five-point plan', and the control of contagious infections. There has been little decrease in environmental infections however, possibly because the doubling of teat end milk flow rates (from 0.8 to 1.6 kg/Q/min) that has been associated with increased yields has led to a 12-fold increase in susceptibility to new infections (Grindal & Hillerton, 1991).

Recording systems

The precise system used by the farmer to keep mastitis records is not particularly important, provided:

- It is used accurately and kept up to date;
- All information is recorded, namely date, cow identity, quarter affected, treatment used, withdrawal period and results of bacteriological samples (if taken);

Table 25.9 The average performance of the 22 herds monitored (Blowey, 1986).

| Period of records | Number of herds being recorded | Herd size | Rolling mean herd milk cell count ($\times 10^3/\text{ml}$) | Annual milk sales (l) | Percentage cows affected | Mastitis cases/100 cows | Intramammary tubes used per cow | Intramammary tubes used per case treated | Percentage cases which recurred |
|-------------------|--------------------------------|-----------|---|-----------------------|--------------------------|-------------------------|---------------------------------|--|---------------------------------|
| Oct. 1979– | | | | | | | | | |
| Sept. 1980 | 22 | 91.7 | 346 | 6011 | 26.5 | 51.0 | 2.6 | 5.1 | 25.0 |
| Sept. 1980– | | | | | | | | | |
| Aug. 1981 | 24 | 105 | 302 | 5820 | 25.4 | 49.6 | 2.7 | 5.8 | 16.3 |
| March 1981– | | | | | | | | | |
| Feb. 1982 | 22 | 101 | 310 | 5921 | 25.8 | 459 | 2.4 | 5.6 | 14.9 |
| April 1982– | | | | | | | | | |
| March 1983 | 16 | 123.7 | 302 | 5949 | 27.2 | 493 | 2.5 | 5.0 | 16.1 |
| April 1983– | | | | | | | | | |
| March 1984 | 16 | 123.8 | 255 | 5651 | 23.6 | 42.7 | 1.9 | 4.2 | 13.1 |
| April 1984– | | | | | | | | | |
| March 1985 | 23 | 111.5 | 243 | 5479 | 19.6 | 31.7 | 2.1 | 7.1 | 10.3 |

- The records are in a form that is acceptable and usable for the person compiling them;
 - They are easily accessible and regularly reviewed by both the farmer and his veterinary adviser and any necessary action is taken following this review.

An analysis of data needs to be carried out at least every six months. Intervals longer than this would fail to achieve the aims of the monitoring (detailed later in this section, p. 350). It is also important to be seen to be using the data, thereby maintaining the interest and enthusiasm of the herdsman for continuing with the recording. Wall charts are the simplest method of recording; computers may be used, while others use a specific mastitis recording booklet, with a page for each cow (Fig. 25.3; Blowey, 1983). This has the advantage

Fig. 25.3 A page from a herdsman's mastitis recording book. This is kept during the life of the cow.

that a cow's lifetime mastitis history is readily available. Whatever system is used, it must be capable of producing information on previous disease, to assist with decisions on culling.

Analysis of information

Regular checks must be carried out by analysing the recorded information in order to:

- Assess the incidence of mastitis on each farm and hence the efficacy of the control procedures in use;
 - Compare the performance of the farm with ‘standard targets’ or with the herds of other members of the group being monitored.

The wide variety of criteria that can be used to monitor mastitis are shown in Table 25.10, which is part of a 'league table' taken from a herd recording programme (Blowey, 1984). Bulk milk cell count is clearly the traditionally used parameter, but this is mainly a reflection of subclinical *Staph. aureus*, *Strep. uberis* or *Strep. agalactiae* contagious mastitis. It provides relatively little information on the incidence of environmental mastitis. The percentage of cows affected gives the proportion of cows in the herd that have been clinically affected by mastitis during a 12-month recording period. Any one of these cows may have had mastitis in one or more quarters and any one quarter may have had two, three or more mastitis incidents over a 12-month period. Defining a case as one quarter affected once, and a remission of clinical signs for six days or more being needed before a new case commences, then the case incidence of mastitis can be calculated. As far as the farmer is concerned, this will be a more accurate reflection of the 'amount of mastitis' occurring in the

Table 25.10 A 'league table' derived from mastitis data analysis.

| Herd number | Number of cows | Rolling mean cell count ($\times 10^3$) | Mean herd yield (annual sales) (l) | Percentage cows affected | For whole herd | | | For mastitic cows | | |
|-------------|----------------|---|------------------------------------|--------------------------|--------------------|--------------------|---------------------|-------------------------|----------------|------------------|
| | | | | | Cases per 100 cows | Tubes used per cow | Tubes used per case | Average number of cases | Recurrence (%) | Quarters per cow |
| 1 | 65 | 321 | 5800 | 38 | 60 | 3.5 | 5.7 | 1.6 | 15 | 1.4 |
| 2 | 81 | 745 | 6000 | 21 | 30 | 0.9 | 2.9 | 1.5 | 12 | 1.3 |
| 3 | 46 | 275 | 5850 | 19 | 40 | 4.1 | 9.4 | 2.2 | 45 | 1.2 |
| 4 | 134 | 267 | 5178 | 21 | 30 | 1.2 | 4.6 | 1.2 | | 1.2 |
| 6 | 95 | 346 | | 29 | 70 | 9.8 | 13.5 | 2.5 | 33 | 1.6 |
| 7 | 110 | 333 | 6500 | 27 | 70 | 2.7 | 3.8 | 2.6 | 40 | 1.6 |
| 8 | 132 | 272 | 6036 | 28 | 60 | 1.8 | 2.9 | 2.2 | 29 | 1.6 |
| 9 | 50 | 441 | | 30 | 70 | 2.1 | 3.1 | 2.2 | 36 | 1.4 |
| 10 | 60 | 210 | | 18 | 60 | 1.7 | 2.8 | 3.4 | 35 | 2.2 |

herd. If a herd has a low percentage of cows affected, but a high number of cases per 100 cows (for example herd 7, Table 25.10), then that herd has a problem with either (i) a large number of down-calving cases, with maybe all four quarters affected at the same time or (ii) a proportion of 'chronics' in the herd, which have had repeated attacks of mastitis in one or more quarters over the lactation. This can be expressed as the proportion of treated cases that recurred and is clearly very high for herd 7.

These two situations can be separated by monitoring the percentage that recurred, namely the proportion of treated quarters that required a second or subsequent treatment during a 12-month recording period. Additional information can be obtained by calculating indices for the cows affected, namely for 'mastitic cows' (Blowey, 1984). For example, in this category (i) 'cases per mastitic cow' gives an indication of the average frequency with which a cow gets mastitis during a 12-month period and (ii) 'quarters per mastitic cow' then gives a further indication of whether it is one quarter being regularly affected, or all four quarters affected at once.

In many instances, intramammary antibiotic tube usage is obtained from different sources, e.g. the veterinary practice or other sales invoices. This has the advantage in that it provides a check on the accuracy of the data being supplied by the farmer. For example, if it is calculated that 10 tubes are used for each case treated, there are several possible explanations:

- (1) The cases treated are very slow to respond, either because the wrong antibiotic is being used, or because there is an unusually resistant organism or because treatment is not instigated until the case is quite well advanced.
- (2) Tubes are being used at a rate well in excess of the manufacturer's recommendations.
- (3) Tubes are being used for purposes other than the treatment of mastitis.
- (4) Not all cases of mastitis are being recorded. This is the most likely cause of an extremely high tube usage per case.

The mean tube usage per cow in the herd and per case treated as recorded by Wilesmith *et al.* (1986) was slightly higher than that recorded by Blowey (1986) (Table 25.9). However, on individual farms Wilesmith *et al.* (1986) found that average tube usage over a 12-month recording period varied from 0.9 to 53.5 tubes per case treated (Table 25.11). It was for this reason that they concluded that tube usage was not a reliable indicator of mastitis incidence within a herd. However, coincident with a decrease in mastitis incidence from 54.6 to 41.2 cases per 100 cows per annum, there was a decline from 280 to 259 tubes used per 100 cows.

Table 25.11 Case incidence and tube usage over a 3-year recording period. Source: Wilesmith *et al.* (1986).

| | 1980 | 1981 | 1982 |
|--------------------------|-------------------|-------------------|-------------------|
| Cases/100 cows | 54.6 | 49.8 | 41.2 |
| Tubes used/100 cows | 280 (33–1032) | 273 (23–1112) | 259 (19–1003) |
| Tubes used/clinical case | 6.1 (1.1–29.4) | 6.1 (0.9–53.5) | 5.8 (0.9–19.5) |

Table 25.12 Targets for herd mastitis incidence. Source: Blowey & Edmondson (2000a).

| | Target | Interference level |
|--|--------|--------------------|
| Percentage cows affected per annum | 20 | 25 |
| Cases/100 cows per annum ('mastitis rate') | 30 | 40 |
| Milking cow antibiotic tubes/cow in herd per annum | 1.4 | 2.5 |
| Milking cow tubes used per case | 4.5 | 6.0 |
| Percentage cases requiring a repeat treatment during a 12-month period | 10 | 20 |
| Percentage dry cows affected per annum | 1.0 | 2.5 |

Similarly, in the data of Blowey (1986) (Table 25.9), tube usage fell from 260 to 210 tubes used per 100 cows in a period when mastitis incidence declined from 51.0 to 31.7 cases per 100 cows per annum. Tube usage would therefore appear to give some indication of mastitis incidence, although it is not a figure that should be used in isolation.

Target figures

Targets for mastitis incidence have been suggested by some authors and are shown in Table 25.12. These can be used by an individual farmer to assess the progress of a control scheme.

Uses of mastitis monitoring

Most points have been referred to already, but an appraisal of the uses of recording makes a useful summary of the subject.

- To monitor the progress of an individual cow. Any cow that has had four or more cases in one quarter during a 12-month period should be considered for culling, or at least for special treatment.
- To monitor herd status. Is mastitis incidence acceptable or should more effort be put into control? The surveys of both Blowey (1986) and Wilesmith *et al.* (1986) showed a marked decrease in mastitis incidence over the recording period and it is likely that the simple discipline of recording, leading to an increased awareness of the problem, will lead to improvements.
- A recording system provides an opportunity for greater veterinary involvement in on-farm advice and discussion. Recording in itself often provides the herdsman with greater motivation in mastitis control, and this is particularly the case if league tables are supplied, indicating how well a specific herd compares with the others being monitored.
- If problems occur, an analysis of the records can sometimes indicate the likely epidemiology of the organisms involved and hence the control measures required. For example, a herd with a high percentage of cases requiring repeat treatments is likely to be affected by staphylococcal or streptococcal cow-to-cow transmitted mastitis. Alternatively, because a heavily contaminated environment tends to expose all cows to the same level of infection, a high incidence of environmental mastitis would be seen in the records as a high percentage of cows affected, almost an equal number of cases per 100 cows, but only low numbers of cases per mastitic cow and a low percentage of cases recurring. For herds with environmental mastitis, clinical case incidence will commonly be high but the cell count remains low.

The equipment

A milking machine installation consists of a pipework system linking various vessels and other components, which together provide the flow paths for air and milk. The forces necessary to move air and milk through the system arise from the fact that the system is maintained at a vacuum. Thus it is atmospheric pressure that forces air, intramammary pressure that forces milk, into the system and the combination of these forces causes flow.

A milking machine has five basic components and any machine, no matter how big, can be broken down into these components (Figs 26.1–26.3):

- Vacuum pump: to supply the vacuum
- Regulator: to control the vacuum level
- Pulsators: to open and close the liners
- Clusters: to attach to the cow
- Containers: to store the milk

Figure 26.1 shows diagrammatically the flow of air and milk through a bucket milking machine. Milk enters the teatcups and travels through the short milk tubes to the claw where air is admitted to break up the columns of milk and improve milk flow away from

the claw. The milk and air travel along the long milk tube to the container (bucket). A pulsator is normally situated on the lid of the container and this admits air, which aids in the collapse of the liners during the closed phase of pulsation. Air is also admitted through the regulator, which is situated on the vacuum pipeline.

The flow pattern is similar in the milking pipeline machine except that the milk and air from each claw flow through the milk pipeline to a common receiver where air and milk are separated (Fig. 26.2). Depending on the type of milk pump used, air may be admitted when milk is released from the receiver and pumped to the bulk tank.

The flow pattern of the recorder type of machine is similar to the milking pipeline machine except that air admitted at the claw is separated from the milk at the recorder jar (Fig. 26.3). Air has to be admitted at this point through a special inlet or through the teatcups at the end of each milking operation to force the milk from the recorder jar to the receiver jar (which is under vacuum). Some air may pass along with the milk as the jar empties, especially if the controls are not very expertly handled. This air is separated from the milk at the receiver jar.

Functions of main components of a milking machine

Vacuum pump: To extract air and maintain the machine under vacuum.

Interceptor: To prevent the ingress of foreign matter into the vacuum pump.

Sanitary trap: To prevent milk vapour from entering the pulsators.

Vacuum regulator: To maintain a constant vacuum level. It limits the maximum level by admitting air into the plant when a predetermined vacuum level

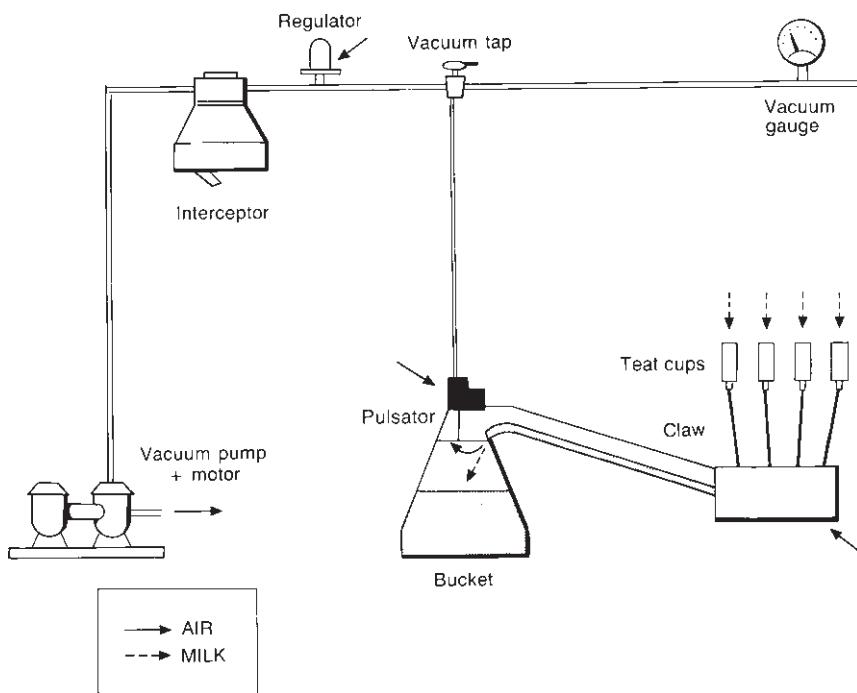

Fig. 26.1 Bucket milking machine.

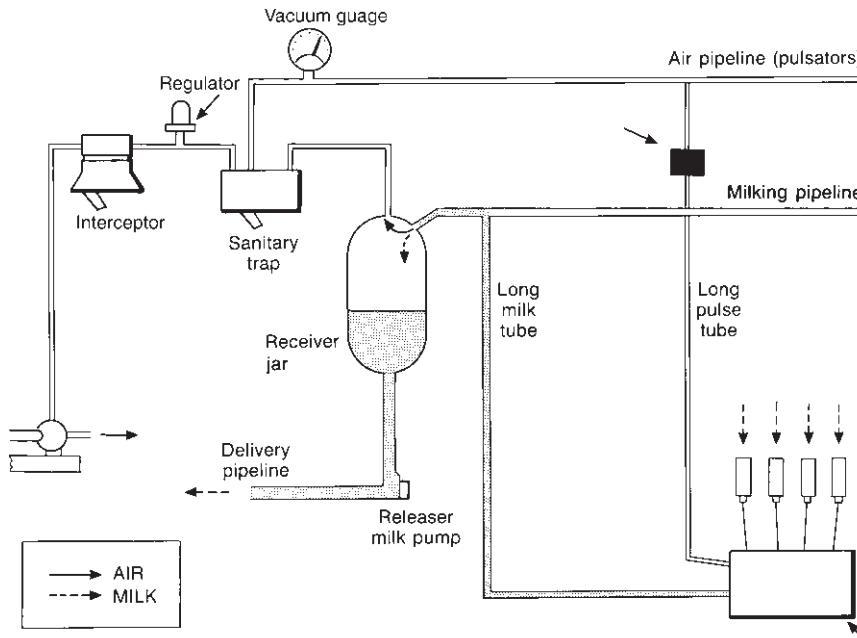

Fig. 26.2 Milking pipeline machine.

has been reached. When the vacuum level drops, the regulator closes; this stops admission of air and the vacuum level rises until the preset level of vacuum is reached, at which time the regulator opens again and admits air.

Pulsation: This causes the liner to open and close: when there is vacuum in the pulsation chamber the liner opens and milk flows; when air is admitted into the pul-

sation chamber the liner collapses, milk flow stops and the teat is massaged. In fact, milk generally flows when the liner is more than half open. The exact function of pulsation has not been established but is now thought to be relief of congestion around the teat orifice. Figure 26.4 shows a typical pulsation chamber waveform containing four phases: (i) a phase, liner opening; (ii) b phase, liner fully open; (iii) c phase, liner closing; and (iv) d phase, liner fully closed.

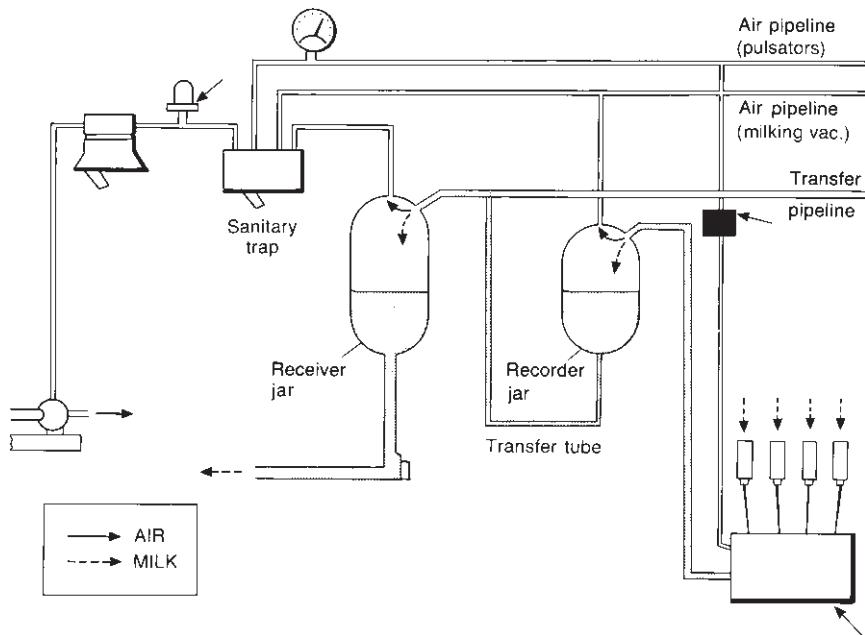

Fig. 26.3 Recorder milking machine.

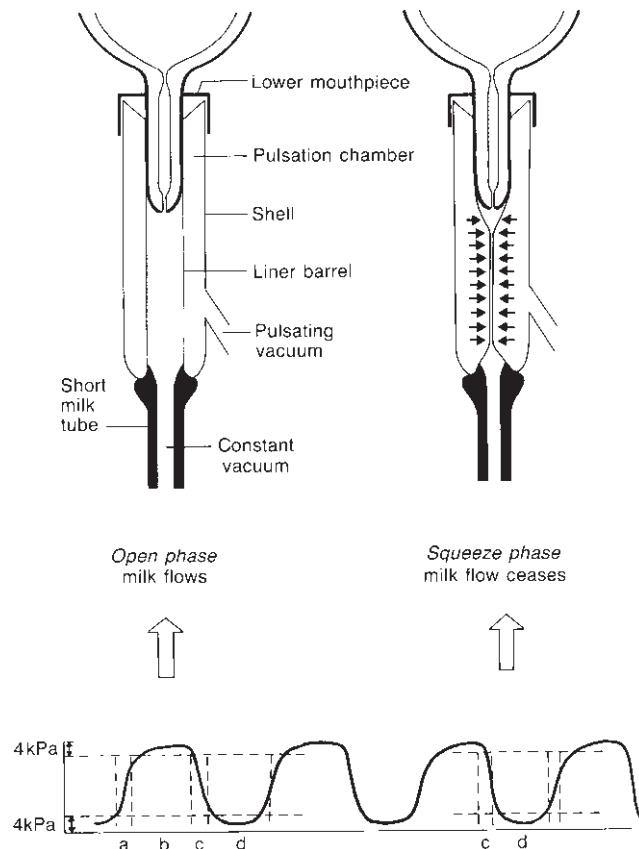

Fig. 26.4 Pulsation chamber waveform.

Liners: The performance of liners is related to various dimensions of liners and various other physical properties of the liner. The liner is the major determinant of milking characteristics (O'Shea, 1982).

Milking machine testing

Milking machines are tested to assess whether they are in good mechanical condition and conform to working standards as laid down by the standards institution of that country where used. Static and dynamic tests are used.

Static test

This type of test has been carried out for many years. It is basically an engineer's test to check for correct functioning of the components of the machine. The machine is set for milking and plastic bungs placed in the liner mouthpieces. No milk flows and, therefore, the test does not give an indication of how the machine will perform during milking.

There are three measurements to look for when interpreting a static test report:

- (1) *Effective reserve.* Vacuum within the plant is created by the vacuum pump. Air is used by the pulsators, air holes in the claws and leaks in the plant, etc. The spare vacuum capacity left after compensating for these leakages is called the effective reserve. The effective reserve is used to compensate for additional leakages during cluster application and removal and cluster fall-off.
- (2) *Pulsation.* Table 26.1 shows the recommendations for pulsation characteristics.
- (3) *Leakages:* The static test will measure the air consumption of the major components in the machine

Table 26.1 Recommendations for pulsation characteristics.
Source: O'Shea (1982), reproduced with permission.

| Parameter | Acceptable range |
|-------------------|-------------------|
| Rate | 53–63 c/min |
| Ratio (atb : ctd) | 55–70% |
| d-value | Not less than 15% |

and there is a set of standards for the maximum consumption allowed. It is worth checking that the results of the test are within the normal range.

Practical tips

As a veterinary surgeon in practice there are two simple ways of checking the effective reserve of a machine:

- (1) Put plant in milking position with plastic bungs in the liners. For every five units, open one and let air in. If the effective reserve is sufficient the vacuum level, as read at the vacuum gauge, should not drop by more than 2 kPa (about $\frac{3}{4}$ inch Hg) (O'Shea, 1982).
- (2) Again put plant in milking position with plastic bungs in the liners. By letting air in the plant, via the gate valve, drop vacuum to 33 kPa (10 inches Hg). Close off air leakage. The vacuum should return to 50 kPa (15 inches Hg) within 3 seconds (Mein, 1984).

Dynamic test

Dynamic testing was indicated in only 1 per cent of herds (O'Callaghan *et al.*, 1982) where there was a mastitis problem and the static test had revealed no faults. At that time, equipment was either very sophisticated and expensive (UV recorder) or crude (pulsation pen recorder). In recent years, with the advent of computer technology, new recording machines specially designed for dynamic testing have been developed.

In dynamic testing the vacuum level is measured at the clawpiece and other areas of the machine, e.g. the recorder jar, throughout the milking of a number of cows. This allows the determination of what is happening when milk and air are flowing in the machine and also assessment of the ability of the milker to use the machine properly.

There are three measurements to look for when interpreting a dynamic test reading:

- *Cyclic fluctuations*: generated within the claw as a result of pulsation (Fig. 26.5).

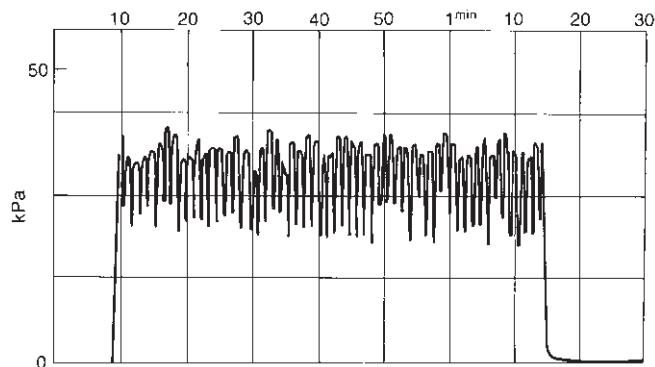

Fig. 26.5 Vacuum changes (cyclic fluctuations) at the teat end during milk flow.

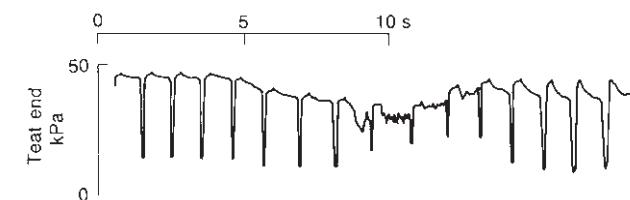

Fig. 26.6 Vacuum changes (irregular fluctuations) at the teat end during milk flow. Source: Nyhan (1968).

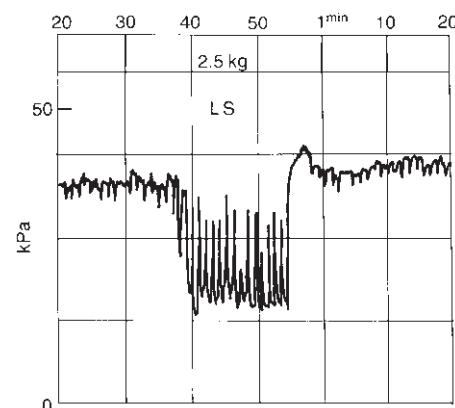

Fig. 26.7 Liner slip at the teat end during milk flow. LS, liner slip; 2.5 kg, flow rate of 2.5 kg/min.

- *Irregular fluctuations*: occur as a result of changes in airflow during milking, which leads to a drop in vacuum (Fig. 26.6).
- *Liner slip*: sudden air admission between the liner and the teat (Fig. 26.7). A problem exists if more than five slips or falls per 100 cows require correction by the milker(s) (Mein, 1984).

It should be noted that 50 per cent of the faults detected in a dynamic test are operator related.

Milking machines and mastitis

The milking machine can act as vector in three ways: (i) cow-to-cow transfer of bacteria via contaminated clusters; (ii) internal flow between clusters within the plant; and (iii) quarter-to-quarter transfer within the cow via the claw.

A farm survey in Ireland in 1967 showed a highly significant regression of bulk milk cell count on effective reserve of the milking plant, i.e. as effective reserve decreased cell count increased (Nyhan & Cowhig, 1967). Subsequent work showed that unstable vacuum (a combination of large irregular fluctuations and moderate cyclic fluctuations) caused higher new infection rates than stable vacuum.

Further work carried out at the National Institute for Research in Dairying (NIRD) at Reading in the early 1970s (Cousins, 1972; Cousins *et al.*, 1973; Thiel *et al.*, 1973) found that large irregular fluctuations or large cyclic fluctuations *per se* did not increase new infection rates. However, any combination of large irregular fluctuations with substantial cyclic fluctuations caused a large increase in new infections. The results also suggested that infections were most likely to be initiated towards the end of milking.

During the late 1970s research workers at Moorepark in Ireland (O'Callaghan *et al.*, 1976; O'Shea *et al.*, 1976, 1979, 1981; O'Shea & O'Callaghan, 1978, 1982) showed that plant vacuum stability *per se* had little effect on new infection rate. It was suggested that the effect of generalized vacuum instability is mediated via increased liner slip, i.e. sudden air admission between the liner and the teat. Liner slip, in turn, is largely a function of liner design and also of vacuum stability.

When slip occurred in one quarter, impacts of milk droplets were detected in other quarters connected by the claw to the teat in which the slip occurred and a higher number of new infections occurred in these impacted quarters.

This liner slip theory is compatible with many other results. Liner slips are more frequent at foreteats; infections are more often seen in hind quarters (Rabold & Picher, 1980). Slip frequency is most common at morning milkings and high flow rates and infections are

most frequent in cows with high milk flow rate (O'Shea *et al.*, 1980).

Further work carried out on simulated liner slips at Moorepark in the early 1980s (O'Shea *et al.*, 1981) yielded the following results:

- There were equal numbers of new infections with inaudible and audible liner slips.
- Liner slips at start of milking or the end of milking only, or during the total milking caused almost equal numbers of new infections.
- Liner slips increased new infections when teats were heavily contaminated with environmental bacteria (*Escherichia coli* and *Streptococcus dysgalactiae*).

Liner slip is now considered to be the major mechanism of spread of mastitis at milking (O'Shea *et al.*, 1981).

Baxter *et al.* (1990) found that new intramammary infection rates (IMI/100 cow days) were 0.379 in cows milked with high-slip liners and 0.277 in those milked with low-slip liners ($p=0.056$). Clinical cases per 100 cow days were 0.211 in the high-slip group and 0.158 in the low-slip group ($p > 0.05$). Rogers and Spencer (1991) found that variation between cows in machine liner slips, and manual milking machine adjustments within and across lactation number and days in milk can be partially explained by udder and teat morphology. Wider teats (distances between teats) were associated with increased liner slips and increased manual milking machine adjustments. More tilted udders (rear quarters lower than front quarters) were associated with increased liner slips and tended to be associated with increased manual adjustments. In addition, poor unit alignments, larger teat diameter and longer teats tended to be associated with increased liner slips.

Developments in milking machine technology

Shields

During the late 1970s research workers at Reading developed shields (deflector plates) in the teatcup chamber between the short milk tube and the teat end (Fig. 26.8). Trials on 15 herds in England and 16 herds

Fig. 26.8 Shielded liner. Photo courtesy of Institute of Animal Health (IAH), Compton.

Fig. 26.9 Ball claw cluster. Photo courtesy of Institute of Animal Health (IAH), Compton.

in Australia showed that shields prevented about 10 per cent of quarters from becoming infected (Griffin *et al.*, 1980a).

Ball claw

In the early 1980s research workers at Reading developed a cluster to prevent the transfer of pathogens between teats during milking (Griffin *et al.*, 1980b). It was a simple practical modification of the clawpiece for each of the four short milk tube connectors (Fig. 26.9). Field trials showed an overall 14 per cent reduction in new infection rate due to the clawpiece (Griffin *et al.*, 1982). However, there was an unexpected larger reduction (17 per cent) in new infection rates from environmental sources of exposure (*Streptococcus uberis*, coliforms and others) than from those (8 per cent) transmitted mainly at milking time within the udder or on teat sores (*Staphylococcus aureus*, *Strep. agalactiae* and *Strep. dysgalactiae*).

Hydraulic milking

Following research on the ball claw, Griffin and Grindal carried out an experiment to ascertain the effects of blocking the air bleed on new infections. Initial results from a closely controlled small scale experiment in a research herd showed that teat end condition was improved and that it was at least equal in preventing mastitis to milking with the valve clawpiece with airbleeds (Griffin, 1985). This new method of milking was christened 'hydraulic milking'. Research at Compton on the ball claw under hydraulic milking conditions has shown that as the liner starts to open, high vacuum levels (up to 90kPa) are generated beneath the teat (Grindal, 1987). Although high vacuum levels have been shown to increase teat damage during conventional milking (Smith & Peterson, 1946), further trials with hydraulic milking have not shown this to be a

problem. Grindal and Griffin (1989) carried out four trials comparing hydraulic milking with the valve clawpiece with airbleeds. Milk flow rate was increased by 20 per cent and milking time was decreased by 26 per cent with hydraulic milking. Quarter infection ratios were low in both groups with only two out of 88 quarters infected with challenges with *Streptococcus agalactiae* and *S. dysgalactiae* in each treatment group.

Automatic milking systems

About 100 automatic milking systems are currently in use on farms in Germany (Schon *et al.*, 1997). Milking robots are used at 200 Dutch dairy farms and it was forecast that >800 farms would be using them by 2000 (Ipema *et al.*, 1998). Data (1996–98) on milk quality were compared between 28 Dutch dairy farms using milking robots and those with machine milking three times/day (28 farms) and twice/day (49 farms). Parameters were somatic cell count, pH of milk fat, freezing point, clarity, fatty acids, milk fat and milk proteins. The use of a milking robot resulted in increased somatic cell counts and pH of milk fat, and decreased percentages of milk fat (from 4.43 to 4.37 per cent) and milk proteins (from 3.49 to 3.42 per cent). The main differences are due to the construction, design and cleaning of milking robots and cooling tanks (Klungel *et al.*, 1998).

Working and utilization of a milking robot were studied in a herd of 40 cows during the first 12 weeks of lactation (Pomies *et al.*, 1998). After a training period, cows had free access to the robot for 18 hours/day. During starting phase, frequency of breakdown of the robot was 1.4 times/week, the rate of automatic attachment of the cluster when a cow entered the robot was 80 per cent (70 per cent within the first two attempts) and manual attachment was 2.6 per cent. Five cows were removed from the robot due to problems on the front right quarter (reference for attachment of

Table 26.2 Recommendations for sizes of milking pipelines.

|-----------------|---------------------------------------|
| 2–5 | 31 |
| 6–8 | 38 |
| 9–20 | 50 |

cluster). The number of daily milkings was 2.4 and the daily milk yield was 27.9 kg. Clinical mastitis and milk composition and quality were similar to normal values of the herd, except for butyric acid bacterial counts, which were three times higher in the robotic-milked cows.

Automatic cluster removers

Automatic cluster removers (ACRs) are an important development in eliminating overmilking and improving labour efficiency. Persistent and excessive overmilking can cause external damage to the teat, which may increase the susceptibility to udder infection (Shepherd, 1985). However, ACRs are not recommended in two stalls per unit herringbone parlours. Limited overmilking does not increase new infection rate. ACRs do not reduce the work routine time, unless operators have been spending time moving up and down the pit to remove clusters as soon as cows have stopped milking. ACRs improve throughput in rotary parlours, provided teat disinfection is automated; in this case one operator less is needed. ACRs which admit air blasts into the claw (to activate the automatic shut-off) at cluster removal should not be used (O'Shea *et al.*, 1984). Ramussen (1993) showed that early cluster removal (400 g/min), when compared to normal level for cluster removal (200 g/min), decreased machine-on time by 0.5 minutes, increased average milk flow rates slightly, improved teat condition significantly and reduced the change in teat end thickness during milking of first lactation cows. Early removal did not affect milk yield or composition or the incidence of subclinical mastitis.

Large-bore pipelines

These are used in the USA, where it is not uncommon to see milk lines of 75 mm (3 inches) in diameter. At present, standards for sizes of pipelines are recommended by the International Dairy Federation (Table 26.2). At a National Mastitis Council Meeting in the USA, it was stated that the American standards for 38 mm (1½ inches) and 50 mm (2 inches) pipes are rea-

sonable, while the 62 mm (2½ inches) and 75 mm (3 inches) may not have been thoroughly evaluated (Spencer, 1981).

High- and low-line plants

Milking systems can be divided into two types depending on the level of the milking pipeline in relation to the cow's udder. Where the milking pipeline is above the udder it is called a high line and a low line if it is below the udder.

Midi-level pipelines (1.2 to 1.5 m above cow standing level) are recommended. Very high pipelines increase the level of cyclic fluctuations at the teat end (Thiel *et al.*, 1968). Low-level pipelines (under the cow standing level) decrease fluctuations and increase milking rates by 3 to 8 per cent (Phillips & Copeman, 1969). However, low-level plants are susceptible to contamination by urine and faeces. In herringbone parlours one unit must be used per stall, which is only 60 per cent as efficient as two stalls per unit (O'Callaghan *et al.*, 1982). In midi-level pipeline plants vacuum fluctuations are reduced by having air admission holes in the claw (Thiel *et al.*, 1968) but if these holes are not kept patent mastitis levels are likely to increase (Hopkirk *et al.*, 1943).

Liner design

Liner design can have a greater effect on milking characteristics than any other machine factor. Six-fold differences in strip yield, eight-fold differences in the incidence of liner slips and 33 per cent differences in milking times between liner types have been reported.

Machine-induced congestion and oedema is reduced by milking with a 'narrow-bore' liner with a soft mouthpiece. The internal diameter of a liner is usually measured at a point 75 mm below the mouthpiece. Liners should have a barrel diameter about 1–2 mm less than the average diameter of the teats after milk letdown (approximately 21–22 mm). Liners should be designed to fit teatcup shells. The mouthpiece should not be distorted by the shell, but the liner should be held firmly enough not to twist easily in the shell. Teatcup shells should all be the same length (within 2 mm) to ensure uniform liner tension and to distribute the cluster weight more evenly between the four quarters (National Mastitis Council, 1996).

In North America narrow liners with a supple mouth are preferred, as these are thought to reduce the risk of oedema of the teats. It is considered that the diameter of the liner should be 1–2 mm less than that of the teat after milking, thus providing sufficient friction between the liner and the teat. The liner should also be long enough to enclose the teat completely. The liner must be well aligned in the teatcup. Liners may be made from

natural rubber, synthetic rubber, silicone or a mixture of these products; the material used will largely determine the lifetime of the liner (Levesque, 1998). Most manufacturers recommend that rubber liners are used for between 2000 and 2500 cow milkings and then changed. The recommended life of silicone liners is 5000 cow milkings or 5 months – whichever comes first. Theoretically they have a longer life than rubber liners as silicone does not absorb fat. However, in practice they are more susceptible to tearing and puncturing than rubber liners and are likely to split if cows step on them, as well as being three to four times more expensive.

Backflushing

Liners are a potent method of disseminating pathogens both within and between cows. The number of pathogens recoverable from liners after milking infected cows is related to the number of bacteria in milk from the infected cow. Consequently, it is recommended that clusters should be disinfected between the milking of infected cows. The most common practice is to dip the cluster in a disinfectant solution for a couple of seconds. Such a practice generally reduces the number of pathogens transferred from cow to cow. However, such practice has often been rendered ineffective because contamination of milk neutralized the disinfectant solution, air locks within the cluster prevented entry of the disinfectant or the milker failed to carry out the procedure correctly.

Results from studies carried out at NIRD (Neave, 1971) indicated that circulating water at 85°C through the cluster for at least 5 seconds is the best way to achieve near sterilization of liners between milkings, although a cold hypochlorite flush reduced numbers of bacteria to very low numbers (Table 26.3).

Laboratory experiments showed a large reduction in bacteria (about 99 per cent) after backflushing with cold water (Jasper & Bushnell, 1978) and an initial flushing with an iodine disinfectant appeared to give better results. The authors concluded that even though complete sterility may not be achieved, backflushing should be helpful in reducing cow-to-cow transfer of pathogens on liners. Around this time automatic back-flushing systems using cold water rinses with or without a chemical disinfectant between cold rinses were developed.

Eriksen and Rasmussen (1994) carried out a 9-week experiment with 283 cows in two groups, a control and an experimental group. The teatcup liners of the experimental group were backflushed with the Airwash system between milking each cow. The liners were flushed with a combination of compressed air and luke-warm water through small inlet valves placed in the short milk tube. The flushing sequence was water for 4s and compressed air for 2s, repeated for 30–40s. Automatic backflushing of liners reduced the total bacteria count by 50 per cent, coliforms by 68 per cent and *Staphylococcus aureus* by 61 per cent without having any effect on udder health and somatic cell count.

| | Dipping | Hand spraying | Auto spraying |
|-----------------------|-----------|---------------|---------------------|
| Time taken (min/cow) | 0.08–0.10 | 0.04–0.08 | Nil |
| Teat-end coverage (%) | 95–100 | 79–97 | 96–99 |
| Volume used (ml/cow) | 5–10 | 10–13 | 30 |
| Chemical type | Various | Iodophor | Dilute hypochlorite |

Automatic teat disinfection

Several automatic teat disinfection systems are available. These are fitted to the exit race of the parlour and consist of a pressure spray unit fitted with a set of nozzles. The spray is activated by an electronic control unit, which detects the presence of the cow (Hunter, 1985). Table 26.4 shows that with automatic teat spraying it is possible to achieve as good coverage as dipping. Automatic spraying will use more chemical. However, as it is outside the parlour it is possible to use the much cheaper chemical hypochlorite.

Control measures

The milking machine is only one component that can be involved in mastitis. Mastitis control involves continued implementation of each of the recommendations in the five-point control programme. Changing some of the components in the milking machine may help in the short term, but only a concerted effort in carrying out the full programme will control mastitis in a herd in the long run.

The following points are recommendations that should help to reduce mastitis resulting from the milking machine:

- Maintain proper vacuum levels.
- Attach and remove clusters properly to minimize massive changes in vacuum and resulting from entry of air into the clawpiece.
- Make sure clusters are attached properly on each cow.
- Select liners with low slip characteristics. Replace rubber liners every 2500 milkings or every 6 months, whichever comes first, and siliconized at 5000 milkings or every 5 months, whichever comes first.
- Dry teats before attaching clusters in order to reduce the number of bacteria.
- Have the machine tested at least once a year.

Introduction

Teat lesions in milking cattle are due to a variety of causes, infectious and non-infectious. Viral skin infections of the bovine teat and udder are principally due to pseudocowpox virus, bovine herpesvirus 2 and papillomavirus, but, on occasions, teat lesions may occur in association with a generalized viral infection, such as foot-and-mouth disease, vesicular stomatitis, or mucosal disease. Although the vernacular use of ‘cowpox’ to describe any teat infection is common, cowpox (as caused by cowpox virus) is an unusual disease and has been recognized only in Europe. There are several bacterial and non-infectious skin conditions of the teats and udder that can be equally as troublesome as viral infections. Irrespective of cause, when teat infections occur in a milking herd they predispose cattle to secondary bacterial infection by *Staphylococcus aureus*, *Streptococcus dysgalactiae* and other bacteria. Cows, and particularly newly calved heifers, become difficult to milk and the milking time may be prolonged by as much as 50 per cent.

Currently, there are no vaccines in use to protect cattle from any of the viral teat diseases and treatment

is palliative. Differentiation of the diseases affecting the teats and skin of the udder is important, however, for reasons of public health and exotic disease control; cowpox and pseudocowpox are zoonotic diseases causing skin infections that can affect milking personnel or herdspersons and any vesicular lesions on the teats should always raise suspicion of foot-and-mouth disease.

In this chapter, particular attention is given to bovine herpes mammillitis and pseudocowpox, the two diseases that cause greatest concern to dairy farmers in the industrial nations of the world.

Infectious lesions of the teat

(see Table 27.1)

Bovine herpes mammillitis (BHM)

Aetiology

Bovine herpes mammillitis (BHM) is caused by bovine herpesvirus 2 and is closely related, if not identical, to Allerton virus (p. 887), the causative agent of pseudolumpy skin disease; it is unrelated to bovine herpes virus 1, the aetiological agent of infectious bovine rhinotracheitis.

The genome is linear double-stranded DNA, 220 kbp. The virus produces intranuclear inclusions and syncytia in infected cells.

Epidemiology

Also known as bovine ulcerative mammillitis, BHM was first recognized in Scotland. The virus has since been isolated from affected cattle worldwide in countries such as the USA, Australia and Brazil.

In the northern hemisphere, BHM commonly occurs as a seasonal disease between August and December. In a completely susceptible herd, the disease spreads quickly with nearly all cows developing infection over one to two months. In other herds, only the newly calved heifers introduced into the milking herd for the first time are affected. Recrudescence of clinical disease

Table 27.1 Infectious conditions of the teat and udder skin of cattle.

| |
|--------------------------------------|
| Cowpox and vaccinia |
| Pseudocowpox |
| Bovine herpes mammillitis (BHM) |
| Bovine papillomatosis (warts) |
| As part of generalized disease, e.g. |
| foot-and-mouth disease |
| rinderpest |
| lumpy skin disease |
| mycotic dermatitis |

is unusual, even though latent infections do occur. Whether latently infected older cattle are the reservoir of infection from which the newly calved heifers become infected is conjectural. It is thought that susceptible pregnant cows may become infected some time before parturition, but do not develop the lesions until calving.

The method of transmission of the virus between farms with closed herds is unknown, although biting flies have been incriminated as possible vectors.

Clinical signs and lesions

Bovine herpes mammillitis is a disease initially characterized by a painful oedematous teat swelling. The incubation period ranges from three to seven days. The disease is generally more severe than either cowpox or pseudocowpox and the lesions are ulcerative rather than proliferative. Newly calved heifers are usually the most severely affected, particularly if they have post-parturient oedema of the udder. Initial lesions are followed by the development of an irregularly shaped vesicle (0.5–5.0 cm in diameter) (Plate 27.1). Within 24 hours, the vesicles rupture, leaving an ulcerated surface that exudes copious serum (Plate 27.2). Upon drying, this exudate forms a thick, dark reddish-brown scab (Plates 27.3 and 27.4). In the absence of secondary infection, healing is complete in three weeks by granulation and regrowth of the epithelium (Plates 27.5–27.8). Lesions on the udder may coalesce with those of the teat and may extend to the perineum resulting in vulvovaginitis as a sequel to infection of the skin of the mammary gland.

Differential diagnosis

Bovine herpes mammallitis usually occurs in summer and autumn. The oedema of teats, vesication and ulceration and extensive scab formation over most of the teat surface are strongly suggestive of BHM. Epidemics of BHM can occur in a region, which can lend support to the diagnosis.

Pseudocowpox

Aetiology

Initially confused with cowpox virus, it was not until 1963 that it was demonstrated in the USA that pseudocowpox virus was a member of the genus *Parapoxvirus*. Pseudocowpox virus is closely related to the virus of orf (contagious ecthyma, contagious pustular dermatitis) of sheep, and also to the bovine papular stomatitis virus.

The virus contains a linear double-stranded DNA, 130 kbp, and produces intracytoplasmic inclusions in infected cells.

Epidemiology

Referred to in the past as false cowpox, varicella, waterpox, udderpox and natural cowpox, pseudocowpox occurs in most countries of the world. It is the most common infectious cause of teat lesions in North America and the UK. Lesions of pseudocowpox may be seen in a herd during any season of the year. The immunity is short-lived, lasting four to six months; thus, pseudocowpox is commonly seen as a chronic problem in most herds. Although herd morbidity may reach 100 per cent, only 5–10 per cent of the herd may be infected at any one time. Nevertheless, it may occur as an acute herd problem, which spreads rapidly affecting a majority of the cows in the herd. Lesions in such primary outbreaks are frequently more extensive.

Clinical signs and lesions

The clinical presentation of pseudocowpox is variable. Usually no systemic illness is noted and vesicle formation may not be observed. After an incubation period of about six days, localized erythematous and oedematous areas appear on the teats. These lesions are painful, making cows difficult to milk. Within 38 hours, a small orange papule develops, followed by the formation of an elevated small dark red scab (2–3 mm) (Plate 27.9). In some cases, a vesicle will form in the centre of the papule, but this is rare with pseudocowpox in contrast to bovine herpes mammillitis. The progressive enlargement of the edges of the lesions (Plate 27.10) leads to umbilication of the central scab. Healing of the lesion is centrifugal and the primary scab is often shed after 10 to 12 days, leaving the classical raised ‘horseshoe’ or ‘ring’ lesion, which is pathognomonic for pseudocowpox (Plate 27.11). As adjacent lesions enlarge, they may coalesce to form linear scabs extending the entire length of the teat (Plate 27.12). Pseudocowpox lesions are primarily found on the teat; however, 5–10 per cent of affected animals develop lesions on the udder. Healing usually occurs within four to five weeks, leaving no scars.

In herds where 'teat chaps' are common, pseudocowpox virus can be detected in many of the lesions.

In humans, pseudocowpox virus causes localized infection on the fingers or hands, commonly called 'milker's nodule'. These nodules are painful and may extend to the entire arm of the person affected.

Differential diagnosis

In contrast to BHM, pseudocowpox is a chronic problem in most herds. Lesions are proliferative, progressing to small 'ring' or horseshoe type lesions rather than ulcerative. Atypical lesions (Plates 27.13–16) may be observed and confused with warts or mild traumatic injuries to the teats and udder but, in general, a careful examination of the herd will allow the clinician to differentiate pseudocowpox from other diseases. It must be remembered that pseudocowpox is often present in herds where the major problem may be due to BHM or even cowpox.

Papillomatosis (teat warts) (see p. 882)

Aetiology

Bovine teat papillomatosis (teat warts) is a common finding of dairy cattle throughout the world. The causative agents of teat warts are several distinct strains of bovine papilloma virus (BPV). The strains most commonly implicated are BPV-1, BPV-5 and BPV-6. These strains of BPV are classified as members of one of two subgroups. Strains in subgroup-A, which include BPV-1 and BPV-5, produce warts with both dermal and epithelial components (fibropapillomas). Subgroup-B strains, of which BPV-6 is a member, produce warts with only epithelial proliferation (papillomas). The virus contains a closed, circular, double-stranded DNA approximately 8000 bp in size.

Epidemiology

The method of infection is thought to be similar to other bovine cutaneous warts in that transmission is by direct contact with infected animals or fomites. The virus needs cutaneous damage, such as abrasions, to gain entry into susceptible tissue. After infection occurs, incubation times of 1 to 6 months have been demonstrated under experimental conditions. Abattoir studies have shown that teats often have multiple warts and that prevalence increases with increasing parity.

Clinical signs and lesions

Because of the tendency of BPV strains to produce morphologically distinct warts, presumptive identifica-

tion of the causative BPV strain of a teat wart may be possible through gross examination. BPV-1 has been demonstrated to be responsible for fibropapillomas of the penis and teats. The teat warts have a filamentous or frond-like appearance. These warts are normally seen on younger animals and will typically regress over a period of 1–12 months. BPV-5 produces small 'rice grain' fibropapillomas, so named because of their white and elongated appearance. These warts are seen in cattle of all ages, and, if natural regression occurs, it does so over periods of greater than a year. The warts produced by BPV-6 are papillomas that have a frond appearance and are considered the most common type of teat papilloma. These frond papillomas may regress, usually in a time frame of greater than a year.

Cowpox

Aetiology

Cowpox virus shares with Jenner a central role in the development of vaccines and the control of smallpox in man. The current use of vaccinia virus (the derivative virus used for protection of man from smallpox) in a new role as a recombinant vaccine vector for many diseases, maintains attention on cowpox. Few people realize that cowpox was considered an unusual disease even in Jenner's time. Occasional outbreaks of cowpox still occur in Europe, but from the perspective of the dairy industry they are of little importance.

The causative agent of the cowpox is an orthopoxvirus, very similar to, but distinguishable from, vaccinia virus by its biological properties in laboratory animals and its larger genome (220 kbp compared with 185 kbp for vaccinia virus). The virus produces intracytoplasmic inclusions in affected cells.

Epidemiology

The epidemiology of cowpox is unknown. Cowpox virus has been isolated from skin infections in man and carnivores in which no direct contact with cattle could be established. It is currently thought that rodents are reservoirs of the virus.

Once infection is present within a herd, however, the disease appears to spread by the milking machine and the hands of milkers. Between and within herds, biting insects may also be responsible for mechanical transmission. At present, the disease is confined to western Europe. In other areas of the world, outbreaks of teat lesions, clinically indistinguishable from cowpox but caused by vaccinia virus from an uncovered vaccination site in an attendant, have been reported. Since the eradication of smallpox in 1979, most countries have discontinued vaccination against smallpox, although

military personnel and others are now vaccinated because of the threat of bioterrorism. Currently, there is little likelihood of vaccinia infections occurring naturally on the teats of cattle in most parts of the world, but if widespread use of vaccinia recombinants becomes popular, either in man or domestic animals, a resurgence in vaccinia mammillitis in cattle is conceivable.

Clinical signs and lesions

The incubation period is approximately five days, after which an irregular prodromal fever and tenderness of the teats is noticed. A roseolar erythema occurs at the site of future pock development: oedema may be localized to the area of the erythema or may involve the whole teat. A vesicle forms three to four days after the initial onset of signs (Plate 27.17) and rapidly progresses to a pustule, which subsequently ruptures and suppurates (Plate 27.18). The classical development of a thick red scab ranging in size from 1 to 2cm in diameter and said to be pathognomonic for cowpox may now form (Plate 27.19), but more frequently an ulcerated surface is observed (Plate 27.20). Healing is centripetal and, in uncomplicated cases, takes place within three weeks. Immunity to reinfection is said to be lifelong.

Vesicular stomatitis (see p. 710)

Aetiology

Vesicular stomatitis (VS) is a sporadic disease of cattle in the US, but is endemic in other areas of the western hemisphere. VS is caused by a vesiculovirus of the family Rhabdoviridae. Vesicular stomatitis virus has a genome that consists of a single-stranded, negative-sense RNA approximately 11 kbp in length.

Epidemiology

The epidemiology of vesicular stomatitis virus is not completely understood at this time. The disease is seen most commonly in the form of sporadic outbreaks, but the inter-epidemic host is, as yet, unknown. Outbreaks are seen less frequently in more temperate climates and after the first frost of the year. The virus is probably transmitted by direct contact with contaminated milking equipment, ingestion of contaminated materials, and a number of different biting insects. The antibodies produced by natural infection seem to provide little protection from reinfection. Persistent viral infection has been theorized, but has not been clearly demonstrated.

Clinical signs and lesions

Following an incubation period of only 24–48 hours, fever and vesicle formation will be observed in cattle infected by vesicular stomatitis virus. The vesicles will develop into erosions on the mouth (especially the tongue), teats and, rarely, the coronary band. The oral lesions will lead to the clinical signs of excessive salivation and feed refusal. The teat lesions produced by VS are often indistinguishable from those produced by foot-and-mouth disease. For this reason, VS is considered of great regulatory importance.

Laboratory diagnosis

Sample collection

An accurate diagnosis of the cause of teat lesions may be possible with a thorough examination of both affected and apparently healthy cows within a herd (or group in larger herds). However, for a definitive diagnosis, laboratory confirmation is required. An accurate laboratory diagnosis requires adequate tissue samples to be submitted. For submitting good quality samples when a virus is suspected as the causative agent, the clinician should remember the following guidelines.

- During the early stages of the disease, the titre of the virus is highest at the affected sites.
- Viruses require living cells and may be inactivated by disinfectants, light exposure, pH extremes and desiccation.
- Secondary bacterial infection of skin samples is common in later stages of the diseases.
- Skin scrapings should come from animals with early lesions and be transported on cold packs.
- Samples for virus isolation should be collected into virus transport media and transported on cold packs.
- To avoid erroneous results, more than one animal and multiple lesions should be sampled.
- An area that will be collected as a skin scraping or biopsy should be washed with saline, not alcohol (alcohol will inactivate the viruses).
- Scrapings should extend to the periphery and base of a lesion.

A wide range of laboratory tests may be used for making the diagnosis of the viral agent responsible for a teat lesion. Brief descriptions of common diagnostic laboratory tests are included below.

Diagnostic techniques

Electron microscopy

Electron microscopy has emerged as a very accurate and useful test for practitioners. The advantages of

electron microscopy include a rapid diagnosis and the ability to detect non-viable virus and combined viral infections.

Tissue culture

Virus isolation using tissue culture is an alternative if electron microscopy is not available. Acceptable samples may be derived from early scabs, vesicular fluid or scrapings of the raw surface of lesions. Some strains of pseudocowpox may fail to grow *in vitro*, but vaccinia virus can be distinguished from cowpox virus on tissue culture.

Histological identification

Collection of a biopsy of a teat lesion is seldom easy. If one is collected, the tissue should be preserved in 10 per cent formol saline or preferably Bouin's solution. Each of the infections discussed above has a characteristic histopathology if an early lesion is sampled. Combined with immunohistochemistry, this technique is useful for the differentiation of the specific causative strain of BPV responsible for teat warts. The disadvantage of this diagnostic technique is the difficulty in collecting a teat biopsy and the necessity of an early lesion of sampling.

Paired serum samples

Paired serum samples collected during the acute stage of the infection and 14 days later may provide a diagnosis. A diagnostic 4-fold rise in serum antibodies is observed in cowpox and BHM, but pseudocowpox generally does not elicit a serological response. A primary problem with this test is that the cow may already be past the acute stage of the illness by the time she is tested. This is especially true of BHM, for which acute stage serum samples must be taken within two days of the appearance of lesions. For practical purposes, however, a clinical diagnosis of BHM may be made by the detection of high BHV-2 antibody titres in a single sample.

Treatment

There are many differing opinions on the treatment of ulcerative teat lesions produced by viruses. However, all the treatments have the similar primary therapeutic objectives of promoting healing and limiting secondary bacterial infection. Many treatment protocols rely on the use of different combinations of astringents and topical antibiotics. Topical corticosteroids and anaes-

thetic ointments have also been recommended, but in large herd outbreaks this type of treatment may be difficult to justify financially. Large multiple-use containers of ointments should be avoided, as they may become contaminated with virus and serve as a source of new infections. Strict hygiene must be followed if applying ointments by hand, as the hands of treatment personnel may transfer the infection to uninfected teats. A commonly recommended alternative therapy is the spraying of a teat dip containing emollients (such as 10 per cent glycerin) to reduce bacterial and viral numbers and soothe damaged skin.

Teat warts, on the other hand, may often go ignored until an increase in size interferes with milking and requires treatment. Surgical removal of the warts, either by excision or cryosurgery, may be effective. Autogenous and commercial vaccines have also been used as treatments, with varying degrees of success. Vaccine failures in the past were possibly due to a combination of using one strain of BPV to treat a lesion caused by a different strain and a lack of cross-protection between strains. Vaccination has been reported to be effective for the prevention of warts caused by BPV-1 and BPV-6, but not for BPV-5. Autogenous vaccines probably provide the best potential for success.

Prevention and control

Although the treatment of individual cows suffering from teat lesions is necessary, it is also important to institute prevention and control strategies within the herd. Ideally, new herd additions should be quarantined for at least 14 days before their introduction into the herd. All infected cows should be isolated or, more reasonably, milked last. All milking equipment should be thoroughly disinfected after use on an infected cow. Milkers should wear gloves in the parlour and disinfect the gloves between cows. Concerted efforts should be made to reduce the fly and insect population. Teat skin condition must be preserved by removing sources of trauma, including improperly functioning milking equipment and poorly maintained housing. Finally, the use of autogenous vaccines (such as in the case of papillomatosis) may provide some protective benefit.

Non-infectious lesions of the teat end (see Table 27.2)

Introduction

In addition to infectious lesions of the bovine teat and udder are those caused by traumatic events, chemical injury, environmental conditions, insects and the

Table 27.2 Non-infectious conditions of the teat and udder skin of cattle.

| Insect induced |

milking machine. As discussed earlier, teat lesions, regardless of cause, are frequently colonized by staphylococci and *Strep. dysgalactiae*. Lesions occurring at the teat end increase the risk of mastitis. Consequently, high new infection rates and increased numbers of clinical cases of mastitis are common sequelae in herds where lesions involving the teat end are prevalent (Plate 27.21). Lesions of the teat barrel are less likely to cause mastitis directly, but do cause greater milking difficulty. The increased risk of mastitis occurs more as an indirect response to the pain experienced by the cow during milking, resulting in reduced milkout and milking speed.

Theleitis

This is a non-specific condition of the inner wall of the teat often associated with inflammation due to traumatic injury or infectious conditions of the teat and udder. Inflammation involving the teat results in a thickening and hardening of the wall of the teat cistern that in the most severe scenario could lead to partial or complete occlusion of the teat. Theleitis is believed to be a significant, if not primary, reason for the development of non-functional teats or 'blind quarters'. However, a Florida study suggests that many blind quarters are due to non-mastitis/theleitis related factors. Blind quarters are generally described as those with an absence of mammary tissue or those which lack a functional teat or teat sphincter. Duraes *et al.* (1982) studied the incidence of blind quarters in 1177 first parturitions in a Florida herd where all five major dairy breeds (Holstein, Guernsey, Jersey, Brown Swiss and Ayrshire) plus Holstein-Guernsey cross-breds were represented. A total of 38 (3.2 per cent) heifers had 48 (1 per cent) blind quarters at calving. The highest incidence occurred in Holsteins. The other breeds includ-

ing the cross-breds did not differ in frequency of occurrence. Adjusting production figures for length of record, cows with one blind quarter produced only 59 kg (130lb) (1.7 per cent) less milk for the lactation. Despite the seemingly insignificant impact on performance, records indicated that animals with blind quarters were culled an average of 57 days earlier than herd mates.

Teat trauma (see p. 1127)

Traumatic lesions of the teat are most commonly the result of the cow stepping on her teats or wire cuts. They are a troublesome problem for the veterinarian as well as the dairyman. Histologically, the teat wall contains an abundance of elastic connective tissue that provides for expansion and contraction of the teat as it fills and evacuates milk in the lactating cow. The near constant movement associated with these physical dynamics of the teat combined with milking preparation procedures and milk collection complicate the normal process of healing.

The dairyman's challenge is in getting cows with teat lesions milked. Because these lesions are generally painful and cows resist preparation and milking procedures they are difficult if not hazardous to milk.

A further complication is mastitis. Teat lesions are readily colonized by bacteria and thus serve as an important reservoir of infection. Udder preparation cloths, hands of the milker and milking machine components facilitate the transfer of infectious organisms between quarters of the same cow and can be responsible for cow-to-cow transmission as well. Emphasis on milking hygiene procedures becomes crucial in control of new infections whenever teat lesions are present.

Depending on severity and the period of time prior to discovery, teat lacerations may be repaired surgically. Fresh superficial lacerations of the teat skin (within 12 hours of occurrence) in which the vascular supply has not been significantly damaged have the best prognosis. These are generally amenable to surgical closure. If, on the other hand, such lesions go unnoticed for a couple of days and become heavily contaminated, cleansing in mild disinfectant solution and removal of the skin flap tissue is likely to be the best therapeutic approach.

Teat lacerations (see Chapter 66) that extend into the teat cistern are of greater concern and generally carry a more guarded prognosis. Exposed edges of the teat cistern lining must be sutured using a suture pattern that will turn the edges inward creating an impervious seal. If this is not achieved healing cannot occur and draining fistulae will often develop. The teat wall

muscle layers and skin may be closed separately. Most advise intramammary and/or systemic therapy for four to five days as a precaution against the development of mastitis. A protective bandage allowing access to the teat end for milking is recommended. Some suggest that milk be retrieved from the gland through the use of teat cannulas. Mastitis is a frequent secondary complication.

Pastured cattle have a lower incidence of teat trauma than confined cattle. Housing factors of primary importance are associated with the amount of space available to the cow for resting and rising. Further, individual cow characteristics and conformation increase the potential for teat trauma in some cows.

Chemical injury

Postmilking teat dipping is widely advocated for control and prevention of new mastitis infections. However, this practice has also increased the potential for chemical injury of teats and teat ends. The accidental or inadvertent use of concentrated udder wash or cleaning products in place of teat dip has been observed to cause serious teat lesions with a single application.

Teat lesions may also occur as a result of the application of an improperly mixed or defective teat-dip product. Iodophor-based teat dips, primarily because of their widespread use, are frequently the offenders. However, the problem has been observed with quaternary ammonium dips, chlorhexidine-based dips, dodecyl benzene sulfonic acid and hypochlorite teat dips. Lesions appear as dry, roughened, proliferative regions around the teat end that are usually discoloured by the teat dip. This discoloration may be present on 40–50 per cent of the teats in the affected herd. Changing to a dip with better conditioning properties will result in the rapid improvement of teat skin health.

In the case of the iodophor dips, problems have arisen secondary to freezing of the dip on farm or in transit. When these solutions freeze they separate, sending emollients to the bottom of the container while leaving excessive amounts of the active ingredients in a layer suspended above. The subsequent application of this concentrated iodine can cause teat irritation and lesions. Depending on the degree of insult these lesions can be quite severe.

Environmental injury

Teat chaps

Teat chapping is a common problem in the more temperate regions of the world where climatic conditions favouring dampness and cooler temperatures prevail.

Activities associated with milking such as udder preparation, the milking process and postmilking teat dipping all exacerbate chapping problems. Chaps usually occur as horizontal cracks in the teat skin. Serum exudates from these cracks result in the formation of linear scabs (Plate 27.22). The surrounding teat skin may appear dry or leather-like and flake.

The primary significance of chaps is that they are readily colonized by staphylococci and *Strep. dysgalactiae* and thus constitute a threat to individual cows affected as well as the herd. Drying of the teats and udders before cows leave the milking parlour, particularly during inclement weather conditions, is an important preventive measure. Further, the use of teat-dip products containing hydroscopic skin softening agents such as glycerine or lanolin is helpful in controlling chapping problems.

Freezing or frost-bite

Initially, frozen teats will appear reddened or pale. If severe, the lesion progresses to the state where a scab forms over the distal half of the teat. In time, usually several days, this scab will loosen and fall off, exposing a raw, denuded teat end. As a second scab begins to develop the duct may become occluded. Milking becomes difficult and may require opening of the streak canal surgically.

In less severe cases, scab formation does not occur and cows become receptive to milking after only a few days. Cows immediately leaving the milking parlour with wet teats (from dip or milk) to areas with inadequate protection during cold weather may develop frost-bite on the teat ends. Freezing of the droplet on the teat end confines the lesion to the teat-end orifice area. The result is as described above for frozen teats.

Treatment consists of attempts at keeping the teat duct patent and preventing the development of mastitis. Severely affected cows may need to be culled. Drying of the teats and udder prior to exit from the milking parlour and provision of adequate wind breaks and shelter for milking cows is essential. The suspension of teat dipping procedures should be considered during extremely cold winters.

Sunburn

Severe reddening and drying of the teats and udder are observed in sunburn conditions, when blisters may form. Lesions are most severe on unpigmented skin or where the skin is devoid of hair. The application of moisturizers, ointments and salves to the affected areas is advised for treatment. For burns caused by fire see p. 934.

Photosensitization (see p. 884)

This condition occurs when photodynamic agents are eaten in their preformed state. Upon exposure to sunlight, the unpigmented skin areas develop an erythema and oedema, which results in severe lesions that most commonly appear on the lateral aspects of the teats and udder (Plate 27.23). Medial aspects of affected teats remain soft and cool. These lesions are highly susceptible to secondary bacterial infection.

Milking machine-induced teat lesions

The milking machine is assumed to be a major cause of teat lesions. However, most lesions associated with the milking machine are mild unless malfunction results in extremely high vacuum or pulsation failure. Damage may be by direct trauma to the teat or indirect, occurring over an extended period of time through the induction of degenerative changes in the teat. These changes in teat tissue health are primarily associated with circulatory disturbances, resulting in oedema and hyperkeratosis. Proper pulsation is essential for the circulation of blood and lymph in the teat. When normal circulation is disrupted teat-end health diminishes.

Direct damage to the teat may be caused by excessive milking vacuum, inadequate pulsation and careless use by the operator. Although rare, subcutaneous haemorrhages in the teat epithelium and prolapses of teat duct tissue are possible consequences with severe malfunctions of milking equipment or its use.

Calluses and hyperkeratosis of teat ends

Because of its appearance, hyperkeratosis of the teat end is often mistakenly diagnosed as a prolapsed sphincter. Hyperkeratosis of teat ends is a common finding in hand milked dairy cows as well as beef cattle. Histopathology of this material will confirm it to be excess keratin, which some refer to as callouses. These callouses may be rough or smooth and thus logically implicated as possible risk factors for mastitis. However, according to studies in the USA, the presence of hyperkeratotic lesions at the teat end had no effect on the prevalence of mastitis unless accompanied by erosions or scabs.

The exact cause of hyperkeratotic lesions in dairy cattle is unknown, but appears to be related to certain milking practices and milking-machine-related factors. For example, high levels of milk production and extended milking times, failure to apply appropriate premilking stimulation and overmilking increased the degree of lesions. Vacuum levels and pulsation ratios (within normal limits) had no effect on the degree of

hyperkeratosis observed. On the other hand, a Wisconsin study indicated that hyperkeratosis of teat ends appeared to increase in relation to the compressive load of the milking machine liner.

Black spot

This condition is observed as a lesion of the tip of the teat commonly associated with excessive vacuum levels and overmilking. It is a particularly troublesome problem as the lesions are quite painful and frequently harbour mastitis pathogens, notably *Staphylococcus* sp. *Fusobacterium necrophorum* is also usually present in the lesions, but difficult to isolate. The specific location of this lesion at the tip of the teat end significantly increases the risk of mastitis in affected animals. Control of the condition requires correction of the predisposing cause and application of an effective teat dip containing emollients or other skin conditioning agents such as glycerol.

Insect-induced teat lesions

Summer mastitis is an acute suppurative disease of the non-lactating mammary gland (see Chapter 24). First described in Europe, it has been reported in the USA and other countries as well. It occurs sporadically throughout the year in Europe, with annual incidences in England and Wales estimated to be around 2 per cent of heifers and dry cows. In the USA, some estimate incidences of 5–6 per cent on certain farms during the summer months.

While some questions remain, in both the USA and Europe epidemics of summer mastitis have been coincident with periods of greatest fly challenge. Further, data indicate that effective fly control reduces disease incidence. These findings support the possibility of insect involvement. European data suggest that biting flies are responsible for the initial damage to the teat end and implicate the cattle fly, *Hydrotaea irritans*, as the infectious vector in summer mastitis (see Chapter 24).

Differential diagnosis of skin lesions of the bovine teat

The following is an aid to the diagnosis of lesions of the udder and teats in severely affected milking herds (see Table 27.3; Plates 27.1–32). With the exception of teat chapping and milking machine damage, the aetiology of which appears to be complex, most outbreaks of teat lesions in cows are due to three types of virus: (i) cowpox, (ii) pseudocowpox and (iii) BHM.

Table 27.3 The clinical appearance and diagnosis procedures for teat conditions (other than BHM, cowpox, bovine vaccinia mammillitis and pseudocowpox).

| Condition | Clinical appearance | Confirmatory diagnostic procedure |
|---|---|---|
| Blackspot (Plate 27.27) | Scabby infection of teat orifice with <i>Fusobacterium necrophorum</i> but often other organisms | Isolation of <i>F. necrophorum</i> (often unsuccessful) |
| Chaps (teat) (see Plate 27.22) | Skin fissures often through dermis. Haemorrhage may occur with scab formation at the fissure edge. Often horizontal lesions | None. Parapox virus particles may be found but their importance unknown. Heavy bacterial contamination of lesion common |
| Folliculitis and impetigo | Pustule with surrounding erythema | Isolation of <i>Staphylococcus aureus</i> |
| Foot-and-mouth disease (see Plate 27.24) | Vesiculation of teat, buccal and interdigital mucosae. Pyrexia | Presence of virus. <i>Notifiable</i> in most countries |
| Mud abrasion (Plate 27.28) | Abrasions on lateral surface of the udder | |
| Photosensitization (see Plate 27.23) | Lesion progresses from erythema, oedema to serous exudation through skin. There is then necrosis, ulceration and scab formation. Pigmented areas of teat unaffected | |
| Ringworm (Plate 27.29) | Typical grey crusty lesions | Isolation of <i>Trichophyton verrucosum</i> |
| Theleitis and serous exudate from udder skin in peracute mastitis (Plate 27.30) | Teat swollen, painful with udder skin involved. Cow febrile and toxic | Isolation of bacteria |
| Vesicular stomatitis | Vesiculation of teat, buccal and interdigital mucosae | Virus isolation. As similar to foot-and-mouth may need to notify |
| Warts | | |
| Filiform (Plate 27.31) | Pedunculated attachment to teat | |
| White nodule (Plate 27.32) | Broad attachment to teat. Variable in size. Some warts intermediate between filiform and nodule | |

Accurate diagnosis is important for various reasons. A major factor is the zoonotic potential of cowpox and pseudocowpox. Secondly, there is the need to differentiate foot-and-mouth disease as occasionally vesicles occur on the teats before their appearance in the mouth and foot (Plate 27.24).

When investigating an outbreak it is best to examine as many cattle as possible because the lesions in a single cow may not be typical. Often mixed disease occurs (Plates 27.25, 27.26) and an assessment of the development of lesions rather than just examination of the most severely affected cattle helps in the diagnosis.

On occasion the clinical appearance of the lesions can be modified by environmental factors, thereby making recognition of the condition difficult. Such factors include the teat cluster, mud or coloured teat dips. In these problems laboratory diagnosis becomes essential, although it is advisable in all disease investigations.

Introduction

Most countries with a developed dairy industry now pay producers on the basis of both total volume sold and compositional quality, and with the slowly increasing move for a larger proportion of milk to be used for manufacturing, this trend is likely to continue. In addition, many countries also have a milk quota system and to maximize profitability, a farmer must produce a specified amount of milk of optimum quality. Much attention has therefore been paid to factors affecting milk quality, the most important aspects of which are reviewed in this chapter. The composition of average Friesian/Holstein milk is given in Fig. 28.1. Feeding has by far the greatest impact on milk quality and as such will be discussed first.

Feeding and milk composition

This is an extremely complex area to study, since it is often difficult to differentiate the separate effects of, for example, plane of nutrition, system of allocation of food, frequency of feeding and feed composition. Superimposed on this are effects of feeding before and after calving and the problem of differentiating between compositional values and overall yield. For example, in a high-yielding cow the milk fat content

(g/kg milk) may be reduced, but the overall fat production (g/day) may be increased.

Feeding before calving

Severe underfeeding, leading to cows calving down in condition score 2 (overall scale 1–5, see p. 10) or less, will reduce milk yield, fat, protein and lactose and although these effects are greatest in early lactation, they will persist throughout it. The extent of the depression is approximately 20 g/kg (0.2 per cent) in milk fat and 10 g/kg in protein. Less severe underfeeding has little effect on milk protein, and provided that high quality diets are provided after calving, some of the effects on milk quality can be eliminated (Garnsworthy & Topps, 1982).

Feeding a high energy density diet (11.7 MJ/kg DM) precalving significantly increases milk fat concentration in early lactation; however, this effect does not persist and there is no significant effect on fat yield and no effect on protein concentration or yield.

Very fat cows have an increased fat content in their milk, and it has been estimated that milk fat increases by 2 g/kg for each 1.0 unit rise in condition score. This effect lasts for the first five to six weeks of lactation only, and is related to fat concentration only; indeed total fat yield is often depressed in very fat cows.

Feed constituents (see p. 112)

The greatest effect arises from the forage:concentrate ratio in the ration and its influence on milk fat content. Milk fat is synthesized from the fatty acids acetate and butyrate, products of the ruminal fermentation of forage and other feeds containing fibre. As the level of concentrates in the ration increases, the proportions of acetate and butyrate fall and that of propionate rises. There is also a decrease in ruminal pH and a depressed activity of cellulolytic degradation, which can eventually result in depressed dry matter (DM) intake. The extent of the depression varies with the materials being fed, but as an approximate guide, forage:concentrate ratios should not be allowed to fall below 60:40 (or 50:50 if fed as a total mixed ration). For example,

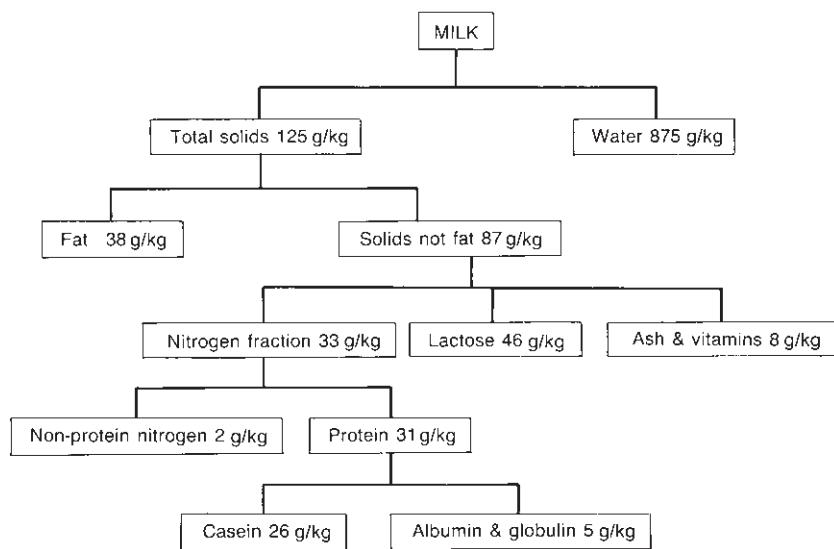

Fig. 28.1 The compositional quality of milk.

Table 28.1 Effect of proportion and type of concentrate in a mixed diet on milk production in early lactation. Source: Sutton *et al.* (1985).

| | 600 (g/kg diet) | | 700 (g/kg diet) | |
|---------------------------------------|------------------------|------------------------|------------------------|------------------------|
| | Starchy concentrate | Fibrous concentrate | Starchy concentrate | Fibrous concentrate |
| Consumed (kg air dry feed/day) | | | | |
| Hay | | 7.2 | | 3.5 |
| Concentrates | | 10.8 | | 14.0 |
| Dietary ADF (g/kg DM) | 192 | 231 | 136 | 180 |
| Milk yield (kg/day) | 26.3 | 26.5 | 32.0 | 25.5 |
| Fat concentration (g/kg) | 41.5 | 42.9 | 22.6 | 36.2 |
| Fat yield (kg/day) | 1.09 | 1.12 | 0.73 | 0.91 |

ADF, acid detergent fibre.

Sutton (1986) calculated that milk fat fell by 5 g/kg (0.05 per cent) for every 100 g/kg decrease in the proportion of hay in the diet, even when the overall energy content of the ration remained constant. However, there was a good deal of variation and probably a better way of estimating dietary effect is to express the overall fibre content of the diet on the basis of acid detergent fibre (ADF). Milk fat has been shown to fall when overall dietary ADF drops to below 200–250 g/kg DM. This is equivalent to approximately 450 g long forage/kg dietary DM, although on much higher forage diets, milk yield could be depressed.

The type of concentrate also has an effect. The energy fraction of a concentrate can be derived from four main sources, namely:

- Sugar, for example molasses.
- Starch, for example barley and maize.

- Digestible fibre, for example sugar-beet pulp, cotton seed, citrus pulp, etc.
- Fats and oils.

Table 28.1 (Sutton *et al.*, 1985) shows that concentrates containing a high level of digestible fibre cause less depression of milk fat and produce an overall higher fat yield (kg/day), even though total milk volume is reduced due to lack of starch. This was particularly noticeable at the higher levels of concentrate feeding. It is, of course, the amount of starch in the ration and its conversion into propionate and glucose that is one of the main determinants of the volume of milk produced. The energy in digestible fibre products such as sugar-beet pulp is derived from cellulose and hemicelluloses and is slowly fermented. Maize is also slowly fermented and as such causes less depression of milk fat, compared with other more rapidly fermented starch

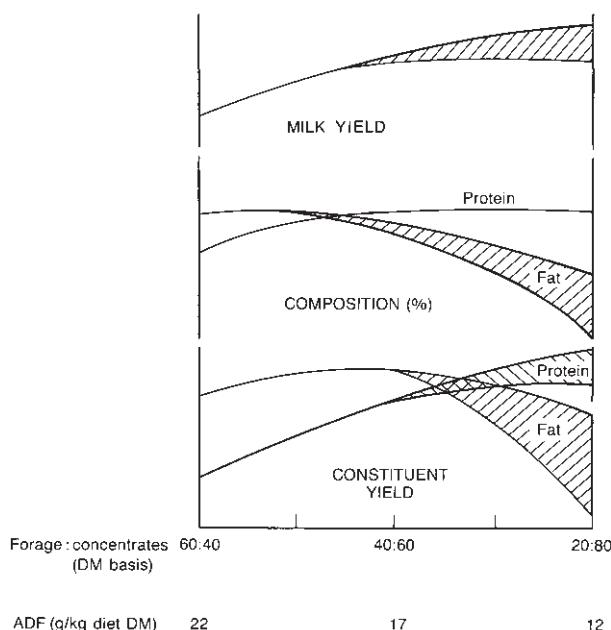

Fig. 28.2 The relationship between forage:concentrate ratio or acid detergent fibre (ADF) and milk yield and composition.

sources such as barley. Uncooked ground maize will, to a certain extent, pass through the rumen and into the small intestine. This possibly explains why maize-based concentrates give an overall lower level of yield than conventional barley products. Both features are particularly noticeable at higher concentrate intakes. Root crops, e.g. fodder beet, have most of their energy stored as the sugar sucrose. Generally, they produce better levels of fat, but lower yields than a comparable amount of starch.

The effect of diet on milk protein is different from that seen with milk fat. On high-forage diets, increasing the proportion of concentrate in the ration (especially high-starch concentrate) will increase milk protein, but only up to a level of 50–60 per cent of concentrate in the diet. Beyond this, milk yield may rise and milk fat concentration will fall, but protein levels will remain constant. The net effect is an overall rise in protein yield. These changes are represented diagrammatically in Fig. 28.2.

Increasing the intake of rumen bypass protein will also increase milk protein, even if requirements for metabolizable protein have been met. This effect is enhanced if the amount of rumen bypass starch is increased, suggesting that the mammary gland requires a balance of precursors and energy to produce higher levels of dietary protein.

Clearly, within a quota system there will be an optimal level for a farmer, both in terms of milk yield

and milk quality, but this will depend on the economic milk price:concentrate cost ratio prevailing at the time, and a full discussion is well outside the scope of this review.

Of course, low forage intakes may not occur intentionally. Poor quality fodder such as very wet, very acid or very butyric silages will depress intakes and thereby increase the concentrate:forage ratio. A more common problem is probably inadequate access. Self-feeding consolidated silage, particularly behind an electric wire, may depress intakes of even good quality material by as much as 5–10 per cent and could further exacerbate the problem.

There is no requirement for 'long fibre' in the basal ration to maintain milk quality, and diets containing long fibre length generally give the same milk quality as finely chopped silage (Thomas, 1984). However, there is some evidence that silage diets give better milk quality than rations of equal metabolizable energy intake based on hay. Fine grinding of forage will depress milk fat when used as the sole ration, but if used as a supplement to conventional forage it has no effect (Thomas, 1984).

Dietary fat

Manufacturers may increase the energy content of a concentrate by adding fat, either directly into the product or by fat-spraying the outside of the cubes. Fat 'prills' may also be added to the ration, e.g. a complete diet, as a separate constituent. Provided that saturated (or 'hard') fats such as tallow, coconut or palm kernel oil are used, and only to a maximum of 5–6 per cent, this will increase the fat content of the milk. However, milk protein content will be slightly depressed, but as milk yield is likely to increase, overall milk protein yield remains constant. Levels of fat above 7 per cent interfere with ruminal function, leading to a depression of both total milk yields and the fat and protein contents.

Increased levels of unsaturated ('soft') fats, such as maize, cotton seed, groundnut and especially fish oils, should not be used because they will coat the surface of fibre particles in the rumen, thereby depressing fibre digestion and leading to a fall in the milk fat content. However, if the fat can be protected from rumen degradation (such as with heating or formaldehyde treatment), the fat will bypass the rumen, resulting in no depression of fibre digestion. This will allow the long-chain fatty acids to be utilized more fully and overall milk fat will therefore rise. Protecting unsaturated fat also has a significant impact on the fatty acid composition of milk. As a result of hydrogenation of dietary fatty acids in the rumen, milk fatty acids are primarily (75 per cent) saturated fat. Protecting unsaturated fat can significantly increase the proportion of unsaturated

fats in milk (and reduce the proportion of saturated fat). Mansbridge and Blake (1997) showed that inclusion of either full fat soybeans or partially oil-extracted rapeseed in the diet resulted in a significant reduction in the proportion of palmitic acid (the predominant saturated milk fatty acid) in milk. Additionally, feeding oil-extracted rapeseed significantly increased the concentration of oleic acid (a mono-unsaturated fatty acid) and linolenic acid (a polyunsaturated fatty acid), while feeding full fat soyabean resulted in significant increases in linoleic and linolenic acid. Milk and milk products produced from cows fed protected diets could be a valuable aid in reducing saturated fat intake.

Dietary protein (see p. 106)

The effects of dietary protein on milk quality, including milk protein, are less well defined. It is the energy content of the ration that has the major effect on milk protein, particularly at high forage intakes. Severe dietary protein deficits will depress milk protein, although this may be partly because the requirements of the ruminal micro-organisms have not been met and as such total dry matter intake, and therefore the overall dietary energy intake, is inadequate.

Feeding systems

It is possible to overcome some of the effects of high concentrate, low forage diets by feeding the cows more frequently. In a series of experiments at the National Institute for Research in Dairying (Sutton, 1986), cows were given concentrate diets varying from 600 to 900 g/kg (namely 40 per cent to 10 per cent forage) fed either twice daily or up to six times daily. The results are given in Table 28.2 and show that for all levels of concentrate feeding, milk fat was higher with a greater frequency of daily feeds. As one might expect, the differential was greatest at the highest level of concentrate feeding, where twice daily feeding had produced a severe depression of milk fat. The concentrate used was a standard material containing high levels of starch. Had a highly digestible fibre product been used, it is unlikely that the depression of milk fat would have been so great – hence the response to more frequent feedings would also have been considerably less. It is generally assumed that diets leading to high propionate and low acetate in the rumen will reduce milk fat. However, increasing the frequency of feeding does not seem to depress propionate concentrations sufficiently to account for the full benefit to milk fat synthesis. It would appear that high plasma insulin concentrations are the main factor depressing milk fat and that the release of insulin is stimulated by peaks of propionate production, such as occurs after a large feed of concen-

Table 28.2 Effect of number of daily meals of starch-based concentrates on milk yield and composition. Source: Sutton (1986).

| Concentrates | 10.0 | 11.5 | 12.8 | 14.0 |

trate, rather than the steady supply of propionate that will be a feature of more frequent feeding. The effect of increased levels of insulin is to promote lipogenesis in adipose rather than mammary tissue.

Table 28.2 shows that milk protein is unaffected by frequency of feeding, or by the level of concentrate fed at these high levels of concentrate:forage ratio.

Complete diets (see p. 120) offer an opportunity for even feeds of concentrate throughout the day. When milk fat is low, due to depression by an excessive concentrate:forage ratio, feeding the same constituents in a complete diet will lead to an increase in the fat content. Milk protein may also increase on complete diets, but this is thought to be due to the effects of an increased dry matter intake, rather than any particular effect on frequency of feeding.

Since the introduction of milk quotas in the UK (see p. 24), there has been a greater tendency to feed forage, and concentrates have been fed on a ‘flat-rate’ basis, rather than the more traditional system of a basic allocation for maintenance and an increasing quantity of concentrate depending on yield. Provided that good quality forage is available *ad libitum* (and this is essential to the success of the system), there is no significant effect on milk quality throughout the lactation. Since high levels of ‘starchy’ concentrates promote high yields, cows calving onto a ‘flat-rate’ system tend to ‘peak’ at a lower level in early lactation and hence the ‘dilution’ effect of high yields depressing milk quality is not seen. Any reduction in milk quality on a flat-rate system is compensated for by slightly higher quality later in lactation. If access to forage is restricted, then clearly decreasing concentrate in early lactation will depress milk protein.

The depression of milk fat caused by high-concentrate diets can also be counteracted by the use of buffers. The most commonly used compound is sodium bicarbonate, fed at 12.5–15 kg/t, or 100–125 g/cow per day. The extent of the improvement depends on the original level of milk fat, the response being greatest in herds where butterfat is already low due to high levels of starchy concentrate being fed twice daily. Feeds such as sugar beet pulp also have a good buffering capacity (sometimes also known as the cationic exchange capacity), whereas others, such as maize gluten, can lead to a more acid fermentation. It is interesting to speculate on the effects of the use of sulphuric acid as a silage additive. This is a ‘strong’ acid, thus requiring a greater buffering, and could exacerbate milk fat problems in a way that formic or lactic acids would not.

Non-nutritional factors

Age of cow

Heifers generally have the highest milk quality, there being a fall of about 3 g/kg (0.3 per cent) in fat and 7 g/kg (0.7 per cent) in solids not fat (SNF) per lactation thereafter. The rate of decline continues until approximately the fifth lactation, after which it becomes more gradual. The decline in SNF is primarily due to a decline in lactose and mainly occurs during the first three lactations. Protein declines by only approximately 1 g/kg (0.1 per cent) per lactation over this period.

Stage of lactation

Milk quality is, of course, very high at calving (colostrum has at least double the dry matter content, i.e. 25 per cent, of normal milk, see p. 211), but then declines as yield increases, reaching a minimum at about 50–70 days after calving. Milk fat may drop by as much as 10 g/kg (1.0 per cent) and protein by 3 g/kg (0.3 per cent) over the period. This depression is partly due to a ‘dilution’ effect of high yields and partly to the inherent inability of the early lactation cow to consume sufficient energy to meet the demands of production. Feeding high levels of ‘starchy’ concentrates and, in so doing, boosting the volume of milk produced, can in some circumstances exacerbate the decline in milk quality. Both milk fat and protein tend to increase after 70 days, but milk protein only rises significantly if the cow becomes pregnant, and the rapid rise in both fat and protein that occurs in later lactation (e.g. six months after calving) is greater in the pregnant animal. Farms practising ‘block calving’, for example from August to October, often experience a marked fall in milk quality two to three months later (e.g. November

Table 28.3 The effect of silage feeding at grazing on milk quality. Source: Phillips & Leaver (1983).

| | Grazing | Restricted grazing and silage |
|---------------------|---------|----------------------------------|
| Milk yield (kg/day) | 19.9 | 18.9 |
| Milk composition | | |
| Fat (g/kg) | 35.6 | 39.4 |
| Protein (g/kg) | 35.1 | 34.8 |
| Solids yield | | |
| Fat (g/day) | 708 | 745 |
| Protein (g/day) | 698 | 657 |

to February) due to the fact that a large number of cows are at peak yield and relatively few are pregnant.

Changes in lactose follow an opposite pattern. The lactose content of colostrum is low, but rises rapidly after calving to reach a peak by two weeks into lactation. This level is maintained until six weeks, but there is then a steady fall, the rate accelerating towards the end of lactation. Changes in lactose are therefore a mirror image of changes in fat and protein.

Season of the year

In the UK there is a sharp fall in milk fat at the end of winter, when cows are turned out to grazing. This can be partly offset by providing access to hay or straw, although intakes of such forages are often poor when highly palatable grass is available and, if only 1–2 kg are consumed, this will have little benefit. To overcome the situation (and to improve grassland management and conservation), a system of ‘storage’ or ‘buffer’ feeding has been introduced, whereby cows are kept in at night on silage. Experiments carried out at Crichton Royal Farm (Table 28.3) showed that this significantly improved butterfat and although yields were marginally lower, overall fat yield was increased. However, protein yields were lower.

Often there is also a fall in milk protein during the winter housing period (November to March in the UK), probably due to a lower energy content of the diet at this time of the year and also to a stage of lactation effect. Protein levels then rise rapidly in April and May, following turnout to spring grazing. There is very little seasonal change in lactose concentrations.

Disease

Liver fluke (see p. 276) can depress both milk fat and milk protein and this depression in milk quality may be

Table 28.4 Approximate breed variations in milk yield and quality. Source: MMB (1983).

| | Milk yield (kg) | Milk fat (g/kg) | Protein (g/kg) |
|------------------|--------------------|--------------------|-------------------|
| Ayrshire | 4988 | 39.0 | 33.8 |
| British Friesian | 5610 | 37.8 | 32.6 |
| British Holstein | 6292 | 37.3 | 32.0 |
| Guernsey | 4017 | 46.4 | 36.3 |
| Jersey | 3876 | 51.9 | 38.5 |

seen in the absence of any other clinical signs of fluke. Heavy infestations of lice (see p. 741) and gastrointestinal worms (see p. 267) may also reduce milk quality, but these are unlikely in adult milking cows.

Mastitis (see Chapter 23) leads to a reduction in yield, lactose and butterfat. For example, a herd with a cell count of 750000 cells/ml could be losing 750–900 l/cow per year, 50g/kg (0.5 per cent) lactose and a smaller amount (30g/kg, 0.3 per cent) of milk fat. Milk protein levels will increase slightly with mastitis, but the protein is of lower quality, with increased levels of globulin and decreased casein. High cell count milk is therefore of reduced value for manufacture.

Genetic variation

It is well known that Channel Island cattle such as the Jersey and Guernsey have higher milk quality than other breeds. Approximate breed values are given in Table 28.4. Of course there are large variations between individual animals within a breed, and this is the basis of genetic selection. The selection of animals on the basis of yield alone could lead to a decrease in fat and protein contents and care should be taken to ensure that bulls with a high improved contemporary comparison (ICC) for both fat and protein are selected. There is less genetic variation within breeds for protein and lactose than for fat and hence the greatest rate of genetic progress will be made by selecting for fat. For example, the range of fat content within a breed is over 20g/kg, whereas genetic variation for protein is only approximately 10g/kg (Crabtree, 1984). The genetic variation for lactose is even lower.

Management factors

Milking intervals would appear to have an effect on milk quality in that on twice-daily milking, the fat content is higher in the afternoon. This is entirely due to a 'carryover' effect (Dodd, 1984). At the end of milking, some 10–20 per cent of the milk present remains in the udder and cannot be removed. The fat content of this milk is very high, 150g/kg (15 per cent) or higher, and it is withdrawn at the next milking. If there is an uneven interval between milkings, milk produced after the shorter interval will have a higher fat content because of the reduced 'dilution' effect of the additional milk produced. The total daily fat production remains constant, irrespective of the variation in milking interval and therefore of fat content. Increasing the frequency of milking to three or even four times daily does not alter milk quality significantly, although yields may rise by 10–15 per cent.

Introduction

The examination of immunological methods to increase resistance of the dairy cow to pathogens which cause mastitis has been ongoing for almost a century. This is a controversial area of bovine immunity with the existence of two schools of thought on the role of immunological intervention in mastitis control programmes. The first believes it is not possible to generate protective immunity in the mammary gland and control measures should be based on management, therapeutic strategies and genetic selection (Mellenberger, 1977). The second opinion is vaccination has a role in a mastitis control programme (Colditz & Watson, 1985). The latter view, founded on an improved knowledge of the bovine immune system and the principal pathogens of the gland, is supported by reports which indicate heightened resistance to infection with certain pathogens. The success of coliform mastitis vaccines has spurred novel studies on *Streptococcus uberis* mastitis. Such vaccines will complement conventional control measures which are less effective against environmental pathogens.

Anatomy of the bovine mammary gland (see Chapter 22)

The bovine udder comprises four mammary glands. The main arterial supply is from the bilateral external pudendal arteries. The venous return is via the external pudendal veins and the subcutaneous abdominal veins. There are two lymph vascular systems: a superficial and a deep set. The superficial set drain the cutaneous area and the teat walls. The deep set is associated with the finer branches of the arteries and veins. The lymphatics drain into the superficial inguinal (supramammary) lymph nodes and the lymph passes to the deep inguinal node.

The mucosa of the teat or streak canal is arranged in longitudinal folds and is lined by stratified squamous epithelium which constantly undergoes keratinization. A slightly projecting fold marks the proximal end of the teat canal, the Furstenberg's rosette area. The teat cistern (sinus) is the cavity directly proximal to the teat canal, and this continues into the parenchyma of the udder as the gland cistern (lactiferous sinus), which possesses a two-layered columnar epithelium. The secretory tissue is divided into lobes which are composed of lobules and there is an extensive duct system. The epithelium of secretory alveoli is a single layer of cuboidal cells. The alveoli are surrounded by a stromal layer which is more pronounced in the non-lactating gland.

Defence mechanisms of the gland

Non-specific and specific defence mechanisms exist in the bovine mammary gland (Outeridge & Lee, 1988). Non-specific factors include teat and teat duct shape and structure, teat duct patency and teat duct keratin. Teat duct keratin owes its protective properties to fatty acids and basic proteins. During milking there is a mechanical flushing of the teat canal. The enzyme lysozyme can cleave certain bacterial cell walls, but is present at very low concentrations in bovine secretions. Lactoferrin can bind iron and reduce the availability of

iron to micro-organisms, but citrate inhibits this protein. The lactoperoxidase/thiocyanate/hydrogen peroxide system has activity against micro-organisms. Complement can be activated by the lipopolysaccharide of Gram-negative organisms and cause lysis of these bacteria by the alternative pathway.

Four specific defence mechanisms operate in the gland. These are mediated by antibodies directed against epitopes of the pathogens or their toxins, in conjunction with phagocytic cells and complement. The mechanisms include prevention of bacterial adherence to epithelial cells, neutralization of bacterial toxins, opsonization of pathogens and direct lysis of pathogens. The key role of humoral immunity reflects the extracellular location of mastitis pathogens. A role for cellular immunity has not yet been established although laboratory studies have shown the ability of staphylococci and streptococci to achieve an intracellular location in cultured mammary epithelial cells.

Two methods can be employed to heighten resistance. One could increase non-specific protection which would be widely effective against all pathogens. The strategic use of cytokines at key points in the lactation cycle has yielded encouraging results. The administration of gamma-interferon lessens the severity and duration of experimental *Escherichia coli* infection, but there are no reports of field trials describing the effect of such administration on naturally occurring infections. An alternative approach is to stimulate specific immunity for each mastitis pathogen. The latter is difficult because there are many causative bacteria. The challenge is to characterize the virulence factors of the principal pathogens, identify their protective epitopes and then establish and maintain sufficient protective antibody in milk.

Immunoglobulin in lacteal secretions

(see p. 323)

Four classes of antibody have been described in the bovine (Butler, 1986): IgA, IgE, IgG and IgM. IgG₁ and IgG₂ are two subclasses of IgG. The half-life in serum of IgA, IgM, IgG₁ and IgG₂ is 3, 5, 17 and 22 days respectively. Serum IgA of cattle is probably synthesized by bronchial or gut associated lymphoid tissue, while IgM and IgG are most likely synthesized by the spleen and peripheral lymph nodes. Immunoglobulin concentrations in serum and colostral secretions are listed in Table 29.1.

Antibody present in lacteal secretions may be synthesized locally or derived from serum via selective transport or transudation. Inflammation of mammary epithelium causes an increase in the passage of antibodies from blood to lacteal secretions via transudation. IgA is the major immunoglobulin in most bovine

Table 29.1 The concentration of immunoglobulin in serum and colostral secretions. Values are expressed in mg/ml.

| | IgA | IgM | IgG ₁ | IgG ₂ |
|----------------|------|------|------------------|------------------|
| Serum | 0.37 | 3.0 | 11.2 | 9.2 |
| Colostral whey | 4.7 | 7.1 | 48.2 | 4.0 |
| Milk whey | 0.08 | 0.08 | 0.5 | 0.06 |

secretions, but not in milk. Around 50 to 100 per cent of milk IgA is produced locally. Plasma derived IgA is selectively transported into most mucosal secretions by vesicular transport following its binding to secretory component on epithelial cells. There are conflicting reports concerning the origin of milk IgM with some indicating it is entirely serum derived while others suggest that 75 per cent is locally synthesized. Most milk IgG₁ is serum derived. About 90 per cent of IgG₂ found in milk is locally produced. To increase specific IgG₁ in milk one must increase the serum level of specific IgG₁, whereas for IgA one must generate appropriate plasma cells in the lamina propria.

Biological activity of antibody

(see Chapter 22)

Antibody molecules can be considered as having two components. Firstly the two antigen binding sites recognize and bind antigen. Secondly, the Fc portion of the molecule is considered the effector part because it can fix complement components and interact with specific Fc receptors on phagocytic cells. For certain protective effector functions, antibody must not only be directed against a particular epitope but must be of the correct isotype.

Secretory IgA serves to protect mucosal surfaces from colonization and penetration by undesirable micro-organisms. It can augment the bacteriostatic effects of lactoferrin and can function as an opsonin. Lacteal IgA is largely associated with milk fat globules. IgG₁ and IgG₂ are efficient at fixation of complement and able to neutralize bacterial toxins. Cytophilic antibodies are capable of attaching to certain cells in such a way that these cells can subsequently adsorb specific antigen. It has been shown that IgG₂ is cytophilic for bovine blood neutrophils and for ovine mammary neutrophils. Bovine macrophages were found to be capable of binding both IgG₁ and IgG₂ *in vitro*. Live vaccines are believed to preferentially stimulate IgG₂. IgM is 10 to 20 times more effective than IgG in complement fixation. This ability to fix complement may explain why IgM is bactericidal for Gram-negative pathogens. In this manner it can also opsonize micro-organisms for uptake by phagocytic cells. IgM can also agglutinate bacteria and permit them to be flushed out at milking.

Table 29.2 The cellular composition of gland secretions (%).

| | PMN ^a | Macrophage | Lymphocyte | Epithelial |
|---------------------|------------------|------------|------------|------------|

| Milk | 3 | 79 | 16 | 2 |
| Dry gland secretion | 3 | 89 | 7 | 1 |

^a PMN, polymorphonuclear neutrophil.

Complement (see Chapter 58)

The complement system consists of more than 29 distinct plasma and membrane proteins, several of which are enzymes. The system is activated either by antibody binding to the bacterium (classical pathway) or by carbohydrate structures on the surface of the organism (alternative pathway). Triggering of the system results in a sequence of biochemical reactions in which one component activates another component in a cascade fashion. Complement thus bridges the innate immune system based on recognition of foreign carbohydrates and the induced immune system based on specific antibody formation.

The terminal part of the reaction is the formation of a membrane attack complex which causes lytic lesions to form in the membrane of the invading microorganism. Resistance to complement (serum resistance) is the only virulence factor identified among strains of Gram-negative bacteria isolated from cases of bovine mastitis. Serum-sensitive bacteria are either killed or do not grow in normal milk, whereas serum-resistant organisms generally multiply, and only the latter are able to cause mastitis.

There are several effector mechanisms by which complement aids phagocytosis. When the complement cascade is activated, component C3b is deposited on the surface of the bacterium. This C3b coating promotes adherence to and ingestion by phagocytes, which possess surface receptors for C3b. Products of complement activation include C3a and C5a which are chemoattractant for neutrophils and C5a can activate neutrophils. The inflammatory mediators responsible for the influx of neutrophils into milk have not been conclusively identified. Infusion of activated complement induces inflammation in dry glands but not in lactating glands. Levels of complement in lacteal secretions are highest as lactation ends, in the dry period and in colostrum. In normal milk the concentration of C3 is 1–4 per cent of serum, but milk does contain anti-complementary activity. In mastitis there is an increase in complement components in milk due to transudation.

Table 29.3 Lymphocyte composition using flow cytometry.

| | T cell | B cell | Null | Macrophage |
|---------------------|--------|--------|------|------------|
| Peripheral blood | 48 | 20 | 10 | 22 |
| Milk | 52 | 14 | 9 | 25 |
| Dry gland secretion | 43 | 19 | 11 | 27 |

Cells of the mammary gland

In dry and lacteal secretions the predominant cell type is the macrophage while in colostrum the polymorphonuclear neutrophil (PMN) serves this role. The number of cells per millilitre in dry period secretion is greater than that of normal milk. The cellular composition of gland secretions is outlined in Table 29.2.

Identification of cells in milk and blood can be performed by microscopic examination of stained smears. Flow cytometry is a sensitive technique which allows further differentiation of the mononuclear cell population in blood and gland secretions (Table 29.3). It is unclear why these two techniques yield different results for the macrophage content of dry gland secretion.

Mammary lymphocytes can respond to mitogens and particulate and soluble antigens; however, these responses are lower than those of peripheral blood lymphocytes from the same animal. T lymphocytes can produce cytokines which effect recruitment and activation of other cell types. T cells may be further subdivided according to their accessory molecules (CD4 or CD8) or antigen receptors (alpha-beta or gamma-delta). The majority of T cells in milk express alpha-beta T cell receptors. The ratio of CD8⁺ to CD4⁺ cells in blood is 1.5, while in mammary secretions it is 0.85. Some activated CD8⁺ cells may suppress the proliferation of CD4⁺ cells in the course of *S. aureus* mastitis and this may adversely effect antibody production by B cells.

The mammary *macrophage* functions in phagocytosis and killing of bacteria, eliminates fat in the involuting gland and plays a role in local immunity through antigen processing and presentation. After they have phagocytosed bacteria, mammary macrophages generate chemoattractants for PMN, while after exposure to endotoxin they release cytokines. Although critical for phagocytosis of *Strep. uberis* they may provide an intracellular location for *Staph. aureus* and their phagocytic capacity is reduced by dry secretion. A considerable population of macrophages exists beneath the alveolar and ductal epithelium.

Milk from normal uninfected glands contains less than 300 000 cells per millilitre and the predominant cell is the macrophage. Subclinically infected quarters contain around 750 000 cells per millilitre, while the secretion of infected quarters contains millions of cells per millilitre and in both these instances the predominant cell is the polymorphonuclear *neutrophil* leukocyte (PMN). A pre-existing leukocytosis confers increased resistance to infection; however, increased amounts of serum factors in the milk typically accompany this leukocytosis. When intramammary devices increase cell counts to 900 000 per millilitre in stripplings, protection against a wide variety of mastitis pathogens is achieved. Such high cell counts are not desired by the dairy industry.

There is a large pool of mature neutrophils present to fight infection. The half life of the cell in the bloodstream is about nine hours, with a substantial number developing in the bone marrow. Upon infection of the gland, PMNs adhere to capillary endothelium via receptors and pass through it by diapedesis. They then migrate down chemotactic gradients and enter the lumen of the gland through the mammary epithelium. Antibody and complement promote contact and recognition of the pathogen, which is ingested and exposed to the microbiocidal system of the PMN. Both oxygen dependent and independent pathways exist within neutrophils to kill ingested microbes. Some bacteria such as *Staph. aureus* possess defence mechanisms against oxidative damage by neutrophils and may survive within the phagosome. PMNs are viable for 1–2 days in the mammary gland, then undergo apoptosis (programmed cell death) before ingestion by macrophages.

Phagocytosis by mammary PMNs is much less efficient than that by blood PMNs. PMN function in the mammary gland is impaired by milk fat globules, casein and the lower glycogen content of milk PMN compared to blood PMN. PMN function can also be impaired by bacterial toxins. Cows vary in both the ability of their PMN to phagocytose and in the capacity of their milk to support phagocytosis. Despite high levels of phagocytic cells in the gland during the dry period, the gland is very susceptible at this time to new infection. This

may reflect the poor phagocytic efficiency of these cells or the unfavourable nature of the non-lactating gland for them. Fc receptor function is impaired by dry secretion and colostrum.

PMN function has limitations, as evidenced by chronic infections with some pathogens persisting in the face of a high SCC. To increase the efficacy of phagocytosis one could increase and maintain a high level of opsonin in milk through immunization, select for cows with superior phagocytic ability or decrease PMN mobilization time in response to pathogen invasion. Antigen-specific inflammatory responses can be established in the gland by parenteral immunization and one of the effector inputs of vaccination is the more rapid response of the PMN to infection. One could also increase and maintain a high PMN concentration in milk; however, this will adversely affect milk quality.

Cytokines

Cytokines are a group of regulatory proteins which act as intracellular communication signals and are secreted in very low amounts by a variety of cell types. Most cytokines possess multiple biological properties and regulate the activity of cells which participate in specific and non-specific immunity. Some can also alter physiological processes and cause pathological changes. The immunomodulatory capacity of these molecules is complex and interactions exist between cytokines – the cytokine network. Tumour necrosis factor (TNF), interleukin-1 (IL-1), interleukin 2 (IL-2), interleukin 6 (IL-6) and interleukin 8 (IL-8) have been detected in milk during inflammation. These and other cytokines have been shown to affect bovine mammary leukocytes *in vitro* and to a lesser extent *in vivo*. Their role as vaccine adjuvants and therapeutic agents is being evaluated.

Intramammary infection

(see also Chapter 23)

To induce mastitis a pathogen must pass the teat canal and enter the gland, survive the bacteriostatic and bactericidal mechanisms and use the available nutrients to replicate. Colonization of the gland reflects both the adherence capacity of the pathogen and its ability to utilize nutrients in lacteal secretion to multiply. *Strep. agalactiae* and *Staph. aureus* adhere readily to ductular epithelial cells, while *Escherichia coli*, *Klebsiella* spp. and *Arcanobacterium pyogenes* adhere poorly. If they are to maintain infection within the gland, bacteria must multiply at a rate which exceeds that at which they are eliminated. The outcome of infection depends on the rate of growth of the organism, the production,

absorption and activity of toxins and the immune status of the host.

Virulence factors and immune response to major pathogens

Escherichia coli (see also Chapter 23)

Escherichia coli mastitis is an opportunist infection. When 290 *E. coli* isolates were examined, 82 per cent could be grouped into 63 O-serogroups, the remainder being untypable (Linton & Robinson, 1984). Mastitis isolates do not possess the virulence factors associated with invasive or enteropathogenic strains of *E. coli* and cannot be distinguished from faecal isolates. Serum resistance, which is the capacity to withstand killing by complement, is the key feature of mammary isolates. The contribution of a capsule is unclear because most unencapsulated strains are serum resistant. Serum-sensitive strains are killed rapidly, with over 90 per cent killed in 15 minutes by freshly collected 10 per cent normal bovine.

When serum-resistant strains gain access to the lactating gland they commence to multiply and lipopolysaccharide (LPS), also called endotoxin, is released from the bacterial cell wall. Endotoxin is found in 50–100 per cent of lacteal secretions and 15 per cent of blood samples of cows with coliform mastitis. The exaggerated response of the host to endotoxin is often responsible for the severity of this mastitis. Fever, disseminated intravascular coagulation, hypotension, shock, complement activation and death can occur. Macrophages are the principal method by which endotoxins are removed. In the presence of LPS macrophages become activated and secrete IL-1, IL-6 and TNF. These cytokines mediate endotoxic events and are responsible for many of the clinical signs associated with this condition.

E. coli does not adhere to mammary epithelial cells. The organisms grow in secretions and there is little tissue invasion. Mammary lesions in *E. coli* mastitis are confined to the superficial layer of the teat and lactiferous sinus where extensive sloughing and necrosis of epithelial cells is evident. Secretory tissue is not involved. The response of cows to *E. coli* infection of the gland may be a function of the physiological state of the gland. The dry gland is much less responsive to endotoxin than the lactating gland and mild histopathological changes are noted following infusion. *E. coli* is incapable of establishing itself permanently in the gland in the first half of the dry period and this may be due to lactoferrin (Bramley, 1976). One experiment revealed that in the 30 days before parturition bacteria maintained infection in 14 of 37 inoculated quarters and

all of these quarters had peracute toxic mastitis after parturition.

Following infusion of 500 colony forming units (CFU) of *E. coli*, newly calved cows mobilize PMN slowly and appear to be refractory to the presence of irritants in the udder. This permits great bacterial replication and a large subsequent release of endotoxin which is often fatal (Hill, 1979). Killing of some *E. coli* strains within the udder requires a neutrophilia only, whereas for others up to 30 per cent serum products are required. For virulent strains a PMN response and opsonin are typically required. In decomplemented non-immune serum, colostrum and whey, the main opsonin for *E. coli* is IgM and there is no absolute requirement for complement in the opsonization of *E. coli* by the adult dairy cow. Later research found IgG₂ from immune bovine serum or whey opsonic for *E. coli*. Encapsulated isolates are more resistant to uptake by PMN and require greater amounts of opsonin than non-encapsulated isolates.

The Gram-negative cell wall consists of an inner cytoplasmic membrane and a cell wall which is composed of mucopolysaccharide-peptidoglycan, phospholipid protein and lipopolysaccharide. LPS is composed of three distinct subunits. The outermost O polysaccharide is linked to the core polysaccharide which is covalently bound to the lipid A. Free lipid A in soluble form expresses all the typical *in vivo* properties of endotoxin. Resistance to the bactericidal activity of normal serum is attributable to the O antigen of the LPS. When compared to serum-sensitive strains, LPS from serum-resistant strains is relatively enriched in long-chain O antigen subunits. These O polysaccharides may mask lipid A which could activate the alternative complement pathway. If the longer polysaccharide chains do bind C3b, the distance from the outer membrane of the bacteria is too far for insertion of the complement membrane attack complex.

The O polysaccharides are made up of a series of identical repeating oligosaccharide units containing three to five sugars each. The O polysaccharide is immunodominant and displays great diversity in length and sugar constituents whereas the core polysaccharide is conserved. Antibody to the O polysaccharide antigen or LPS affords protection against homologous challenge only. Because of the great diversity of the O polysaccharides of LPS, a search for shared epitopes on other parts of the molecule has been undertaken in an effort to find an antigen that could be used for active immunization. Gram-negative core antigens have immunological homology across bacterial species, but are typically masked by the immunodominant O polysaccharide.

In contrast to smooth organisms, rough mutants, called so because of their colonial morphology, have

incomplete synthesis of O polysaccharide side chains and consequently varying amounts of the core glycolipid are exposed. The *E. coli* J5 strain is an Rc mutant of *E. coli* O11:B4 and has an LPS devoid of O antigen (see p. 1016). Animals immunized with killed J5 bacteria are able to make antibodies to the core region and are protected from challenge with heterologous live organisms. Antibody to J5 cross-reacts with LPS extracted from other Gram-negative bacteria which cause mastitis, in particular *Klebsiella* spp. The protective factor induced by vaccination is considered to be antibody to core glycolipid which binds to invading bacteria at a time when the core antigens are most exposed, that is, early in their growth phase. This antibody promotes opsonization of Gram-negative bacteria and may also be bactericidal or reduce growth of the organism. The protective ability of antibodies to core glycolipid may also reflect their ability to bind to released LPS, neutralize the toxic effects of lipid A and thereby diminish systemic signs. Such release would occur during bacterial growth or after antibiotic therapy, phagocytic destruction or complement mediated lysis.

Initial studies of IgG₁ antibody titres to the core antigens of J5 showed that titres of less than 1:240 were associated with 5.33 times the risk of clinical coliform mastitis (Tyler *et al.*, 1988). This vaccine has been the subject of several field trials. In one trial, 246 cows received three doses of J5 killed cells (7.5 billion bacteria per dose) in Freund's incomplete adjuvant, twice in the dry period and once after calving, while 240 unvaccinated cows served as controls. Six cases of clinical coliform mastitis occurred in vaccines with 29 occurring in control cows (Gonzalez *et al.*, 1989). In a separate trial which lasted 30 months, cows received either vaccine or placebo at dry-off, 30 days later and at calving. There was no difference between groups in the percentage of quarters infected with Gram-negative bacteria at calving. In the control group, 67 per cent of these infections became clinical in the first 90 days of lactation compared to 20% in the vaccinated group (Hogan *et al.*, 1992a).

Cows directly challenged with coliform bacteria via the intramammary route have provided data which are less supportive of the efficacy of the J5 vaccine. One experiment found no difference between vaccines and control cows subsequent to challenge with 150 CFU of a serum-resistant strain (Hill, 1991). Both groups displayed acute clinical mastitis with systemic signs, a decrease in milk production and large numbers of bacteria in the milk. In an American study, cows immunized at drying off, 30 days later and at calving were challenged with a virulent field strain 30 days into lactation (Hogan *et al.*, 1992b). Lower milk bacteria counts were observed in vaccines but SCC and local clinical signs did not differ between groups. Milk yield

and dry matter intake was higher in vaccines. In a separate trial of similar design, cows were challenged one month after calving with a field strain known to cause mild clinical mastitis. No differences in temperature, milk production and systemic signs were observed between groups, but vaccination reduced the duration of both infection and local clinical signs.

It is known that cows which succumb to natural clinical coliform mastitis are in a complex physiological state with alterations in neutrophil function, including receptor expression, rate of diapedesis and phagocytic capacity. Measurement of these parameters can predict which cows will suffer severe clinical mastitis in response to experimental challenge. These animals may receive greatest benefit from vaccination and field trials would more accurately reflect this benefit. For immunological prevention of Gram-negative infection to be a possibility three requirements must be met. A common antigenic structure must exist; this must function as an immunogen and the response to this immunogen must generate protective antibodies. Large field trials indicate that the J5 bacterin achieves this goal. Cows vaccinated in the dry period and at calving have a lower incidence of clinical coliform mastitis in early lactation. The vaccine does not reduce the incidence of intramammary infection with coliforms at calving, but reduces the number of infected quarters which display clinical signs. Two new areas of research include the use of a *Salmonella typhimurium* Re17 bacterin to prevent coliform mastitis and the effect on *E. coli* of antibodies specific for membrane proteins involved in iron transport.

***Klebsiella* spp.** (see also Chapter 23)

Klebsiella pneumoniae (*K. pneumoniae*) and *K. oxytoca* are environmental pathogens and opportunist invaders of the bovine mammary gland. Within the genus *Klebsiella* there are over 70 capsular types and eight somatic types or O groups. Thirty-three capsular types of *K. pneumoniae* were isolated from cows belonging to 12 herds and within individual herds up to 13 types could be found. The primary feature of pathogenic strains is their ability to withstand the bactericidal effects of normal serum. Some are also adapted to grow in the secretion of non-lactating glands. Following infusion of small numbers of serum-resistant bacteria into normal mammary glands a severe mastitis is evident. This mastitis is prevented by a pre-existing leukocytosis or by the presence of specific antibody.

Cell wall O antigens are responsible for resistance to serum bactericidal activity. The capsule confers resistance to phagocytosis in the absence of specific antibody. Although type-specific protection can be achieved by vaccination with the homologous capsular polysaccha-

ride, the numerous capsule types recovered from lacteal secretions preclude the use of a polyvalent capsular vaccine. Antibody specific for core glycolipid of *E. coli* J5 strain cross-reacts with endotoxin extracted from *K. pneumoniae*. This antibody is reputed to bind to these core antigens during the log phase of bacterial growth and in this manner afford protection.

Mycoplasma spp. (see also Chapter 23)

Mycoplasmas lack a cell wall and are surrounded by a membrane which is similar to the cytoplasmic membrane of bacteria. Several species of mycoplasma cause mastitis but *Mycoplasma bovis* (*M. bovis*) is most prevalent. Cows in all stages of lactation are susceptible but those in early lactation suffer more severely. Antibiotics have little success but after a prolonged time cows may recover. Resistance to killing by serum is a virulence determinant and a pre-existing leukocytosis does not prevent cows from challenge. Neutrophils are not capable of killing *M. bovis* unless specific antibody is present.

Udders with a quarter which had resolved infection were examined and it was found all quarters of the udder were resistant to challenge. Quarters recovered from infection were immune for up to six months, but over one year postinfection all quarters were susceptible to reinfection. Studies of the immune response to *M. bovis* have failed to differentiate between resistant and susceptible animals. Systemic antibody does not appear to protect from infection and the immunity may be based on locally produced IgA and IgG and the action of T lymphocytes. Immunization with protein extracts assists cows in eliminating infection. No attenuated strains have been identified.

The summer mastitis complex

(see also Chapter 24)

There are conflicting views on what are the causative organisms of summer mastitis and how these organisms spread and invade the gland. Summer mastitis typically affects the non-lactating gland of heifers or dry cows and involves mixed bacterial infections. *Arcanobacterium pyogenes* (*A. pyogenes*), *Peptostreptococcus indolicus* (*P. indolicus*), a microaerophilic coccus and *Streptococcus dysgalactiae* are the pathogens believed to have a role in this condition. *Fusobacterium necrophorum* and *Bacteroides melaninogenicus* have also been recovered from the secretion of affected glands. Sorensen (1972) could induce summer mastitis in heifers with *A. pyogenes* and *P. indolicus* or with these two organisms and a microaerophilic coccus. Cultures were more virulent if grown together and infused rather than grown separately and then mixed for infusion.

A. pyogenes does not adhere to mammary epithelial cells and this may explain why summer mastitis is typically associated with the non-lactating gland. This bacterium grows best in lacteal secretion when the pH is greater than 7, as in the dry gland, and secretes haemolysin and proteases. *P. indolicus* stimulates the growth and haemolysin production of *A. pyogenes*. High titres of protease antibodies are found in the serum of infected cows. *P. indolicus* and the microaerophilic coccus produce enzymes which can damage tissue.

Early vaccines were composed without regard to the complex nature of the aetiology, typically containing *A. pyogenes* with or without hemolysin, and the results were poor. Sorensen showed that *A. pyogenes* alone had no protective effect but that a triple bacterin preparation composed of *A. pyogenes*, *P. indolicus* and the microaerophilic coccus gave encouraging results and merited further study (Sorensen, 1972). There is a marked lack of data on the immune response of the cow to these pathogens and approaches to vaccination will remain empirical for some time.

Staphylococcus aureus (see also Chapter 23)

Staphylococcus aureus has been described as a persistent pathogen of the gland due to the failure of therapy during the lactating period to achieve bacteriological cures. It is a contagious pathogen and infusion of 10 CFU into the teat sinus can cause mastitis. Much research has been performed to ascertain the benefit of immunization with staphylococcal antigens. Early attempts at vaccination were unsuccessful and these failures can be explained to a degree by the low numbers of bacteria used and by the culture of these bacteria in conventional media which does not support the expression of certain surface polysaccharide virulence factors. Later work demonstrated limited protection against homologous strains, a reduction in the severity of clinical infection and a reduction in spread of *Staph. aureus* mastitis in vaccinated herds.

The cell wall is composed of peptidoglycan, teichoic acid and protein A. Protein A can bind to the Fc portion of IgG molecules. Peptidoglycan was once considered to be the key cell surface component involved in promoting opsonization of *Staph. aureus*. Most bovine mammary isolates of staphylococci produce additional surface polysaccharides which are located outside the peptidoglycan layer. These polysaccharides may block antibody binding to peptidoglycan or prevent bound antibody interacting with phagocytic receptors. Their precise composition remains obscure and they have been described as exopolysaccharides, pseudocapsules and slime. Their production is typically associated with growth in milk. Such growth increases the virulence of a strain, induces anti-phagocytic properties and

increases adherence to epithelial cells. A typing scheme based on chemically characterized capsular polysaccharides has been described for staphylococci. Serotyping of bovine isolates for capsular polysaccharides 5 and 8 typically found 50 to 70 per cent of isolates possessed one of these microcapsules, though in some countries non-typeable isolates predominated.

Staphylococcus aureus produces around 30 extracellular proteins, some of which have been shown to be virulence factors (Sutra & Poutrel, 1994). Alpha-toxin is believed to be responsible for much of the tissue damage seen in staphylococcal mastitis and beta-toxin has been shown to cause inflammation of the gland. Following experimental infection ulcerative and erosive lesions in the epithelial layer are evident throughout the ductal system. Toxins can also damage PMNs whose role in defence against *Staph. aureus* became apparent when anti-bovine leukocyte serum converted a chronic staphylococcal mastitis to an acute gangrenous type. Neutralizing antibodies can be induced through vaccination and these lessen the damage to secretory tissue.

The surface of staphylococci contains proteins which can bind the host tissue proteins fibronectin, fibrinogen and collagen. Attachment to ductal epithelial cells is an important step in colonization and is thought to be mediated by fibronectin binding protein. Specific antibody has been shown to prevent this adherence. During infection toxins may expose subepithelial connective tissue components to which the organism can bind in a specific manner.

Staphylococcal enterotoxins were originally described for their ability to cause food poisoning or toxic shock syndrome in humans. There is variation between countries in the proportion of bovine *Staph. aureus* isolates secreting these molecules. Recent research suggests they may have a role to play in staphylococcal mastitis by causing immunosuppression. Enterotoxins may activate CD8⁺ T lymphocytes and decrease the response of CD4⁺ T lymphocytes to staphylococcal antigens. As superantigens, enterotoxins may also contribute to inflammation by activating cells in a non-specific manner and causing the release of inflammatory cytokines. Bovine mononuclear cells proliferate in response to enterotoxin and secrete IL-2, gamma-interferon and TNF. It is difficult to stimulate neutralizing antibodies to these molecules.

In a field trial with a staphylococcal bacterin-toxoid preparation, fewer new infections, less culling and lower somatic cell counts were evident in vaccinated cows as opposed to controls. Each dose of bacterin contained 10 billion CFU of each of two strains of *Staph. aureus*, whose exopolysaccharide cross-reacted with most field isolates. The toxoid component contained alpha- and beta-hemolysins. A second trial found fewer clinical and subclinical cases in vaccines but this difference

was not statistically significant (Nordhaug *et al.*, 1994). Isolated exopolysaccharide in liposomes afforded sheep protection from infection.

Studies performed in Australia found vaccination with live bacteria protected the gland from infection. The protection afforded by vaccination with live bacteria is due to the generation of specific IgG₂ which is cytophilic for PMN. The use of live bacteria has significant disadvantages and consequently bacteria grown in a medium containing milk whey and then killed have been used. Killed bacteria stimulate IgG₂ when administered with the adjuvant dextran sulphate. In normal glands there is a 24 hour lapse between entry of bacteria into the gland and the accumulation of 500 000 PMNs per millilitre and this delay allows infection to become established. Vaccination can decrease this lag period to 6 hours and PMNs may enter the gland, carrying IgG₂ on their membrane.

Australian workers developed a vaccine containing killed bacteria, alpha-toxoid and beta-toxoid, emulsified in an adjuvant of mineral oil and dextran. Experiments have been performed to establish the efficacy of this Australian vaccine (Watson *et al.*, 1996). In challenge studies in sheep the incidence of peracute gangrenous and acute clinical mastitis and the decrease in milk yield was lower in the vaccines. Heifers which received the vaccine had lower SCC and greater milk production after challenge, compared to controls. A field trial conducted on seven herds and over 1800 cows found 45 clinical cases of *Staph. aureus* mastitis in vaccines and 67 cases in controls. This difference was not statistically significant. One of the herds had a high incidence of *Staph. aureus* mastitis and in this herd clinical and subclinical cases of mastitis were significantly lower in vaccines compared to controls.

A better understanding of *Staph. aureus* suggests that protection depends on antibodies being generated to several virulence factors. Vaccines should generate antibodies specific for matrix binding proteins to prevent adherence and to the surface polysaccharides to promote opsonization. Neutralizing antibodies specific for alpha- and beta-toxins would lessen clinical damage and protect the cellular defences of the gland. The results of trials with experimental vaccines based on these three components will clarify whether vaccination has a role in preventing staphylococcal mastitis. When attenuated strains are administered by the intramammary route, they replicate but are eliminated by the gland. The capacity of such strains to stimulate protective immunity is being examined.

Streptococcus spp.

There are no cross-reactive protective epitopes shared by the streptococci which cause mastitis.

Streptococcus agalactiae (see also Chapter 23)

Streptococcus agalactiae (*Strep. agalactiae*) is a Group B streptococcus and is an obligate parasite of the bovine mammary gland where it colonizes the milk ducts. It can be eliminated from a herd through culture and therapeutic means. This easy step should take precedence over the task of generating protective antibody. The group-specific polysaccharide is common to all strains and *Strep. agalactiae* can be divided into five distinct serotypes based on the presence of type-specific surface antigens. A protein antigen designated X is frequently associated with bovine mastitis isolates. Attachment to epithelia is a prerequisite for colonization and surface lipoteichoic acid may aid in this attachment. *Strep. agalactiae* produces CAMP factor which is lethal for mice and rabbits.

The bactericidal activity of neutrophils for *Strep. agalactiae* is dependent on antibody and complement. Most opsonizing antibody is directed to the weakly immunogenic, type-specific polysaccharide and such antibody is a more efficient opsonin when it binds complement. The sera of cows contain low levels of natural opsonin. Mackie *et al.* (1986) found heifers became hyperimmune following systemic vaccination by the subcutaneous and intravenous routes. Despite high titres there was little real difference between the hyperimmune and non-vaccinated heifers following challenge with around 40 million bacteria and it was concluded that locally produced antibody may be required for protection. Antibodies to protein X increase the ingestion of bacteria by PMNs but do not increase the number of bacteria killed by PMN.

Streptococcus uberis (see also Chapter 23)

Streptococcus uberis (*Strep. uberis*) has been examined serologically, biochemically and by molecular biological techniques. It does not fit into the Lancefield classification with 25 per cent of strains typing as group E and smaller numbers belonging to other serogroups. A similar percentage of strains is CAMP positive. Sensitive molecular typing methods indicate most isolates are genetically dissimilar. This organism can be recovered from several body sites of the cow and from manure and soil. It has become a significant cause of mastitis and as an environmental pathogen is less affected by conventional control methods.

The susceptibility of the dry mammary gland to infection with *Strep. uberis* increases with time and in the second half of the dry period all quarters are susceptible. This bacterium binds low amounts of fibronectin, fibrinogen and type II collagen. Adherence to mammary epithelial cells has been described *in vitro*, but in experimental infections most bacteria were

found in the alveolar exudate with just a small number associated with damaged epithelial cells. After infection there are many neutrophils in gland secretions but few contain *Strep. uberis*. The role of this cell in defence against *Strep. uberis* is unclear because isolates possessing a hyaluronic acid capsule resist uptake by neutrophils and capsular material can damage PMNs. Macrophages may be the key defence cell since they can ingest isolates which have been opsonized by IgG₁ and IgG₂.

Quarters previously infected with *Strep. uberis* are significantly protected from subsequent infection by the same bacteria. Immunization with killed bacteria via the intramammary or subcutaneous route offered protection from challenge with the immunizing strain and a strong inflammatory reaction was present in the gland. The bacterin did not afford protection from infection with wild-type strains. When live bacteria were administered subcutaneously and bacterial extracts by the intramammary route, a degree of protection was again noted. This protection did not extend to strains not included in the vaccine. As there was only a mild inflammation in the gland it was proposed that live vaccine affected the ability of the organism to replicate and a neutrophil response was not critical for protection from infection (Leigh, 1999).

Streptococcus uberis is unable to produce certain amino acids and must find them in its environment. Studies using chemically defined media found all strains require eight amino acids for growth, with some requiring 13 amino acids. The organism is incapable of hydrolysing proteins directly, but is able to convert bovine plasminogen to plasmin, a protease which can break down casein into peptides. The plasminogen activator of *Strep. uberis* is a protein of 30kD; it is secreted by almost all isolates and specific neutralizing antibodies are stimulated following immunization.

In an experimental challenge trial, vaccination with plasminogen activator gave a significant degree of protection from clinical disease and greatly reduced bacterial numbers in milk (Leigh, 1999). Both of these protection indices were achieved in the presence of a mild inflammatory response and protection was correlated with the titre of neutralizing antibody specific for plasminogen activator. The studies conducted with *Strep. uberis* could be highly relevant to other mastitis pathogens and have underlined the importance of *in vivo* rather than *in vitro* studies.

Streptococcus dysgalactiae (see also Chapter 23)

Streptococcus dysgalactiae (*Strep. dysgalactiae*) is a group C streptococcus and possesses a hyaluronic acid capsule. The group C antigen is a carbohydrate and three type-specific antigens have been identified. This

bacterium is able to cause mastitis on its own and is one of a number of pathogens involved in the summer mastitis complex. Strains of highest infectivity are those which adhere well to mammary epithelial cells. *Strep. dysgalactiae* binds well to fibronectin, moderately to fibrinogen and poorly to collagen. Protein G is present in the cell walls of some *Strep. dysgalactiae* and can bind bovine IgG. Such non-specific binding of immunoglobulin may protect the bacteria from gland defences. Cows develop protective antibody following immunization and hyperimmunized cows showed a degree of resistance to challenge exposure of the homologous strain.

Mucosal immune system

The concept of a common mucosal immune system was proposed following the observation that subsequent to intestinal exposure to antigen, specific immunity was evident at distant mucosal sites. Immunocompetent cells (specific lymphocytes) can migrate from Peyer's patch or mesenteric lymph nodes to distant sites, become resident and respond to sensitizing antigen. This does not seem to be true for ruminants since there is no selective migration of lymphocytes between the mammary gland and the gut of the cow. There are two major groups of recirculating lymphocytes in the cow: a peripheral and an intestinal pool. Labelled lymphocytes from the supramammary lymph node recirculated to the prescapular and supramammary lymph node whereas labelled ileac mesenteric lymphocytes were recovered from intestinal mesenteric lymph nodes. Local administration of antigen to the mammary gland would stimulate lymphocytes in the lamina propria to expand clonally and some of these cells would traffic to the supramammary lymph node.

Generation of immune response

Immune responses designed to protect the bovine mammary gland from infection can be generated by administration of antigen by various routes. Systemic immunization performed by the intramuscular, subcutaneous or intravenous route generates serum antibody. When mammary epithelium becomes inflamed sizeable amounts of circulating antibody pass into the lacteal secretions from the serum by transudation. Antibody has its greatest effect when present in lacteal secretions before infection is established. Direct injection of antigens into the udder stimulates both a local and a systemic response.

The primary course of events for humoral immunity involves antigen processing by macrophages and pres-

entation to CD4⁺ T cells and to B cells. These CD4⁺ cells release cytokines that stimulate the B cells to divide and produce antibodies. A small proportion of B cells become memory cells and if subsequently presented with their specific antigen they will proliferate rapidly and produce large amounts of antibody. Macrophages, T cells and B cells are present in the mammary gland and administration of antigen to the dry gland stimulates local synthesis of IgA and IgG₁. Such production persists well into lactation and is associated with the development of plasma cells in periductal connective tissue and interalveolar areas. The response is much less when antigen is administered to the lactating gland.

Intraperitoneal administration of antigen followed by local infusion recruits cells from systemic lymphoid tissues which have been primed by intraperitoneal immunization. Vaccination in the region of the draining lymph node of the mammary gland stimulates serum antibody and promotes production of local antibody. This may be due to the trafficking of lymphocytes. The J5 coliform mastitis was efficacious when administered subcutaneously or in the area of the supramammary lymph node. The administration of antigen in the region of the draining lymph node accompanied by local infusion is likely to have the greatest impact on the generation of antibodies in lacteal secretions.

The time of vaccination is another important factor since most infections occur at drying off, during the dry period and in the periparturient period. Almost 100 per cent of clinical mastitis occurs during lactation, with 60 per cent taking place in the first 40 days. Vaccination should be designed to offer maximum protection at these times. If systemic immunization is carried out at drying off, a booster given shortly before parturition by the intramammary route allows the gland to give a heightened and prolonged response through the next lactation (Watson & Lascelles, 1975).

Two components of a successful vaccine are the antigen and the adjuvant. As knowledge of the protective antigens of mastitis causing bacteria has grown, it is now appreciated the amount of antigen in a vaccine dose is critical and that the numbers of bacteria used in early studies were too low. Growth of Gram-positive cocci on conventional laboratory media can result in decreased expression of key bacterial antigens which are expressed during *in vivo* replication. Adjuvants are substances which act in a non-specific manner to augment the immune response to an antigen. Mineral oil, saponin and aluminium hydroxide are examples of adjuvants employed in veterinary vaccines. They can affect the magnitude, duration and isotypic composition of the immune response. The mechanism of action of adjuvants is not fully understood but includes slow release of antigen from a depot, alteration of lymphocyte circulation and release of cytokines.

Limitations of vaccination

The scientific literature contains numerous reports documenting the failure of vaccination to protect against intramammary challenge with a pathogen. There are fewer reports of protective products. These studies account for the two opposing views concerning the role of vaccination in mastitis control programmes. Challenge studies often have consisted of placing thousands of bacteria into the teat sinus, which is not an accurate reflection of natural infections in which only a few organisms will traverse the teat duct and reach the cistern to multiply. A better method to establish the efficacy of a vaccine is to perform field trials in herds where natural exposure to the pathogen will occur, with one half of the herd receiving vaccine and the remaining half receiving placebo. The evaluation of infection, clinical inflammation, persistence of leukocytosis, bacterial shedding and the effect on milk production will help determine vaccine efficacy.

The dairy cow undergoes periods of severe stress in each lactation cycle and immune dysfunction occurs at certain times. Immunosuppression can occur during pregnancy, lactation and parturition. Much interest has been directed to the four-day period prior to and subsequent to parturition, the so-called periparturient immunosuppression. Secretion taken just after drying off and at parturition has an inhibitory effect on blastogenic responses to mitogens. Proliferative responses to mitogens by blood and milk lymphocytes are low for one week before parturition and lowest on the day before calving (Kehrli *et al.*, 1989). This may relate to the high incidence of clinical mastitis and intramammary infection which occur at calving and up to 30 days past calving. Certain indices of neutrophil function increased two weeks before parturition and decreased dramatically by the first week after parturition.

Because the concentration of PMNs is used to assess milk quality and a major defence component of the gland involves a leukocytosis with specific antibody, some authors argue that protection afforded by such a leukocytosis is, by definition, mastitis. Such a protective response can be interpreted in this manner. There is mounting evidence indicating that for certain pathogens, appropriate immunization strategies can reduce the number of clinical cases, reduce the number of new infections, improve the response to therapy and decrease the severity of clinical mastitis. If this involves a transient leukocytosis, it is likely farmers will accept the benefits.

The mammary gland of the cow has limited defensive capabilities with regard to PMN function and level of opsonins. In North America, good dairy cows yield on average 30 litres of milk for each day of their lactation.

To maintain levels of antibody in this volume of secretion requires an enormous synthetic rate. Immunization does not confer absolute protection and at best will complement good husbandry and other mastitis control procedures. Vaccines for coliform mastitis will continue to be used widely while products to prevent *Staph. aureus* and *Strep. uberis* should become available in the near future. For other mammary pathogens there is little prospect of vaccines becoming available.

General considerations

Mastitis is the single most common disease of the adult dairy cow, accounting for 30 per cent of all morbidity (Gardner *et al.*, 1990) and 38 per cent of health costs (Kossaibati & Esslemont, 1997). Additionally, in herds where the average culling rate was 23.8 per cent, mastitis was cited as the reason for culling in 10.1 per cent of cases and was the most common cause of death (8.9 per cent) (Esslemont & Kossaibati, 1997). Failure to achieve expected lactation yield as a consequence of clinical mastitis (Lucey & Rowlands, 1984; Rajala-Schultz *et al.*, 1999) and a reduction in milk yield caused by subclinical mastitis are responsible for even greater economic losses (Hortet & Seegers, 1998; Hortet *et al.*, 1999). Efficacious, economical treatment of mastitis is therefore an important component of livestock medicine.

The most frequent causes of mastitis are *Staphylococcus aureus*, *Streptococcus agalactiae*, *Strep. uberis*, *Strep. dysgalactiae*, *Escherichia coli*, *Enterobacter* sp., *Pseudomonas* sp., *Klebsiella* sp., *Arcanobacterium* (*Actinomyces*; *Corynebacterium*) *pyogenes* and

Mycoplasma sp. (see Chapters 23 and 24). Differences in climate, management and national or regional regulatory efforts result in patterns of disease that vary markedly. The arid south-western regions of North America have repeatedly identified prevalences of intramammary *Mycoplasma* sp. infection exceeding those observed in other parts of the world (Jasper *et al.*, 1966; Jasper, 1980). In a survey of 50 California dairy herds (23138 cows) potential mastitis pathogens were isolated from 22 per cent of cows (Gonzalez *et al.*, 1988). *Staphylococcus aureus* was isolated from all 50 herds, *Strep. agalactiae* from 47 herds and *Mycoplasma* sp. from 24 herds. The prevalence of mastitis pathogens (per cent cows) was *Staph. aureus* (9.1 per cent), *Strep. agalactiae* (9.3 per cent), *Mycoplasma* sp. (0.9 per cent), coliform bacteria (1.2 per cent) and other streptococci (0.9 per cent).

Laboratory testing is an integral part of treatment and control programmes and identification of the causal agents will have a direct bearing on subsequent therapy decisions. Several handbooks (International Dairy Federation, 1981; National Mastitis Council, 1999) and articles (Higgs & Bramley, 1981; Buswell, 1995) are available to assist in the identification of mastitis pathogens.

Antimicrobial resistance

Although useful as a guideline for antimicrobial selection, antibiotic sensitivity testing does not guarantee the efficacy of an antibiotic. Generally, the major streptococcal pathogens of the bovine mammary gland are sensitive (>90 per cent) to penicillin, ampicillin and erythromycin (Prescott & Baggot, 1988). Actual cure rates vary with clinical and lactation status.

There appears to have been no significant increase in bacterial resistance of mastitis-causing bacteria in the UK over the past 25 years. Craven *et al.* (1986) found a high incidence (69.8 per cent) of β -lactamase production which was similar to that (66.1 per cent) reported by Jones and Heath (1985). These studies indicated little change from the 70.6 per cent of penicillin-resistant strains reported by Wilson (1961). Recent

surveys have indicated little change (Buswell, pers. comm.). It should also be noted that no staphylococci of bovine origin that are resistant to cloxacillin have been identified (Jones, 2000), despite its widespread use in both lactating and dry-cow intramammary preparation syringes for over 30 years.

Sensitivity patterns for the two most common Gram-negative intramammary pathogens, *E. coli* and *Klebsiella* sp., are reported in Table 30.1 and may be used to guide the choice of antibiotic when treating peracute mastitis (Mackie *et al.*, 1988; Prescott & Baggot, 1988). One should be cautioned that sensitivity patterns will vary locally according to antibiotic use. Historical susceptibility information drawn from individual farms will likely prove more useful. Table 30.2 reports *in vitro* sensitivity (Mackie *et al.*, 1988) and *in vivo* cure rates (Le Loudec, 1978) with respect to *Staph. aureus* for several commonly used antimicrobial agents. It should be noted that the percentage of sensitive isolates consistently exceeds cure rates. The absence of *in vitro* activity indicates bacterial resistance while sensitivity infers, but does not guarantee, clinical efficacy.

Pharmacology of the mammary gland

Antimicrobial therapy is applied in the treatment of clinical mastitis during lactation and in treating sub-clinical mastitis at the end of lactation, while the implementation of preventive measures is essential for decreasing the incidence of infection in the dairy herd. Clinical mastitis is often treated systemically which entails the repeated parenteral administration of an

antimicrobial agent to which the causative pathogenic micro-organisms are susceptible at the drug concentration attained at the site of infection in the udder. The administration of an intramammary preparation in conjunction with systemic therapy is highly desirable, but the effectiveness of an infused antimicrobial is limited

by decreased ability of the drug to ascend partially occluded milk ducts and by frequent stripping of the infected quarter.

Antimicrobial agents, like other drugs, cross the blood–milk barrier, which is a somewhat restrictive functional rather than an anatomical barrier, mainly by passive diffusion. Both non-polar lipid-soluble compounds and polar substances with sufficient lipid solubility passively diffuse through the predominately lipoidal barrier (Baggot, 1977). At a moderate level of milk production the ratio of the volume of blood circulating through the mammary gland to the volume of milk produced has been estimated to be 670:1; this provides ample opportunity for drugs to passively diffuse from the general circulation into milk. The rate of transfer is directly proportional to the concentration gradient across the blood–milk barrier and the lipid solubility of the drug. The milk-to-plasma equilibrium concentration ratio of total (non-ionized plus ionized) drug is determined by (i) the degree of ionization of the drug, which is pK_a/pH -dependent, in blood and milk, (ii) the charge on the ionized moiety and (iii) the extent of binding of plasma proteins and milk macromolecules. It has been shown that only the lipid-soluble, non-ionized moiety of a weak organic acid or base that is free (not bound to proteins) in the plasma can diffuse through the cellular barriers and enter the milk (Rasmussen, 1966). In normal lactating cows (milk pH range 6.5–6.8), weak organic acids attain milk ultrafiltrate-to-plasma ultrafiltrate equilibrium concentration ratios less than 1; oxytetracycline and rifampin, amphoteric drug molecules with moderate and high lipid solubility, attain equilibrium concentration ratios of 0.75 and *ca* 1,

respectively; weak organic bases, apart from aminoglycosides, spectomycin and polymyxin B (drugs with low solubility in lipid), attain milk ultrafiltrate-to-plasma ultrafiltrate equilibrium concentration ratios greater than 1 (Baggot, 2000). The high concentration ratios attained by lipophilic organic bases (macrolides, lincosamides and trimethoprim) are attributed to the ion-trapping effect in acidic milk. Enrofloxacin and its active metabolite ciprofloxacin, formed by *N*-de-ethylation (a microsomal-mediated oxidative reaction) in the liver, would be expected to attain concentrations in milk that would be effective against Gram-negative aerobic bacteria, in particular *Escherichia coli*.

In the presence of mastitis, the pH of milk increases to within the range 6.9 to 7.2. As a consequence the ion-trapping effect on lipophilic organic bases is reduced while the concentrations attained by weak organic acids are somewhat increased. The inflammatory reaction in udder tissues enhances the passage of penicillins into milk. The increased pH of milk does not affect the concentrations attained by amphoteric drugs (fluoroquinolones, tetracyclines, rifampicin), but antimicrobial activity of these drugs is lower in milk than in extracellular fluid or *in vitro* determination would predict.

Intramammary preparations (Table 30.3)

Intramammary preparations are used, often in conjunction with parenteral preparations (depending on severity of infection), to treat clinical mastitis and at the end of lactation to treat subclinical infection and

Table 30.3 Distribution of antibiotics throughout the udder after intramammary administration (adapted from Ziv, 1980).

| Good | Moderate | Poor |

| Pirlimycin | | |

prevent the establishment of new infections during the dry period. The various preparations differ in nature, content and release pattern of the active ingredient(s) and in the length of the withdrawal periods (slaughter and milk withholding) but all preparations must be reasonably non-irritating to the udder. Intramammary preparations are formulated either to provide quick release of the antimicrobial agent or slow release of the antimicrobial over an extended period. The former are used mainly in lactating cows while the latter are used at the end of lactation (after the last milking) and in non-lactating cows. While the formulation of an intramammary preparation determines the pattern of antimicrobial release and may influence the withdrawal periods, the chemical nature and physico-chemical properties (in particular lipid solubility) of the drug govern its uptake and distribution in mammary tissue and its absorption into the blood. Drug transfer from treated to untreated quarters of the udder takes place via the bloodstream.

Following intramammary infusion antimicrobials with high lipid solubility (macrolides, trimethoprim, fluroquinolones, rifampicin) are readily taken up by and distributed widely in mammary tissue. Oxytetracycline is moderately lipid-soluble and the fraction that is not chelated with calcium in milk enters mammary tissue and distributes evenly in a manner that is not subject to the pK_a/pH -dependent ion-trapping effect. However, the antimicrobial effect, which is exerted mainly on streptococcal spp. and coagulase-negative staphylococci, is bacteriostatic. The susceptibility of coagulase-positive *Staph. aureus*, *E. coli* and *Klebsiella* spp. to oxytetracycline is variable and unpredictable. The uptake and distribution of sulfadiazine (pK_a 6.4) and sulphamethoxazole (pK_a 6.0), which are moderately lipid-soluble organic acids, are influenced by the degree of ionization in their local environment. Since sulphonamides are combined with trimethoprim in intramammary preparations the broad-spectrum antibacterial effect produced is bactericidal. The beta-lactam antibiotics (penicillins and cephalosporins), although they exist mainly in an ionized form in milk, are taken up by mammary tissue and distribute reasonably well but do not readily enter epithelial cells or kill bacteria within phagocytic cells (neutrophils and macrophages). The uptake of hydrophilic antimicrobial agents (aminoglycosides and polymixin B) from milk is low and their distribution is very limited and uneven because of selective binding to mammary tissue components. Antimicrobials that avidly bind to mammary tissue (polymyxin B, neomycin, streptomycin, spirofloxacin) have long withdrawal periods.

The frequency of milking and the efficiency of milk-out greatly influence the concentration of antimicrobial that could be attained in the udder. Since frequent strip-

ping of the infected quarter(s) is recommended in cows with clinical mastitis, it follows that only quick-release intramammary preparations are suitable for use in lactating cows.

Intramammary preparations for use in lactating cows should contain a readily available form, usually water-soluble salt, of an antimicrobial agent with a low degree of binding to milk and mammary tissue proteins. The vehicle used and viscosity of the formulation should allow rapid release of the drug and ensure that effective concentrations are maintained throughout the recommended dosage interval. Examples of intramammary preparations that are formulated as suspensions and have a recommended dosage interval of 12 hours include cloxacillin sodium, oxytetracycline hydrochloride, ampicillin sodium–cloxacillin sodium combination and trimethoprim–sulfadiazine combination. Cefuroxime sodium and cefoperazone sodium (second- and third-generation cephalosporins, respectively) are formulated as an oily paste and oily suspension, respectively. While a 12-hour dosage interval is recommended for cefuroxime, a single dose of the cefoperazone preparation is considered to be usually sufficient for treatment. Quick-release intramammary preparations have short withdrawal periods, typically slaughter times of 7 days and milk withholding times of 3.5 days, or either may be less depending on the preparation.

Slow-release intramammary preparations may contain an antimicrobial agent with a high degree of binding to the secretions and mammary tissue proteins. Either a poorly soluble salt of an antimicrobial agent may be used or the formulation of the preparation be such that the rate of antimicrobial release is relatively constant, approaching zero order (Baggot & Brown, 1998). The formulation of slow-release preparations determines the antimicrobial concentration–time profile in the mammary gland to a greater extent than quick-release preparations. Since only a single dose of a slow-release preparation is infused, the antimicrobial content is generally higher than in quick-release preparations. The antimicrobial must remain active (be stable) throughout the extended duration in the udder and the preparation must not cause irritation. Examples of slow-release intramammary preparations include cloxacillin (as benzathine salt) with aluminium monostearate (suspension), ampicillin (as trihydrate)–cloxacillin (as benzathine salt) formulated as an oily suspension, procaine benzylpenicillin (oily paste) and dihydrostreptomycin sulphate–procaine benzylpenicillin (oily paste). The long withdrawal periods for these preparations preclude their intramammary infusion in lactating cows.

Intramammary administration permits delivery of the antibiotic directly to the mammary gland. Penicillin derivatives have demonstrated efficacy in

intramammary treatment of *Strep. agalactiae*. Intramammary preparations for infusion are available as single-use syringes for a course of treatment of one, two or three syringes at 12- or 24-hour intervals depending on the product. Lactating cow (quick-release) products are generally designed for rapid clearance and, consequently, have shorter milk withholding periods. Antibiotics with extensive tissue binding (polymyxin B and aminoglycosides) have extended milk withholding periods (Baggot, 2000). Dry-cow formulations, for the treatment of subclinical mastitis, are designed to produce extended duration of effective drug concentrations. This is achieved by using a higher concentration of the active drug or the benzathine salt of the active drug in oil or a repository vehicle.

For antimicrobial therapy with either a parenteral or intramammary preparation, or the concurrent use of both types of preparation, to be effective an antimicrobial concentration exceeding the MIC for the causative pathogenic micro-organism must be maintained at the site of infection for an adequate duration. Provided the appropriate antimicrobial is selected, the intramammary infusion of a slow-release preparation at the end of lactation may adequately meet this requirement. However, in the case of *Staph. aureus* infection, the administration of a parenteral preparation in conjunction with a slow-release intramammary preparation containing an antimicrobial, which is active against all strains of the bacterium, increases the effectiveness of therapy and consequently the recovery rate.

Parenteral preparations

Severe mastitis is usually treated systemically, although intramammary therapy will often be used adjunctively. An 'ideal' antimicrobial for systemic therapy of mastitis should have the following properties (adapted from Ziv, 1980):

- Low minimum inhibitory concentration (MIC) for the majority of mastitis-causing pathogenic micro-organisms.
- High bioavailability following intramuscular injection.
- Lipid-soluble and predominately non-ionized in the blood, and have a low degree of binding to plasma proteins.
- A long apparent half-life to ensure that concentrations above (preferably several-fold) the MIC are maintained at the site of infection throughout the dosage interval (12 or 24 hours).
- Minimal adverse effects in cows.
- Short withdrawal periods (milk withholding and slaughter).

Parenteral preparations with pharmacokinetic properties that meet most of these criteria include procaine benzylpenicillin, amoxicillin trihydrate-clavulanate potassium combination, trimethoprim-sulfadiazine (or sulphamethoxazole) combination and enrofloxacin. In order to obtain effective concentrations in milk oxytetracycline hydrochloride (conventional preparation) should be administered by slow intravenous injection. Long-acting parenteral preparations of oxytetracycline are not indicated in the treatment of mastitis. Macrolide antibiotics have good tissue penetrative capacity and the ion-trapping effect favours the concentrations attained in milk. An undesirable feature of their distribution is diffusion from the systemic circulation into ruminal fluid (pH 5.5 to 6.5) where the ion-trapping effect also applies. Because of their wide distribution in tissues and passage into ruminal fluid, high doses are required to attain effective concentrations in milk. In the case of spiramycin, the persistence of tissue residues is a major disadvantage. Since parenteral preparations of erythromycin and spiramycin cause tissue irritation at intramuscular injection sites, slow intravenous injection is the preferred route of administration.

Drugs are transferred from the general circulation to the mammary gland by passive diffusion (Baggot, 1977; Ziv, 1980). Consequently, non-ionized lipid-soluble agents that are not extensively bound to plasma proteins more readily reach the mammary gland (Table 30.4). Because milk is weakly acidic (pH 6.5–6.8), drugs that are weak bases (trimethoprim, macrolides, lincomycines) are preferentially concentrated by ion trapping (Ziv, 1980; Baggot, 2000). Of the antimicrobials that distribute well in the mammary gland following parenteral administration, only fluoroquinolones have broad-spectrum activity against Gram-negative pathogens. Because of bacterial resistance concerns for humans, the use of this class of antimicrobial in dairy cows is not approved. The low degree of lipid solubility of aminoglycosides and polymyxin B limits their passage into milk.

Table 30.4 Distribution of antibiotics throughout the udder after parenteral administration (adapted from Ziv, 1980).

| Good | Moderate | Poor |
|------------------|----------------|-----------------------|
| Erythromycin | Amoxycillin | (Dihydro)streptomycin |
| Spiramycin | Ampicillin | Gentamicin |
| Tylosin | Cephalosporins | Neomycin |
| Trimethoprim | Penicillin G | Polymyxins |
| Baquiloprim | Rifamycin | Spectinomycin |
| Fluoroquinolones | Sulphonamides | |
| | | Tetracyclines |

In the presence of clinical mastitis, the pH of the milk increases (6.9–7.2), approaching that of plasma. Under these circumstances weak acids (sulphonamides, penicillins, amoxycillin-clavulanic acid, cephalosporins, rifampin), although typically not concentrated in milk, may reach effective concentrations (Ziv, 1980; Durnford, pers. comm.; Baggot, 2000). Lipophilic drugs of various pharmacological classes will also be concentrated in milk in spite of the decreased ion-trapping.

The site of infection within the udder varies with the causative pathogenic micro-organisms and, in addition to bacterial susceptibility, influences the choice of antimicrobial agent. Since streptococcal mastitis is usually an infection of the milk compartment of the udder, antimicrobial agents that have limited membrane penetrative capacity and produce a bactericidal effect, such as penicillins (benzylpenicillin), may be selected for therapy. Even though coliform mastitis is an infection of the milk compartment, the choice of antimicrobial for systemic therapy is largely limited to enrofloxacin or trimethoprim-sulphonamide since the long withdrawal period for aminoglycosides precludes their use. *Staphylococcal aureus*, the principal causative micro-organism of subclinical mastitis, may reside in the intracellular space and within epithelial and phagocytic cells (Pyorala, 1995). The treatment of staphylococcal mastitis requires the administration (parenteral and intramammary) of an antimicrobial agent which can penetrate epithelial cells and tissues of the udder and is active against staphylococcal beta-lactamase. Amoxicillin-clavulanic acid combination and macrolide antibiotics (erythromycin and spiramycin) meet these requirements. The bacteriostatic effect produced by macrolides and their reduced antibacterial activity in milk could be disadvantageous.

Selection of antimicrobial agent

There are several factors to consider when selecting an antimicrobial agent, and the preparations (parenteral, intramammary) to use, for the treatment of mastitis. They include the nature and severity of the infection, the stage of lactation, the causative pathogenic micro-organism and its susceptibility, the relative cost of the various antimicrobial preparations, the incidence of mastitis in the herd and the usage pattern of intramammary preparations. Early diagnosis and the prompt application of appropriate treatment will reduce the extent of mammary tissue damage and will increase the rate of recovery and the return of milk production to or approaching the original level. It is desirable to select an antimicrobial that produces a bactericidal effect and has a narrow spectrum of activity and essential that treatment should continue for an

adequate duration in order to achieve a bacteriological cure. Apart from preparations containing fixed combinations (trimethoprim-sulphonamide, amoxillin-clavulanate), the use of combination preparations should generally be avoided.

Having made a (tentative) clinical diagnosis of the nature of the mastitis and established the history of infection in the affected cow and incidence of infection in the herd, a pretreatment milk sample for bacterial culture should be properly (aseptically) collected. Immediate examination of a milk sample is a particularly useful aid in selecting an antimicrobial for empirical treatment, which should commence at this time. A parenteral and quick-release intramammary preparation may be used concurrently. The latter should be infused after stripping milk and other products (cellular debris, pus) from the infected quarter(s). Oxytocin, 5 to 10 units of diluted solution (10 units/ml), can be administered by slow intravenous injection to facilitate the completeness of stripping. The half-life of oxytocin is approximately 2 minutes. In addition to antimicrobial administration, supportive therapy should be provided.

Results obtained from the microbiology laboratory, interpreted in conjunction with the tentative clinical diagnosis and knowledge of the distribution of antimicrobial agents in the udder, facilitate selection of the appropriate drug. Mastitis, with the exception of summer mastitis, is usually caused by a single bacterial species. When *Staph. aureus* is the causative pathogenic micro-organism, it can be rapidly determined whether the strain isolated produces beta-lactamase (70 per cent of strains), although it should be recognized that milk induces production of the enzyme. The susceptibility of streptococci can be predicted, but it is necessary to determine quantitative susceptibility, using the broth dilution method (which measures MIC), of coagulase-positive staphylococci and enteric bacteria (*E. coli*, *Klebsiella* spp.). Knowledge of the susceptibility (predicted or measured *in vitro*) of the causative bacterial pathogen and of the pharmacokinetic properties of the antimicrobial agent of choice provides the information required for calculating the dose and selecting the dosage interval for the parenteral preparation. Dosage calculations are based on MIC which is assumed to be related to the concentration attained at the site of infection in the udder. An intramammary preparation containing an antimicrobial that will reach the site of infection and complement the activity of the antimicrobial in the parenteral preparation should be chosen and administered by intramammary infusion (after stripping the inflamed quarter) at the recommended dosage interval, which is usually 12 or 24 hours, for preparations intended for use in lactating cows.

Response to therapy

A combination of methods, applied two to three weeks after the end of treatment, should be used to assess the effectiveness of antimicrobial therapy. They include clinical examination, bacterial culture of an aseptically collected milk sample, tests based on changes in somatic cell count, protein, enzyme and electrolyte contents of milk (indication of inflammation) and return to the expected level of milk production (Pyorala, 1995). Discrepancy between the expected and obtained response to therapy may be attributed to inadequacy of the host defence mechanisms, acquired bacterial resistance, altered pharmacokinetic behaviour of the antimicrobial in the diseased animal or poor distribution in the udder with limited access to the site of infection. In the case of infection caused by *Staph. aureus* bacteria located in microabscesses, macrophages and fibrotic tissue, the bacterial pathogen may be virtually inaccessible to antimicrobial agents or may be in a state of dormancy. The bacteriological cure rate of staphylococcal mastitis is low, particularly when treatment is applied during lactation, while the high self-cure rate of coliform mastitis greatly influences the validity of attributing bacteriological cure to antimicrobial therapy (Sandholm & Pyorala, 1995). A reasonably satisfactory response rate to treatment of staphylococcal mastitis is obtained only when appropriate therapy with a parenteral preparation and a slow-release intramammary preparation is applied at the end of lactation after the last milking. The longer the antimicrobial(s) persists in the udder, the greater the likelihood of at least a moderately favourable response to therapy. The bacteriological cure rate can vary widely.

Therapy of mastitis

During lactation

Factors to take into account when choosing an intramammary preparation include:

- Antibacterial spectrum
- Cost of the preparation for usual duration of treatment
- With/without steroid
- Previous treatment history
- Availability of injectable 'partner' (parenteral preparation)
- Milk withholding time
- Personal preference

Compound preparations containing one or more antimicrobial agents and a corticosteroid (hydrocortisone or prednisolone) are available for intramammary

infusion mainly in lactating cows. Amoxycillin trihydrate–clavulanate potassium and prednisolone are combined in a compound intramammary preparation (oily suspension) which provides greatly enhanced activity of amoxycillin against beta-lactamase producing *Staph. aureus* and has short withdrawal periods.

Steroids (prednisolone) are present in low dose and their activity is of short duration. There has been no convincing evidence of depressed antibody production or cell-mediated responses as a result of the inclusion of prednisolone in an intramammary formulation. In fact, it could be argued that the inclusion of prednisolone is supportable on grounds of cow welfare. Farmers will claim that the inclusion of the steroid will lead to a reduction in size of the inflamed quarter. Trials carried out with an amoxycillin–clavulanic acid formulation containing prednisolone confirm this observation (O'Rourke, 1994) (Fig. 30.1).

Most compound preparations contain antimicrobial agents that are selected on the basis of broadening the spectrum of antimicrobial activity without extending the withdrawal period. These compound preparations (more than one antibiotic) are of doubtful value and are often not successful in eliminating infection. Moreover, the concentration achieved by any one antibiotic in such preparations is likely to be lower than the optimum required for treatment and could facilitate the development of resistance (Egan, 1984). Unless the antimicrobials in a combination preparation act synergistically (Table 30.5) the use of compound preparations should be avoided.

In recent years veterinary practitioners have been debating the concurrent use of an injectable and intramammary preparation in the treatment of mastitis.

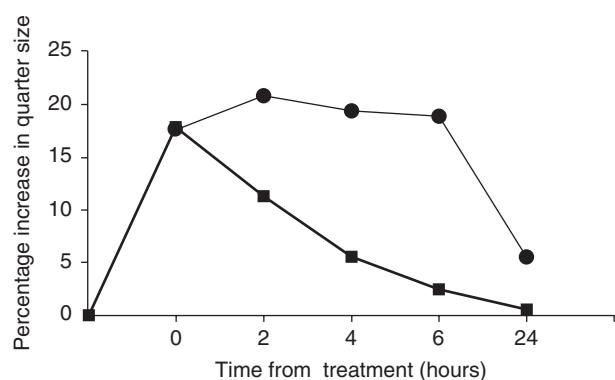

Fig. 30.1 Reduction in quarter size, experimentally infected with *Streptococcus uberis*, after treatment with amoxycillin and clavulanic acid formulations with and without prednisolone (O'Rourke, 1994). ■ = Lactating low formulation containing amoxycillin, clavulanic acid and prednisolone. ● = Same formulation without prednisolone.

There have been a number of studies indicating a beneficial effect in the treatment of *Staph. aureus* infections from the concurrent use of an intramammary and an injectable (Tables 30.6 and 30.7). However, the compatibility of the injectable and intramammary preparations should be taken into account whenever this form of treatment is being considered.

Peracute mastitis

Toxic mastitis is most commonly caused by the coliform organisms *E. coli*, *Klebsiella* spp., *Enterobacter* spp. and

Table 30.5 Clinically useful antimicrobial drug combinations in veterinary medicine (adapted from Prescott & Walker, 2000).

| Indication | Drug combination | Comment |
|--------------------------------------|-----------------------------|-------------------------|
| Bovine <i>Staph. aureus</i> mastitis | Penicillin–streptomycin | Synergistic combination |
| | Amoxycillin–clavulanic acid | Potentiated combination |

Serratia spp. Because of the severity of clinical signs the following therapeutic regimen is suggested:

- (1) Frequent stripping of the affected quarter following the administration of oxytocin is probably the most important, yet most often neglected, component of therapy. Evacuation of the udder serves to remove both bacterial endotoxins and inflammatory host mediators, thus markedly reducing the severity of clinical signs.
- (2) Antibacterial therapy: gentamicin, polymyxin B and potentiated sulphonamides have minimal inhibitory concentrations (MIC) and distribution properties suitable for the treatment of coliform mastitis.
- (3) Intravenous fluids.
- (4) Non-steroidal anti-inflammatory drugs.

The non-steroidal anti-inflammatory drugs have a more selective action than glucocorticoids in that they directly inhibit cyclo-oxygenase, although isoforms of the enzyme are inhibited to a varying degree depending on the drug. The consequence of cyclo-oxygenase inhibition is that the synthesis of prostaglandins

Table 30.6 Bacteriological cure rates for subclinical *Staphylococcus aureus* infections at 21 days post treatment with amoxycillin and penicillin G (Owens *et al.*, 1988). Reproduced with permission of the American Dairy Science Association.

| Route | Regime | Bacteriological cure rate (%) |
|---|---|-------------------------------|
| Intramammary (<i>n</i> = 40) | 62.5 mg amoxycillin six times @ 12-hour intervals | 25 |
| Intramammary + injection (<i>n</i> = 35) | 62.5 mg amoxycillin six times @ 12-hour intervals +9 000 000iu procaine penicillin daily for 3 days | 51.4 |

Table 30.7 Bacteriological cure rates for chronic *Staphylococcus aureus* infections at 20 days post treatment with spiramycin (Ziv, 1980).

| Route | Regime | Bacteriological cure rate (%) |
|---|--|-------------------------------|
| Injection (<i>n</i> = 18) | 10g spiramycin (IM) twice @ 72-hour intervals | 16 |
| Intramammary (<i>n</i> = 40) | 500 mg spiramycin three times @ 24-hour intervals | 40 |
| Intramammary + injection (<i>n</i> = 35) | 10g spiramycin (IM) twice @ 72-hour intervals + 500mg spiramycin three times @ 24-hour intervals | 68 |

involved in central pyresis and pain perception as well as tissue inflammation is inhibited. Unlike glucocorticoids, the non-steroidal anti-inflammatory drugs do not produce immunosuppression. The rate of elimination (hepatic metabolism) of these drugs in cattle differs widely. The half-life of salicylate is 0.8 hours (3.5 hours when administered orally as aspirin, due to slow dissolution/absorption from ruminal fluid), ketoprofen (0.4 hours), flunixin (8.1 hours) and phenylbutazone (42–66 hours). They distribute to a similar extent, mainly in extracellular fluid, and enter milk by passive diffusion. Of these drugs, flunixin meglumine (2.2 mg/kg, administered by intravenous injection at 24-hour dosage intervals) may have a place in the treatment of acute *E. coli* (endotoxin) mastitis. The withdrawal period is slaughter 7 days, milk 12 hours. The antipyretic, anti-inflammatory and analgesic effects produced by the drug are largely dependent on the stage of the inflammatory process at which treatment is commenced. Early diagnosis of coliform mastitis would increase the beneficial effect produced by flunixin administration.

During the dry period

Routine dry-cow therapy provides the following advantages:

- Bacteriological cure of a higher proportion of *Staph. aureus* infections (Table 30.8).
- No loss of milk production.
- Prevention of new infections (including summer mastitis commonly due to *Arcanobacterium pyogenes*), especially in the early dry period.
- Treatment of infections caused by streptococci and other bacteria.

In herds with a high prevalence of contagious mastitis pathogens, the use of dry-cow therapy has been an efficacious and economically effective method of reducing the frequency of intramammary infections (Heald *et al.*, 1977). Berry *et al.* (1997) showed that cows treated with dry-cow therapy at the end of lactation produced 179 kg more milk during the first 120 days of the sub-

sequent lactation when compared with control cows that received no therapy.

The efficacy of dry-cow therapy for subclinical mastitis is not invariably reliable, especially for chronic cases of mastitis caused by *Staph. aureus* (Table 30.9). There are, however, results indicating that an improved cure rate can be achieved when intramammary treatment is accompanied by systemic treatment (Table 30.10).

Strategies for dry period treatment

With consistent application of dry-cow therapy (DCT) in conjunction with other mastitis control measures the prevalence of contagious mastitis pathogens has declined to a low level in many herds (Kirk *et al.*, 1994), as is evidenced by bulk milk somatic cell counts (BMSCC) of <200 000 cells/ml. Some owners of herds with a low prevalence of contagious mastitis pathogens have stopped using dry-cow therapy and others are questioning the practice because of concerns about residues in the milk (Kirk *et al.*, 1994). Macmillian *et al.* (1983) indicated that in herds with low cell counts selective dry-cow therapy may be preferable to whole herd therapy.

A fact sheet entitled Dry Cow Therapy (Anderson & Cote, 1996) from the Ontario Ministry of Agriculture, Food and Rural Affairs recommends that selective dry-cow therapy should be used when the monthly bulk milk cell count (BMCC) is below 200 000 and the quarter infection rate is <15%. The following cows should be treated:

- Cows with peak somatic cell count (SCC) > 250 000/ml.
- Cows which have had a clinical case of mastitis.
- Cows from which a major mastitis pathogen(s) has been cultured.

In New Zealand the SAMM (seasonal approach to managing mastitis) plan was devised by the Dairy Research Corporation. It was adopted by the NZ Mastitis Advisory Committee and launched in 1993. The implementation of the plan contributed to a

Table 30.8 Bacteriological cure rates (percentages) for selected Gram-positive intramammary infections using cloxacillin (adapted from Griffin *et al.*, 1982).

| % response | 60 | 24 | 10 | |

Table 30.10 Bacteriological cure rates for chronic subclinical *Staphylococcus aureus* infections at 15 days postcalving (Johansson *et al.*, 1995). Reproduced with permission of the International Dairy Federation.

| Route | Regime | Bacteriological cure rate (%) |
|---|--|-------------------------------|
| Intramammary (<i>n</i> = 42) | 0.17 g penicillin benzathine +0.4 g dihydrostreptomycin in all 4 quarters | 57 |
| Intramammary + injection (<i>n</i> = 38) | 20 mg/kg benzylpenicillin procaine for 5 days followed by 0.17 g penicillinbenzatin +0.4 g dihydrostreptomycin in all 4 quarters | 79 |

substantial decline in somatic cell count levels in subsequent years (national average cell count is 178 000/ml). The criteria used for determining herd mastitis status and dry-cow therapy are shown in Table 30.11.

The effects of three selection strategies for dry-cow therapy on prevention of new infections and rate of antibiotic usage were compared in a trial involving 1044 cows in 12 herds (Table 30.12) (Browning *et al.*, 1984). Selective cow treatment was identified as the preferred strategy. Blanket treatment resulted in increased antibiotic usage: 15.5 versus 6.4 tubes per infection eliminated with no additional benefit and selective quarter treatment resulted in a higher new infection rate (6.4 versus 3.9 per cent) during the dry period.

Berry *et al.* (1999) confirmed that this is still the case today in a study comparing dry-cow therapy versus no treatment. Dry-cow therapy resulted in a 10-fold reduc-

tion in clinical mastitis during the dry period and a 3-fold reduction in infected cows at calving and clinical mastitis in the first 21 days of lactation when compared to herds where there was no treatment (Table 30.13).

Hovi and Roderick (2000) found that the incidence of new infection during the dry period was three times higher in organic herds when compared to conventional herds (28.9 cases per 100 cows versus 9.2 cases per 100 cows). The authors point out that most organic dairy farmers felt that it was impossible to maintain low SCCs without using dry-cow therapy and culling healthy young cows.

Whilst we may implement selective dry-cow therapy, the key question is: are these untreated quarters more susceptible to infection during the dry period? The physiological process whereby the teat canal becomes closed through the formation of a keratin plug after drying off appears to be a major defence mechanism.

Table 30.11 Criteria used in the SAMM plan for determining herd mastitis status and dry-cow therapy strategy (Woolford *et al.*, 1995). DCT, dry-cow therapy. Reproduced with permission of the International Dairy Federation.

| Criteria | Herd mastitis classification | | |
|---|------------------------------------|--|---------------------------------|
| | High | Medium | Low |
| Average BMSCC, Jan–Mar (000/ml) or % cows >150 000/ml over Jan–Mar or % cows clinical in first month of lactation or 15% cows clinical first 3 weeks of last dry period? or Late season outbreak of clinical cases? | >400 >50% >10% Yes Yes | 150–400 20–50% 3–10% No No | <150 <20% <3% No No |
| <i>Recommended DCT strategy</i> | <i>Total herd</i> | <i>Selective cow</i> | <i>Selective cow</i> |

Table 30.12 Prevalence of infected quarters at drying off and calving plus the new infection rate during the dry period for three different dry-cow strategies (Browning *et al.*, 1984, reproduced with permission of Australian Veterinary Journal). DCT, dry-cow therapy.

| Strategy | Drying off prevalence (%) | Calving prevalence (%) | New infection rate during dry period (%) |
|-------------------|---------------------------|------------------------|--|
| DCT | 13.2 | 6.8 | 2.6 |
| Selective cow | 13.0 | 7.9 | 3.9 |
| Selective quarter | 13.1 | 10.0 | 6.4 ^a |

^a $P \leq 0.05$.

| Strategy | Clinical mastitis during the dry period (%) | Infections at calving (%) | Mastitis in first 21 days of lactation (%) |
|--------------|---|---------------------------|--|
| DCT | 0.0 | 9.6 | 5.5 |
| No treatment | 10.5 | 32.8 | 16.4 |

Williamson *et al.* (1995), reporting on the observations of the dynamics of teat canal closure for a group of 657 quarters after drying off, noted that 50 per cent of teat canals were classified as 'closed' at 7 days after drying off. A further 45 per cent became closed over the following 50–60 days and 5 per cent remained 'open' at 90 days. During this study 83 per cent of all clinical infections during the dry period occurred within the first 21 days. Of the 52 clinical infections that were diagnosed

during the dry period, 97 per cent occurred in teats that had an 'open' canal.

The dilemma is how to protect quarters that are not treated with dry-cow therapy. In New Zealand a non-antibiotic preparation, Teatseal™, is available (Orbe-Seal™ in the UK). Teatseal is a dense, viscous material, which is infused hygienically into the teat as soon as possible after the last milking of lactation. It physically plugs the teat canal immediately after infusion thus

Table 30.14 Numbers of new intramammary infections (IMIs) over the dry period and at calving for the four treatment groups (Woolford *et al.*, 1998).

| Experimental group | NC | PC | TS | TS + Ab |
|--|------|------------------|------------------|------------------|
| Total quarters allocated at drying off | 528 | 528 | 505 | 505 |
| New dry period clinical IMIs | 18 | 2 ^a | 1 ^a | 2 ^a |
| New IMIs at calving | | | | |
| <i>Streptococcus</i> spp. | 50 | 5 ^a | 4 ^a | 4 ^a |
| <i>Staphylococcus aureus</i> | 3 | 0 | 1 | 0 |
| Coagulase-negative staphylococci | 6 | 1 | 6 | 2 |
| Coliforms | 4 | 4 | 1 | 1 |
| Other organisms | 2 | 2 | 0 | 1 |
| Clinical – no growth at culture | 2 | 0 | 0 | 0 |
| Total non-streptococcal IMIs | 17 | 7 ^b | 8 ^c | 4 ^a |
| Total new IMIs at calving | 67 | 12 ^a | 12 ^a | 8 ^a |
| Total new IMIs | 85 | 14 ^a | 13 ^a | 10 ^a |
| Overall incidence of new IMI rate (% quarters) | 16.1 | 2.7 ^a | 2.6 ^a | 2.0 ^a |

Superscripts denote significant differences within rows between treatment groups and the negative control.

^a $P < 0.01$; ^b $P \approx 0.05$; ^c $P < 0.1$

NC, negative control; PC, positive control (cephalonium); TS, Teatseal; TS + Ab, Teatseal + cloxacillin.

preventing bacteria from entering the teat. The teat canal then becomes closed from day one of the dry period and remains closed for the dry period.

A large-scale study has been carried (Woolford *et al.*, 1998) utilizing a total of 1200 cows across seven herds. Cows with late lactation SCCs of $< 200\,000/\text{ml}$ were identified and sampled aseptically to establish the infection status of every quarter at drying off. At drying off uninfected quarters were randomly allocated to a treatment. The numbers of new intramammary infections (IMIs) during the dry period and at calving are shown in Table 30.14. In the 1998 study all three infused treatments (Teatseal, cephalonium (Cepravin DC), and Teatseal plus 600 mg cloxacillin (prior to infusion of the seal) showed about a 10-fold reduction in new clinical IMIs ($P < 0.01$) relative to the negative control (no treatment). The incidence of new IMI due to *Strep. uberis* at calving was 10-fold lower ($P < 0.01$) for prophylactic treatments compared to the negative control. It is also interesting to note that the prophylactic treatments reduced the incidence of postcalving clinical mastitis by approximately 50 per cent in the subsequent lactation compared to the negative control. This study indicated that use of Teatseal protects the gland against estab-

lishment of infection, by the presence of a physical barrier from day one of the dry period, which remains in place until calving.

Benefits of antimicrobial therapy for mastitis

Improved milk quality

Subclinical mastitis affects the quality of dairy products. Milk from infected cattle is less palatable, has a shorter shelf-life and produces lower yields of processed dairy products. Consequently, cooperatives, commercial concerns and regulatory agencies impose penalties, based on cell count and bacterial counts of bulk milk. The most severe penalty arises with milk that is deemed unfit for human consumption and discarded (BMCC $> 400\,000$ cells/ml in EU, see Chapter 25). Although treatment of clinical mastitis may not result in a microbiological cure, macroscopic milk quality will return to normal more quickly following treatment. The more rapid return to the production of saleable milk is an important benefit of treatment.

Increased milk production

The largest cost associated with mastitis is reduced milk yield as a result of clinical and subclinical infection. Lucey and Rowlands (1984) found that the mean reduction in milk yield where clinical mastitis occurred was 540 kg, the average lactation being 4830 kg. The reduction was greatest when infection occurred before peak yield, the proportional reduction being higher in higher-yielding cows. Where clinical mastitis occurred before peak yield, both peak yield and length of lactation were reduced, though the rate of decline from peak yield was unaltered. Where infection occurred between peak yield and 10 weeks after peak yield, lactation yield and length were both affected. Clinical mastitis occurring after peak yield appeared to have little effect on lactation yield. Results suggested that cows which contract mastitis are unlikely to achieve their full milk-yield potential in the following lactation. In a survey of just over 24 000 dairy cows the daily loss in milk yield during the first 2 weeks after the occurrence of mastitis varied from 1.0 to 2.5 kg. Total loss over the entire lactation varied from 110 to 552 kg and depended on parity and the time of mastitis occurrence. Regardless of the time of occurrence during the lactation, mastitis had a long-lasting effect on milk yield; cows with mastitis did not reach their pre-mastitis milk yields during the remainder of the lactation after the onset of the disease (Rajala-Schultz *et al.*, 1999).

Table 30.15 (a) Reduction in test day milk yield (kg)* in relation to somatic cell counts (SCCs) of Holstein cows without clinical mastitis, and (b) for SCCs of 200 000 cells/ml the reduction in test day milk yield (kg)* at days 50, 150 and 250 postpartum (Hortet *et al.*, 1999, reproduced with permission from Elsevier Science).

(a) Reduction in yield at various SCCs

| | SCC (cells/ml) | | |
|------------------|----------------|---------|---------|
| | 100 000 | 200 000 | 600 000 |
| Primiparous cows | 0.30 | 0.61 | 1.09 |
| Calving 2 | 0.32 | 0.63 | 1.13 |
| Calving ≥3 | 0.30 | 0.60 | 1.07 |

(b) Reduction in yield at SCC of 200 000 cells/ml

| | Day 50 postpartum | Day 150 postpartum | Day 250 postpartum |
|------------|-------------------|--------------------|--------------------|
| Calving 2 | 0.63 | 0.92 | 1.77 |
| Calving ≥3 | 0.60 | 1.09 | 1.85 |

*Reduction in yield was calculated as the deviation from a reference value set at 50 000 cells/ml.

Reduction in milk yield is also associated with sub-clinical infection. Hortet and Seegers (1998) found in a review of 19 papers that there was an average loss of 80 kg of milk in primiparous and 120 kg in multiparous cows for each two-fold increase of the geometric mean of somatic cell count (SCC) > 50 000 cells/ml. The reduction in test day milk yield (kg) associated with SCC of less than or equal to 600 000 cells/ml in cows without clinical mastitis was assessed using monthly cow records collected for a one year period in 105 Holstein herds in France (Hortet *et al.*, 1999). Results indicated that for 100 000, 200 000 and 600 000 cells/ml the reduction in daily milk yield was approximately 0.30 kg, 0.60 kg and 1.10 kg, respectively (Table 30.15).

Effective microbiological cures, eliminating reservoirs of infection

A very real, but often overlooked, benefit of antimicrobial therapy relates more to the overall herd health status than the infected cow. This is because the infected cow is a reservoir of transmissible infection. Each infected cow may represent not only an individual with suboptimal health and production, but also a reservoir of infection. Each infected cow thus poses a threat to the productive capacity of non-infected cattle. *Strep. agalactiae* is an obligate parasite of the mammary gland. *Staphylococcus aureus* and *Mycoplasma* spp., although

not obligate parasites of the mammary gland, are transmitted from cow to cow (Bramley & Dodd, 1984). Identification followed by treatment, isolation or eradication can markedly reduce the numbers of new infections if coupled with appropriate hygienic measures.

Costs associated with antimicrobial therapy

Drug and veterinary costs

These costs will not be detailed, but should be considered when evaluating the costs associated with treatment.

Discarded milk

Available intramammary antibiotic preparations recommend milk withholding periods (discard times) that vary from 36 to 120 hours after the last treatment. Cattle with clinical mastitis are usually treated three times at 12 to 24 hour intervals. The antibiotic-contaminated, and hence discarded, milk may total as much as 420 litres in a high-producing cow. The decision to undertake treatment cannot be taken lightly. Dry-cow therapy is particularly cost-effective because it does not require milk discarding.

Slaughter withdrawal periods

Both systemic and local (intramammary) antibiotic preparations have slaughter withdrawal periods. Treated individuals cannot be marketed for salvage purposes, regardless of the success of treatment, until after the withdrawal period for the administrated preparation has ended.

Risks of new infections/altered host defences

Intramammary infusion of antibiotics is far from being an innocuous procedure. The infusion procedure may remove the keratin lining of the streak canal, an important barrier to intramammary infections (see pp. 313, 400). Strict hygiene must be practised to prevent accidental introduction of micro-organisms at the time of treatment. Only commercially available formulations of known efficacy and guaranteed safety are suitable for intramammary therapy. Special care must be exercised when large numbers of cattle are being treated on a single occasion. Explosive outbreaks of peracute and often fatal mastitis have been known to follow either poor hygiene during infusion of an intramammary product or use of a contaminated product.

approach to hoof trimming and the causes and control of lameness.

Incidence and prevalence

The incidence of lameness is defined as the number of cases recorded over a given period, usually a year. It is a longitudinal measure and is often expressed as the number of cases per 100 cows per annum. A single case of lameness is defined as one lesion in one claw. A repeat or new case can be a different lesion in the same, or another, claw, although it may be a recurrence of the same lesion after a period of time. Prevalence is the number of cases of lameness present at a single point in time, for example when the whole herd is examined on the same day, and is known as a cross-sectional measure.

A further distinction must be made between the incidence or prevalence of *lameness* and the incidence or prevalence of *lesions*, and care must be taken when comparing data. The majority of studies record the prevalence of lesions, as this produces a larger number of observations. Very few studies have examined the proportion of lesions that eventually translate into clinically detectable lameness, and yet this is an extremely important issue if we are to continue to use lesion prevalence studies to investigate the causes of lameness.

The results of studies of lameness incidence will depend on the person recording. Inevitably, studies by veterinary surgeons will give lower figures than those by farmers or stockmen, because rarely are all lame cows on a farm dealt with by a veterinarian. It is difficult to provide an average figure for the proportion of lame cows seen by veterinary practitioners. For example, the study of Clarkson *et al.* (1996) showed that 3 per cent of lame cows were examined by the veterinarian in Cheshire, 20.4 per cent in the Wirral, 21.7 per cent in Wales and 77.3 per cent in Somerset. An American study where observers went to each farm twice to record the number of lame cows showed that their recorded prevalence was 2.5 times higher than that estimated by the herd managers (Wells *et al.*, 1993).

Introduction

Lameness remains a major problem for dairy herds worldwide. There are few other problems which produce as much pain and distress to the cow and very few other problems where the herdsman spends so much time and effort on routine prevention, namely hoof trimming. This chapter examines the incidence and costs of lameness, the anatomy of the digit, an

Table 31.1 The incidence levels of lameness in several British Isles surveys.

| Authors | Date | Recorders | Incidence (cases/100 cows per year) |
|------------------------|------|---------------------------|-------------------------------------|
| Hedges <i>et al.</i> | 2000 | Veterinarians | 68.9 |
| Clarkson <i>et al.</i> | 1996 | Veterinarians and farmers | 54.6 |
| Esslemont & Spincer | 1993 | Veterinarians and farmers | 36 |

| Eddy & Scott | 1980 | Veterinarians | 7 |
| Russell <i>et al.</i> | 1982 | Veterinarians | 6 |
| Leech <i>et al.</i> | 1960 | Veterinarians and farmers | 4 |

Whitaker *et al.* (1983) estimated that in Britain veterinary surgeons saw only a quarter of the total lameness cases, the remainder being treated by the farmer. This was based on a study of 185 herds where the veterinary surgeon treated 25.2 per cent and the farmer 74.8 per cent of all lamenesses. As herds increase in size, the stockman becomes more competent and the number of lame cows seen routinely by the veterinary surgeon decreases.

The use of data produced by farmer recording produces problems of terminology and there will be errors in recording the causes of lameness. Hence many studies refer to 'under-run sole' or 'a foot abscess', when in fact the primary lesion was a white line disorder or a sole or heel ulcer. This produces further errors in our understanding of the incidence and causes of lameness. It is generally accepted that the incidence of lameness has increased over the past 40 years (Table 31.1) when a study provided by both veterinary surgeons and farmers gave an incidence of 3.88 per cent (Leech *et al.*, 1960). The last major British survey was in 1977 and involved 48 veterinary practices which recorded 7526 cases of lameness in 1821 dairy herds (Russell *et al.*, 1982). The average incidence amongst cattle was 5.5 per cent, although this varied between the veterinary practices from 1.8 to 11.8 per cent. Most lesions (88.3 per cent) occurred in the feet and 84 per cent of foot lesions were in the hind feet. The remaining 11.7 per cent of lameness occurred in the legs and trunk and the majority of these involved trauma (Russell *et al.*, 1982). A New Zealand farmer-recorded study of three herds in 1989/90 showed variations in lameness incidences of 38 per cent, 22 per cent and 2 per cent (Tranter & Morris, 1991).

An American study of 18 farms showed a median prevalence of 11.8 per cent of lactating dairy cows were clinically lame in the summer and 14.8 per cent in the winter (Wells *et al.*, 1995). No overall prevalence was provided because of the management differences.

A two-and-a-half-year UK study of 37 farms where both farmers and vets recorded lameness produced a mean annual incidence rate of 54.6 new lamenesses per 100 cows, varying on individual farms from 10.7 to 170.1 (Clarkson *et al.*, 1996). The mean incidence rates for the winter and summer were 31.7 and 22.9 respectively, with 78.7 per cent of the total in the outer claw. The mean prevalence rate was 20.6 per cent, ranging from 2.0 per cent to 53.9 per cent, with winter and summer rates being 25.0 per cent and 18.6 per cent, respectively (Clarkson *et al.*, 1996).

The trial reported by Hedges *et al.* (2000) was an 18-month intervention study involving only five farms in one area (Gloucestershire) of the UK. All lame cows were examined by veterinarians, so the study produced useful data on the incidence of lesions causing lameness. The incidence of lameness treated by both veterinary surgeons and farmers in 90 well-recorded UK dairy herds is shown in more detail in Table 31.2. The authors concluded that it should be a reasonable target for farmers to reduce lameness incidence to second quartile values, i.e. 11 per cent of the herd affected, giving a target of 14 cases/100 cows per annum. From other figures in Table 31.1 this would appear to be a rather optimistic target.

Although enormous research effort over the past 25 years has led to an increase in our understanding of lameness, the incidence has not declined significantly. One major reason for this is the advent of digital

Table 31.2 Incidence of lameness in 90 well recorded DAISY herds (Esslemont & Kossaibati, 1996).

| | Weighted average values | | | | |
|--------------------------------|-------------------------|-----------------|-----------------|----------------|-----------------|
| | Overall | Lowest quartile | Second quartile | Third quartile | Fourth quartile |
| Number of herds | 90 | 22 | 23 | 23 | 23 |
| % of herd affected by lameness | 17.4 | 4.4 | 11.1 | 18.3 | 33.8 |
| Cases per affected cow | 1.4 | 1.0 | 1.2 | 1.4 | 1.8 |
| Cases per 100 cows | 24 | 4.7 | 14.1 | 24.6 | 47.4 |

dermatitis. First reported in the UK in the mid 1980s (Blowey & Sharp, 1988), digital dermatitis now accounts for around one third of all cases of lameness seen. In a UK study of five UK dairy herds involving over 1100 cow lactations over 18 months, where all lame cows were examined and recorded by a veterinarian, the incidence of digital dermatitis was 12.0 cases per 100 cows per annum, compared with sole ulcers at 13.9 cases/100 cows p.a. and white line disease at 12.7 cases/100 cows p.a. (Hedges *et al.*, 2000).

Several studies have attempted to record the frequency of lesions causing lameness, although results must be interpreted with care. Studies which rely on veterinary records of cases for which the farmer has requested attention for treatment will undoubtedly underestimate the incidence of conditions such as digital dermatitis and foul in the foot, as many farmers would treat these themselves. On the other hand, studies involving farmer recording may use vague terms such as 'under-run heel' or 'sole abscess', without defining the initial cause of the lesion (sole ulcer, white line, foreign body penetration, etc.), and these studies would lack accuracy. Table 31.3 summarizes five sets of data on lesions causing lameness.

Heel ulcers are a recently defined condition (Blowey *et al.*, 2000a) and may have been classified as under-run heel or foreign body penetration in other surveys. Axial wall fissures also appear to be of increasing importance worldwide (Vermunt, 1998) and may be a form of white line lesion as many follow the line of the axial groove.

Structure of the foot

The bovine claw consists of three main components, namely (Fig. 31.1):

- Hoof
- Corium
- Bone and associated structures

Hoof

The hoof, or horn capsule, is keratinized epidermis, similar to hair or finger nails. There are five distinct parts to the hoof, namely the periople, the wall, the sole, the white line and the heel. The wall, sole and heel consist of tubular horn, produced by the underlying papillary corium (or dermis). Keratinization of the epidermal cells is a physiological process involving a high rate of synthesis of keratin proteins inside the cell, plus the production of intercellular cementing substances. This must be carried out entirely by diffusion, because the epidermis is avascular. The strength, or quality, of the horn is determined by three main factors:

- The amount of keratin fibrils within the cell and the strength of their cross-linking disulphide bonds to form keratin masses.
- The amount and quality of the intercellular cementing substances which cement the keratinized cells together.
- The architecture of the horn itself, namely the ratio of tubular to non-tubular horn, which is effectively the density of the horn tubules.

Horn tubule density is approximately 80 tubules/mm² in the wall, decreasing to 20 tubules/mm² in the central sole area. There is no tubular horn in the white line. The wall is therefore the stronger part of the hoof, especially at the toe when it is more mature. As the number of horn tubules is fixed at birth, enlargement of the hoof, for example in older cows, is by an expansion of the intertubular cement. The very large flat foot of a cow is generally softer and weaker than the small compact foot of the heifer, because of its lower tubule density.

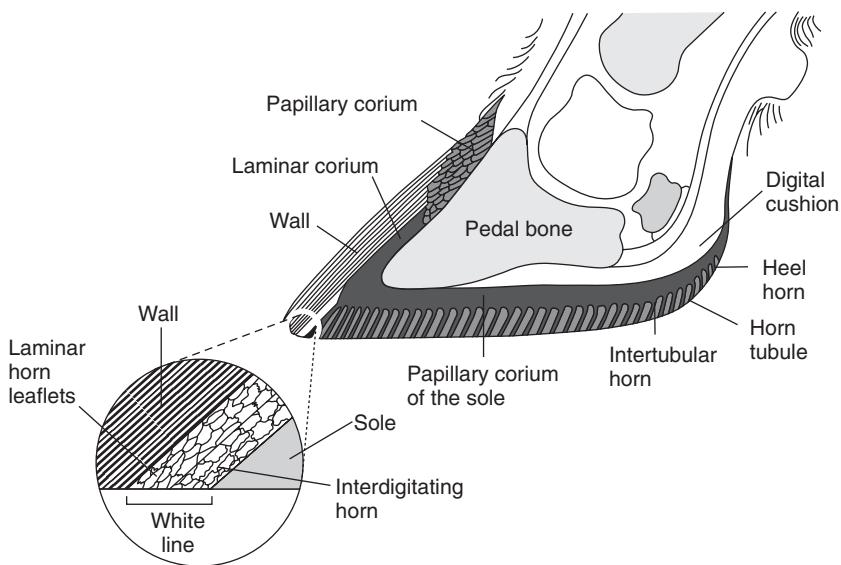

The *periople* is the hairless band of soft horn that separates the wall from the skin at the coronary band. It is continuous from one claw to the other and merges with the bulbs of the heel to give the smooth, waxy coating

Table 31.3 Types of lesion recorded as causing lameness.

| | Study No. | | | | |
|-------------------------------|----------------------|----------------------|----------------------|----------------------|---------------------------------|
| | 1 % of lesions | 2 % of lesions | 3 % of lesions | 4 % of lesions | 5 Cases/100 cows per year |
| Sole ulcer | 12.0 | | | 28 | 13.90 |
| White line disease | 18.0 | 39 | 16.8 | 22 | 12.70 |

| Digital dermatitis | | | | 8 | 12.00 |
| Interdigital dermatitis | | | | | |
| Interdigital skin hyperplasia | 4.2 | | | 5 | 1.20 |
| Interdigital foreign body | 2.0 | | 5.6 | 5 | |
| Overworn sole/bruising | 1.9 | 42 | | 8 | 2.00 |
| Vertical fissure (sandcrack) | 1.1 | | | | 0.54 |
| Aseptic laminitis | 4.7 | | | | |
| Under-run heel | 7.7 | | | | |
| Deep sepsis | 3.1 | | 8.9 | | 0.45 |
| Heel ulcers | | | | | 5.80 |
| Axial wall fissures | | | | | 1.07 |
| Foot lesions | 88.3 | | 82.3 | | |
| Leg lesions | 11.7 | | | | |
| Hind foot lesions | | | 65.0 | | 35.70 |

Key to study numbers:

- (1) Russell *et al.* (1982), UK. Lameness reported by farmers and examined by veterinarians.
- (2) Tranter & Morris (1991) New Zealand study of three dairy herds. All lame cows examined by veterinarians.
- (3) McLennan (1988), Australia. Cases reported to veterinarians.
- (4) Clarkson *et al.* (1996), UK. Lesions recorded by farmers and veterinarians
- (5) Hedges *et al.* (2000), UK study of five dairy herds. All lame cows reported by farmers but examined by veterinarian.

**Fig. 31.1** The structure of the hoof wall and white line. (Diagram: Jane Upton.)

seen on good quality hooves. Its main function is to prevent dehydration of the horn. Deterioration with age or with hot, dry or windy conditions will predispose to vertical fissures.

The *wall*, produced by papillary corium beneath the coronary band (Plate 31.1), flows over the laminar corium at approximately 5 mm per month. As the length of the anterior wall, from the coronary band to the toe,

is approximately 75 mm, new horn takes 15 months ($75 \div 5 = 15$) to come into wear at the toe.

The lamellae of the deeper layers of the epidermis (namely the hoof capsule) interdigitate with the laminae of the dermis (the corium). This produces a structure that is firmly attached to and protects the corium, but allows free movement for the horn wall and acts as a shock absorber during locomotion.

Sole horn is produced by the papillary corium of the sole and therefore consists of tubular horn and intertubular matrix (Fig. 31.1). The sole thickness varies from 10 to 15 mm and thus sole horn comes into wear two or three months after formation.

The *white line* is the cemented junction between the wall and the sole and runs from the heel, along the abaxial wall to the toe, caudally along the axial wall, then dorsally along the axial groove, to end in the interdigital cleft. The white line (Plate 31.2) consists of laminar horn leaflet cells and interdigitating horn cells. Both are produced from the adjacent corium at the toe, where the laminar corium of the wall joins the papillary corium of the sole. There is no tubular horn and hence white line horn is less mature and considerably weaker than the wall or the sole.

The *heel*, or bulb of the hoof, is a continuation of the perioplic layer, with horn tubules running obliquely in an anterior/ventral direction from the heel towards the sole. The softer heel horn can expand and contract during locomotion and, in conjunction with the underlying digital cushion, acts as both a shock absorber and vascular pump preventing venous stasis. Consequently heifers which remain stationary, standing for very long periods, may develop anoxia of the corium with subsequent poor horn production.

Corium

The corium is the modified dermis providing nerve and vascular supplies (and therefore nutrients) to the hoof horn externally and the bones and associated structures internally. Arteriovenous shunts across the top of the foot enable blood to bypass capillaries during weight bearing, although if the shunts remain open for too long, for example as a result of laminitis/coriosis, anoxia and consequently dyskeratotic horn formation result. The corium is structurally modified, enabling it to perform differing functions in various areas of the foot, namely:

- Papillae on the wall and sole extrude tubular horn.
- The laminar corium is a support structure where it interdigitates with lamellae on the hoof wall and in its distal extremities it produces white line cement.
- The digital cushion: within the heel and extending forwards to a point beneath the caudal edge of the

pedal bone, the corium is impregnated with fat, fibrous and elastic tissue, to form a shock absorber and vascular pump. Trauma to the digital cushion results in a permanent replacement of fat and elastic tissue by scar tissue, with subsequent loss of function.

- On its internal aspect the corium provides nutrients and vascular support for the pedal and navicular bones. Arteriovenous shunts allow blood to bypass the foot during periods of weight bearing.

Bone and associated structures

The third phalangeal (pedal) bone, the distal sesamoid (navicular) and the distal interphalangeal (pedal) joint are all contained within the hoof capsule. The deep digital flexor tendon is attached to the flexor tuberosity of the pedal bone and within the heel is separated from the distal sesamoid by the navicular bursa. Small fibrous strands of tendinous structure, sometimes visible in the base of deep sole ulcers, are fragments of the deep flexor tendon. The suspensory apparatus of the pedal bone (Fig. 31.8) supports the caudal edge of the bone. It is firmly attached to the corium on the abaxial aspect and joins the suspensory ligaments of the leg axially.

Weight bearing surfaces, hoof overgrowth and wear

As the primary objective of hoof trimming is to restore the foot to its 'normal' shape, it is important to understand the correct weight bearing surfaces of the foot and the distortions that occur due to overgrowth. In a correctly shaped hoof, weight is taken on the heel, on the abaxial wall and, to a lesser extent, on the white line and 10–20 mm of adjacent sole, and on the axial wall running from the toe caudally along the first third of the axial space. The remainder of the axial surface of the claw should be non-weight bearing (Fig. 31.2). Other dimensions of the claw are given in Fig. 31.3.

Hoof overgrowth

The size and shape of the hoof at any one time will be a balance between the rate of growth and the rate of wear. As one might expect, there are a variety of factors that influence both processes. For example, horn growth is faster:

- In young animals
- With high concentrate feeding
- With more exercise
- On rough surfaces

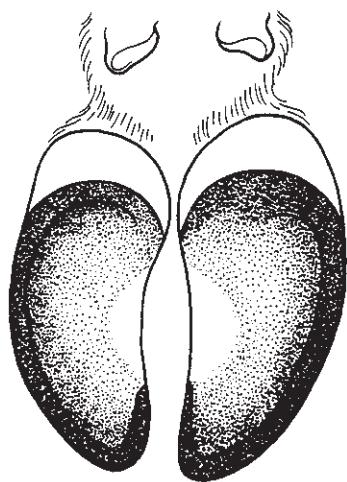

Fig. 31.2 The correct weight bearing surfaces of the foot.

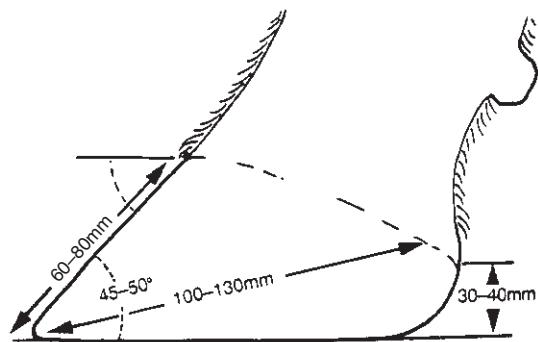

Fig. 31.3 Approximate dimensions and angles of a normal claw.

The rate of wear is increased by factors such as:

- Wet conditions underfoot, leading to softer horn which wears faster
- Excessive standing and walking
- Hard and/or abrasive floor surfaces

Overgrowth at the toe

The horn of the wall is generally harder than the horn of the heel, so although both may grow at the same rate, horn is worn away more slowly from the toe than from the heel. This results in overgrowth occurring *primarily at the toe*. The additional horn at the toe lifts the front of the foot and the front wall then forms a more shallow angle, decreasing from 45° to 30° or 20°, or even to the horizontal. In extreme cases the front wall becomes concave and the toe is lifted off the ground (Plate 31.3). These changes are shown in Fig. 31.4. Internally the pedal bone is rotated backwards, thereby putting even more pressure on its rear edge (the flexor tuberosity) and further increasing the risk of sole ulcers. However,

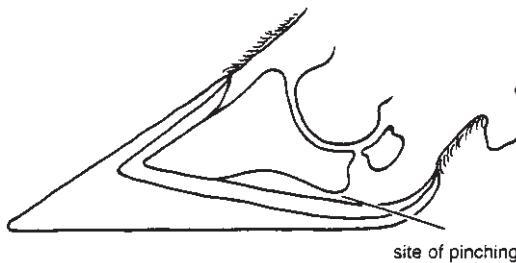

Fig. 31.4 Overgrowth at the toe leads to a caudal rotation of the pedal bone.

the pedal bone remains the same size, irrespective of the degree of overgrowth. In this respect the hoof is very different from the cow's horn, where the cornual bone lengthens with increasing length of the horn.

Overgrowth of the lateral wall

In some animals the wall of one claw grows faster than the other and starts to curl under the sole. This produces a corkscrew effect at the toe. Corkscrew claw may be a genetic trait or can be a result of coriosis/laminitis.

Overgrowth of the sole

A ledge of horn is commonly seen growing from the sole and extending into the axial space (Fig. 31.17, Plate 31.4). In some instances it may even overlap the adjacent claw, and may be so pronounced that it becomes the major weight bearing area of the foot. This has importance in the pathogenesis of sole ulcers, as the overgrowth of sole horn is immediately beneath the flexor tuberosity of the pedal bone and in an area where weight bearing should be minimized.

Disparity of claw size

The lateral claw of the hind foot is often considerably larger than the medial claw. There is no single reason for this and suggested causes include:

- The lateral claw is naturally slightly larger than the medial (Paulus & Nuss, 2002).
- Poorer suspension of the pedal bone within the lateral claw, leading to pinching of the corium and stimulating the growth of horn. The caudal edge of the pedal bone is suspended within a 'hammock', known as the pedal suspensory apparatus (fig. 31.8). This is connected to the laminae on the abaxial wall, and axially to the suspensory ligaments of the leg.
- A greater variation in load bearing on the lateral claw compared with the medial claw when the cow is walking (Toussaint-Raven, 1985).
- A leg conformation in which the hocks point inwards and the toes outwards.
- Excessive engorgement of the udder at calving, forcing the legs apart.
- The hind feet are the major propelling force of the cow during locomotion, pushing her forwards, whereas the front feet are the major weightbearing structures.

In the front feet the position is reversed: the medial claw is commonly larger than the lateral claw.

Negative net growth

At housing, and especially when housing and calving coincide, heifers invariably undergo a period of *negative net growth*. The rate of hoof horn growth is reduced but at the same time there is a rapid increase in wear, especially at the toe. This leads to a shortening and increased angle in the dorsal wall, plus a thinning of the sole. In some heifers the changes may be sufficiently extreme for the horn at the toe to become totally eroded, exposing the corium. Such heifers are said to have 'soft soles' or 'toe ulcers'. The syndrome is seen especially in heifers that have to walk long distances to and from pasture, for example in New Zealand and Uruguay, and also in young bulls introduced into a dairy herd. It may be occasionally seen in maiden heifers when they are housed at the end of their first grazing season.

Hardship lines

Temporary disruptions of hoof formation in the anterior wall lead to circumferential rings of variable thickness known as 'hardship lines'. When horn production is poor, a groove is formed and in extreme cases results in total cessation of horn formation, leading to a horizontal fissure. Because the dorsal wall is longer than the heel, the hardship lines often run from the sole surface

of the abaxial wall, across the dorsal wall to the sole surface of the axial wall. 'Hardship lines' can be used to establish the chronology of previous episodes of coriosis/laminitis, and therefore the potential causes of current hoof problems.

Hoof trimming

A variety of methods have been described, but all have one common aim, namely to restore the foot to its correct shape and weight bearing surface. The manner in which this is achieved is less important and the following text simply describes one approach (Blowey, 1998), with emphasis being placed on the anatomical corrective stages, rather than the precise method used. Other approaches are described elsewhere (Toussaint-Raven, 1985). Although described as a four-stage process, in reality one part of the trimming process merges with the next.

Cut one

The overgrown toe should be cut to its correct length, which is approximately 75–80mm from the coronary band to the toe, or one handspan. Most experienced hoof trimmers would simply estimate this distance but, when learning, it would be better to measure specifically. After cut one the cow is left with a 'square-ended toe'. In Plate 31.5 it can be seen that the white line now passes across the end of the toe and clearly the wall, which should be the correct weight bearing surface, is no longer weight bearing at this point. Although the anterior wall may now be the correct length, the toe is still too high and this means that the front angle of the anterior wall is too shallow. This is demonstrated in Fig. 31.5.

Cut two

The next stage is to remove the excess horn from the sole surface of the toe, thus dropping the toe relative to the heel and bringing the front wall back to a more

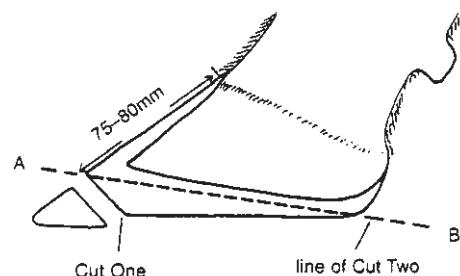

Fig. 31.5 Hoof trimming cuts one and two.

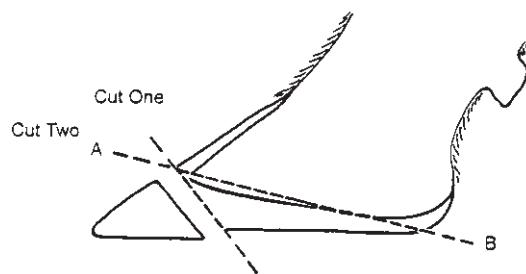

Fig. 31.6 Hoof trimming. Cut one should not be made too short.

upright position. The horn to be removed in cut two lies beneath the line AB (Fig. 31.5), which is a line joining cut one to the base of the heel. The first part of cut two can be performed by removing part of the wall using hoof clippers, but later stages should be carried out with a hoof knife, using thumb pressure to check this area of the sole regularly for signs of softening. A softening of the horn should not occur, but if it does then trimming must stop. There will only be a few millimetres of horn before the corium is penetrated and exposure of the corium in this area of the foot can lead to quite severe and protracted lameness.

If cut one was in the correct position it should be possible to remove horn from the sole surface of the toe until the white line and adjacent wall are once again clearly visible at the toe. The wall is now the weight bearing surface. It is important that this is achieved, otherwise the weaker white line structure would become weight bearing, with obvious adverse consequences.

It is vital that cut one does not make the hoof too short; this scenario is shown in Fig. 31.6. Because cut one was too short, a line drawn from the top of cut one to the bottom of the heel (AB in Fig. 31.6) would lead to exposure of the corium at the toe and this can produce severe lameness.

Cut three

Cut three consists of removing any axial overgrowth of the sole, followed by dishing the axial sole surface of both claws (Fig. 31.7a), so that weight bearing beneath the flexor tuberosity of the pedal bone is minimized. Cut three also slightly increases the space between the digits. This makes impaction by dirt and foreign bodies less likely, decreasing the incidence of diseases such as foul, interdigital dermatitis and interdigital skin hyperplasia ('corns').

Cut four

The final stage is to trim the two claws back to approximately the same size with the lateral claw 4–5 mm

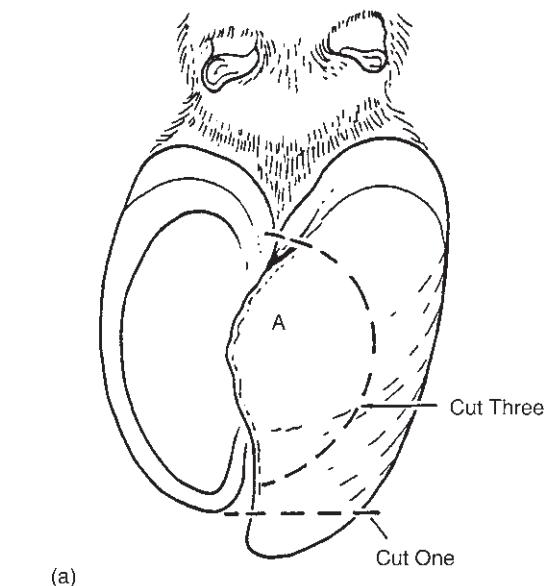

Fig. 31.7 Hoof trimming. Cut three and the finished foot.

longer. This usually means removing additional horn from the outer claw of hind feet and the inner claw of front feet, bringing the legs back to the upright position. This produces more even weight bearing.

General points

When trimming is complete, points 1, 2, 3 and 4 on Fig. 31.7b should all be on the same longitudinal horizontal plane, to provide adequate weight bearing. The two

claws should also be of equal size and their two sole surfaces on the same transverse horizontal plane. Removal of the axial (inner) wall CD (Fig. 31.7b) is a common mistake made by some herdsmen who feel that the toes should not be touching once trimming is complete. This is a fallacy. If the wall CD was lowered the claw would be seriously destabilized, causing it to rotate inwards and allowing overgrowth of the lateral wall. In the worst case excessive removal of the axial wall might expose the corium, leading to severe lameness.

It is preferable not to remove any heel horn unless it is badly under-run, other than as part of cut four. If the heel is only slightly pitted, it is best left alone, since removal of the heel could lead to backwards rotation of the pedal bone and so predispose to sole ulcers.

One theory of hoof trimming recommends that it is advisable first to trim the medial claw to the correct shape and then use this as a template for trimming the lateral claw. Whilst this system may have its merits, it is the opinion of the current author that it is not always a correct course of action, and especially when dealing with lame cows. This is because it may be beneficial on welfare grounds to leave the medial claw slightly larger than normal in order to increase its weight bearing potential when there is a lesion in the lateral claw.

Timing of foot trimming

There is no one correct time to trim feet. Potential options include:

- When overgrowth occurs. Leaving a foot with overgrown horn not only makes walking uncomfortable but it also predisposes to the development of more serious lesions such as sole ulcers.
- When the cow is lame. Clearly all lame cows should have the affected foot lifted, trimmed and examined.
- At drying off. As many of the management and feeding ‘insults’ leading to lameness occur at the time of calving, it is ideal to have feet in optimum shape at this stage. In addition, at the end of lactation there may be a build up of horn from insults suffered in the previous lactation

Lesions causing lameness

The majority of the lesions causing lameness are in the foot. In this section these will be subdivided as follows:

- Sole ulcers and white line defects.
- Other hoof problems: foreign body penetration, horizontal and vertical fissures.

- Conditions of the skin: digital dermatitis, interdigital necrobacillosis, interdigital skin hyperplasia and mud fever.
- Disorders of the pedal and navicular bones.

Sole ulcers and white line defects

Pathogenesis

The horn of the white line and sole is produced by the corium. Damage or disruption of the corium will therefore be the primary change that later leads to the formation of poor quality horn, and this is eventually seen as defects such as sole ulcers and white line disorders. The syndrome is sometimes referred to as ‘claw-horn disruption’, although once again, as the primary defect is in the corium, then this is the area to which attention should be focused. Although the term ‘laminitis’ is often used, the majority of changes affect the whole corium, and particularly the papillary corium of the sole, where there are no laminae. Hence use of the term ‘laminitis’ in cattle is not particularly accurate. It is doubtful if laminitis occurs as a single entity in cattle, and the more general term of ‘coriosis’ is preferable.

Changes associated with the corium

Coriosis can occur as a result of trauma, infection, nutritional imbalance/excess and toxic states and commonly is a sequel to a combination of causes. The overall result will be the same, namely altered horn formation with the risk of lameness when the poor quality horn reaches the bearing surface of the sole.

Osment (1995) describes three stages in the pathogenesis of sole ulcers and white line disease, all of which arise as a consequence of coriosis:

- (1) Disruption of blood flow within the corium, leading to sludging, poor oxygenation of epidermal tissues and consequently poor keratin synthesis.
- (2) The laminar suspension of the pedal bone within the hoof is disrupted and the bone sinks within the hoof.
- (3) Compression of the corium, especially beneath the flexor tuberosity of the sinking pedal bone, leads to further ischaemic necrosis, disrupted horn formation and consequently the production of a sole ulcer.

The changes at the dermal–epidermal junction are still not fully understood. It is thought that they involve an initial release of vasoactive substances. Vasodilation in the corium leads to vascular stagnation and the opening of the arteriovenous shunts exacerbates this. The ensuing hypoxia leads to transudation,

thrombosis and ischaemic necrosis, and consequently poor keratin synthesis and lamellar disruption.

Haemorrhage on the sole is often referred to as 'bruising'. This may be a correct term, although it should always be remembered that the 'bruise' was formed by an insult one or two months previously, when the horn now on the surface of the sole was being produced. As such, bruising of the sole cannot be implicated as a recent cause of lameness. The effect of mixing serum or blood with the horn can be likened to mixing sawdust with concrete – it weakens it considerably. This is particularly the case for the white line, which is an inherently weak structure, and at the sole ulcer site where there may be almost 'neat sawdust' because so much haemorrhage is present. The whole process is very similar to the changes which occur when a fingernail is bruised: the blood spot often starts at the corium of the skin–nail junction and then slowly grows to the distal extremity of the fingernail over the next few months.

Changes associated with the pedal bone

The ventro-axial border of the pedal bone is arched in shape. The pedal bone is suspended within the hoof by the laminae, with a much stronger attachment to the abaxial wall than to the axial wall (Fig. 31.8) of the hoof. When weight is transmitted down the leg the bone rotates slightly on the axial surface, putting increased weight on the flexor tuberosity. Increased weight bearing puts extra pressure on the corium and if it is already in a fragile state, then it is likely to become damaged. Pinching of the corium between the flexor tuberosity of the pedal bone above and the horn of the sole beneath leads to 'bruising' of the corium. This leads to defective horn formation and the changes will be seen on the bearing surface of the sole one or two

months later. The nature of the horn defects will depend on the severity of the initial corium damage, and are likely to appear as:

- Yellow discolouration – if serum only was released.
- Haemorrhage – if the blood vessels ruptured (Plate 31.6).
- A sole ulcer – if the damage to the corium was so severe that horn formation was totally disrupted (Plate 31.7).

If there is a generalized inflammation of the corium, then the suspension of the pedal bone within the foot is disrupted, allowing the bone to sink within the foot, as shown in Fig. 31.9. The corium is then displaced and the following changes occur:

- The 'sinking' bone puts further pressure on the corium, especially beneath the flexor tuberosity, the heel or the toe. Ulceration of the sole, heel or toe may result.
- Lateral displacement of the corium into the white line area leads to weakening and widening of the white line cement with increased risk of white line defects.

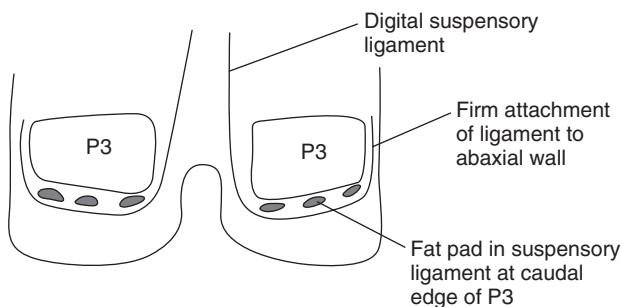

Fig. 31.8 Suspension of the pedal bone within the hoof.

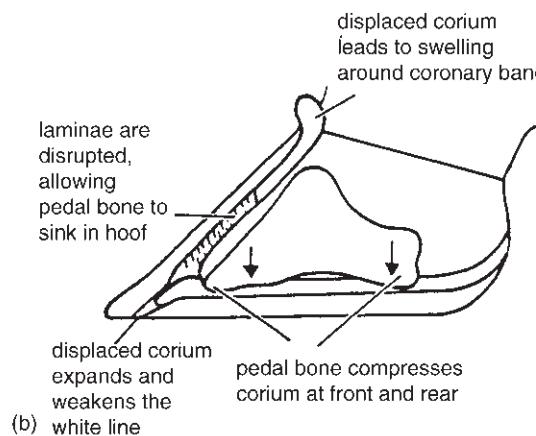

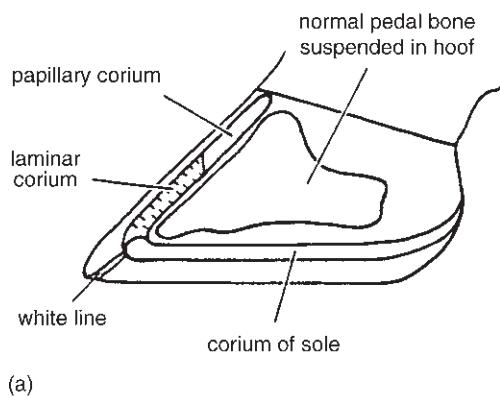

Fig. 31.9 Coriosis leads to disruption of the laminar suspension of the pedal bone.

- Dorsal displacement of the corium may produce a circumferential thickening above the coronary band.
- Antero-ventral displacement of the pedal bone (i.e. movement towards the toe) may leave a horizontal depression or 'furrow' in the heel horn. This is a classic sign of disruption of the laminar suspension with subsequent movement of the pedal bone.

The poor laminar suspension on the axial wall compared with the abaxial wall (Fig. 31.8) leads to the axial aspect of the pedal bone, and especially its flexor tuberosity, having the greatest contact with the corium of the sole. This explains the typical site of the sole ulcer in zone 4 (mid sole) of the hoof. Once the pedal bone has dropped within the hoof it will never regain its original position. In addition, a corium that has been damaged by ischaemic necrosis heals by fibrosis and is therefore less able to produce good quality horn in the future. As a consequence, heifers affected by coriosis during their first lactation are more susceptible to lameness in later lactations. For example, in one study, heifers that developed lameness in their first lactation were almost three times as likely to go lame in their second lactation than their non-lame counterparts. Optimal management of the precalving and periparturient first lactation heifers is therefore vital as a long term lameness control measure.

Continual compression of the corium of the sole can lead to generalized poor horn formation, sometimes seen in older cows where a sole ulcer totally fails to heal. In such animals a layer of very poor quality 'horn', sometimes little more than a layer of fibrous tissue, may form over the ulcer site, and the tip of the flexor tuberosity of the pedal bone can sometimes be palpated as a hard lump immediately beneath.

Sole ulcers

A sole ulcer (Plate 31.7) is a physical condition, caused by trauma to a fragile corium, and treatment must therefore be aimed at minimizing this trauma. The main steps for treatment are:

- Dish the sole ulcer site so that weight bearing is minimized.
- Remove any under-run horn around the ulcer, to eliminate pockets of necrotic horn and infection, thus allowing the formation of new horn.
- Remove protruding granulation tissue.
- Reduce the size of the affected claw as much as possible, and maximize weight bearing on the sound claw. For more advanced cases, apply a block to the sound claw (e.g. Plates 31.7 and 31.20).

Note that no dressings are recommended: in fact many would consider them to be counterproductive. This is referred to later.

Heel and toe ulcers

Although sole ulcers are by far the most common, there can be areas of haemorrhage or even total perforation at other areas of the sole. Toe ulcers are thought to occur when the pedal bone sinks within the hoof 'bows first' – that is, the front of the pedal bone drops before the flexor tuberosity at the rear.

Heel ulcers are seen as small dark red/black marks (Plate 31.8) in the central sole area towards the heel (Blowey, *et al.*, 2000a). Plate 31.8 shows a typical heel ulcer on the left claw and haemorrhage at the site of an early sole ulcer on the right claw. Some heel ulcers simply track down to the corium and fade to nothing. Others lead to under-running and abscessation of the sole at the sole–heel junction and can produce a marked lameness. Heel ulcers represent a significant cause of lameness (Table 31.3). They often occur in association with sole ulcers, although they are seen more commonly on the medial claw of hind feet. The cause of heel ulcers is not known, although one theory is that they are produced by pinching of the corium under the caudal edge of the pedal bone. At this point the bone is suspended in the pedal suspensory apparatus (Fig. 31.8), within which there are three fat pads acting as shock absorbers (Ossent & Lischer, 2000). The central fat pad has been shown to undergo cartilaginous change, and it may be the effect of this that leads to the formation of heel ulcers. Heel ulcers are hence in the *central* sole region at the junction of zones 4 and 6 (zone standardization from the Liverpool International Ruminant Digit Symposium 1990, cited by Greenough *et al.*, 1997). Sole ulcers typically occur in a more anterior and axial position on the *axial* aspect in the centre of zone 4, and toe ulcers are seen in zone 5 at the toe.

White line defects

Weakening of the white line, brought about by the inflammation associated with laminitis/coriosis, can result in a range of white line disorders. The most common of these are:

- Sterile abscessation.
- White line separation.
- White line penetration and abscess formation, with potential complications of infection tracking along the laminar corium towards the coronary band.

Sometimes the internal inflammation within the corium is so severe that pockets of necrotic tissue are formed. These can produce a sterile internal abscess

and as there may be no obvious tracts running from the outside, they may be quite difficult to locate and treat. In severe forms of coriosis the whole sole becomes separated by an accumulation of inflammatory fluid. This is known as a *false sole*.

More commonly fissures develop vertically into the weakened white line, a process known as white line separation (Plate 31.9). This occurs especially if the cows are walking over rough or stony ground, or when they make sudden turning movements, as when escaping from an aggressive cow. Small stones may then become impacted and with continued walking these may eventually penetrate the corium. The most common point for white line separation and penetration is at zone 3, where the rigid abaxial hoof wall joins the flexible heel. During locomotion this is where there are the greatest sheer forces between the rigid hoof wall, the suspended pedal bone and the movements of the flexible heel horn. Once the corium has been penetrated, the invading foreign body (usually a stone or grit) introduces infection. For white line abscesses near to the heel, natural drainage is through the soft horn of the heel. White line abscesses close to the toe do not have such an easy escape route and often infection tracks upwards through the laminae, to discharge at the coronary band. This produces a more severe lameness because at the toe the pedal bone is tightly attached to the hoof, and there is therefore very little room for the pus to expand.

Whereas a sole ulcer results in damage to the underlying corium, the majority of white line lesions primarily produce separation of the horn from the underlying horn-forming corium. Uncomplicated white line lesions therefore normally heal much more quickly than sole ulcers. White line lesions in the axial groove are described on page 426.

The treatment of a white line abscess is very similar to that for a sole ulcer, namely:

- Remove all under-run horn, even if this means removing the wall from the sole to the coronary band, or the whole of an under-run sole. A few authors recommend leaving a bridge of hoof wall to prevent movement of each side of the bisected wall, but the danger of doing this is that the under-run infection will not be fully drained.
- Reduce the size of the affected claw, to minimize weight bearing, and leave the sound claw large.

Blocks and dressings are discussed on page 431.

When using a hoof knife to drain infection from the white line, it is important to remove the short section of adjoining hoof wall. Digging a deep pit into the white line with the curved point of the hoof knife has two disadvantages, namely:

- It leaves a pit which can easily become impacted with stones or dirt, thereby impeding drainage and predisposing to further white line impaction.
- By creating a pit, areas of under-run horn and pockets of infection are much more likely to be missed. If a small area of adjacent wall is removed, it is much easier to expose and drain the affected area.

Protruding granulation tissue is often an indication that there is adjacent under-run horn that needs to be removed, and use of a block on the sound claw to prevent weight bearing on the affected claw improves the rate of healing. A swollen, hot and painful coronary band is caused by infection tracking into deeper structures such as the navicular bursa or tendon sheaths, and in such instances antibiotic therapy and/or more radical treatment is indicated.

Causes and control of coriosis (laminitis)

Coriosis is clearly the primary factor responsible for defects in the horn capsule. In this section the aetiology, and consequently the control of coriosis, is described under the headings of parturition, excessive standing, nutrition and general management.

Parturition

Many authors have shown an association between parturition and increased incidence of lameness, with the peak incidence of white line lesions in first lactation heifers occurring nine weeks after calving, and sole ulcers at 14 weeks postpartum (Leach *et al.*, 1997). In cows the incidence peaks slightly later. Green *et al.* (2002) showed that lameness from all causes peaks in the second and third month after calving. The rings on a cow's horns, one for each calving (Plate 31.10), are said to be a reflection of the natural disruption in horn formation (Blowey, 1998) that occurs at calving. Livesey *et al.* (2000) suggested a decreased incorporation of amino acids into hoof horn at the time of parturition, presumably associated with a repartition of nutrients (sulphur amino acids) towards milk production. Hirst *et al.* (2000) showed that cows that develop lameness in their first lactation are more likely to become lame in subsequent lactations, and suggested yield as a contributory factor. Green *et al.* (2002), in an intervention study involving 1109 cow-years on trial, showed that high-yielding cows were more likely to become clinically lame than lower-yielding animals, but in the affected group, lame cows produced 396 litres per cow less milk than their non-lame counterparts.

The changes that occur in all periparturient cows appear to have a marked impact on the corium, horn

strength and subsequent lameness. There is a decrease in the rate of rumination, and this leads to a 25–30 per cent decrease in dry matter intake, at a time when the cow's requirements (for the fetus and milk production) are rising rapidly. There is an increased risk of rumen acidosis and a marked immune suppression. Dietary change, namely moving from a low concentrate dry-cow ration to a high performance production diet, further increases the risk of rumen acidosis and coriosis.

Whatever the cause, the increased fragility of the corium during the periparturient period means that it is particularly susceptible to trauma. However, in most dairy systems this is when the greatest trauma to the corium occurs, due to excess periods of standing and aggressive interactive movements between cows as they become re-established in a different social group.

Even if they calve outside in a field, for a few days after calving cows, and especially heifers, will spend far more time standing and their lying times will be decreased. There is then more weight on the corium and a greater potential for bruising. It is not known whether the decreased lying times are due to inherent nursing behaviour (attending to the calf), discomfort from the perineum, an enlarged udder or to some other factor.

Diseases such as mastitis and metritis are more common immediately after calving. This also increases the fragility of the corium and in extreme cases will produce hooves with hardship lines and horizontal fissures. Heifers are likely to be worst affected, partly because they have often had no prior experience of the housing and milking system and partly because in many large dairies the heifers have been reared totally separate from the main herd. They are therefore additionally exposed to a whole range of new infections immediately postpartum, when immune suppression is at its maximum, and this further depresses horn formation. This leads to long periods of standing, producing increased hoof wear at a time when hoof growth is minimal. The 'negative net growth' which occurs around parturition and housing is referred to below and on page 415.

Excessive standing

Anything that leads to a decrease in lying times, especially in the immediate postcalving period when the corium is in its most fragile state, will increase the incidence of sole ulcers and white line disease.

One experiment (Leonard *et al.*, 1996) deliberately housed heifers in an overstocked cubicle building (17 cubicles for 35 heifers) immediately after calving.

Although the average lying time of the heifers was ten hours, some animals lay down for as little as five hours each day. This group showed the highest incidence of lameness and quite severe haemorrhage persisted in the sole horn for up to four months after calving. In most dairy systems heifers are forced to spend longer on their feet after calving. They will stand waiting to be milked, they spend longer standing to feed, because they are often last to feed, and need to eat more as lactation proceeds. They will have recently been mixed with the main herd and are now having to compete with older cows and fear may restrict their entry into a cubicle shed, especially if they are of low social dominance and have had no previous cubicle training.

Excessive standing may be bad for the immediate postpartum cow, but standing still is even worse. If the animal does not move, the vascular pumping mechanisms of the heel and digital cushion will be impaired. Vascular stasis predisposes to anoxia and damage to the corium, with resulting poor horn formation. It is essential that there are adequate loafing areas to allow the cows to walk around freely. Overcrowding should be avoided, even in collecting yards. Animals that are packed tightly together have little option but to stand still. Adequate loafing areas also help to improve oestrus expression and hence fertility.

The incidence of sole ulcers and white line disease will therefore be markedly reduced if animals are encouraged to maximize lying times in the immediate postcalving period, for example for the first two to six weeks after calving.

Post-calving comfort: Of all the above factors, cubicle comfort is probably the most important. Cubicles may make the management of cows easier, but they are not always ideal in terms of cow comfort and lameness. Several surveys have shown that the incidence of lameness in cows in straw yards is much lower than in those housed in cubicles. This must point to cubicles being less than ideal, especially for the immediate postcalving cow. A small but increasing proportion of farms are now housing their freshly calved cows in 'maternity' loose yards for the first two to six weeks after calving and then transferring them to cubicles. Experience from such systems suggests that in heifers especially, a postcalving period of loose housing leads to:

- Increased yields.
- A decreased incidence of lameness.
- Improved cubicle acceptance when the heifers are eventually transferred from the yard to the cubicles.

The third factor is perhaps the most surprising. One might have expected that cows and heifers that had got used to a straw yard would be very difficult to retrain

to use cubicles. The fact that the reverse is true probably indicates that parturition is a stressful experience and that it is only when animals have fully recovered that they are able to withstand the rigours of the cubicle system. The major problem with straw yards is the increased incidence of environmental mastitis and hence perhaps the ideal situation would be a 'maternity group' housed in a low stocking density system of luxury cubicles.

Cubicle design: Cubicle comfort is obviously all-important. Ideally, cubicles should be long enough and wide enough (1.15 metres wide and 2.4 metres long) to accommodate the larger Holstein cows and with sufficient space at the front to allow the cow to lunge forward 1–1.5 metres as she stands up. If there are two facing rows of cubicles, a length of 2.2 metres is adequate. Cantilever-type divisions are ideal. Also recommended are a 100mm fall from front to rear, a step of not more than 130mm down into the dunging channel and a brisket rail at the front 1.75 m from the kerb, which prevents the cow from shuffling too far forwards, but at the same time provides ample space for lunging as she stands up.

When attempting to stand, the cow lunges forward 1 to 2 metres and lifts herself first onto her hind feet, then up onto her front feet. When she is lying down or half standing, therefore, much of her weight is taken on her knees. If the floor surface is hard, and particularly if it is also rough, cubicle acceptance will be low. The worst possible cubicle floor is a stone base, poorly compacted and with insufficient straw. In an attempt to get comfortable cows will shuffle forwards, until they are so close to the wall that they are unable to lunge to stand. If a proportion of the cows are too far forward in the cubicles, cubicle comfort should be re-examined.

Most cubicle bases are made of concrete. This is fine provided that it is deeply bedded, although it is often difficult to retain a well-matted straw bed. A variety of mats and mattresses are available and these are certainly much better than concrete alone. However, some bedding should be used, even with mats, otherwise hock sores will develop. A disadvantage of mats is that it is difficult to get large amounts of straw bedding to adhere to them, although the cows enjoy standing on rubber mats. Deep sand cubicles (for example 70mm) also work well and reduce the incidence of mastitis, although sand may lead to problems with slurry disposal systems. Choosing the correct type of sand, which does not compact and consolidate, is essential.

The best cubicles are comfortable cubicles. While design and dimensions may be important, comfort is of even greater significance (see also pp. 40–42).

Nutrition

High starch/low fibre diets that lead to rumen acidosis undoubtedly predispose to coriosis and subsequent lameness, especially if fed both pre- and postpartum. Blowey *et al.* (2000b) used 48 multiparous cows to compare high starch (wheat-based) with equal energy high fibre (sugar beet pulp) rations fed pre- and postpartum. Sole haemorrhage scores at 24 weeks postpartum were significantly higher in the high starch group. Livesey and Flemming (1984) showed that 64 per cent of cows on a low fibre diet developed sole ulcers compared with only 8 per cent on the high fibre ration.

Concentrate intakes should be built up slowly after calving, to reach a peak at no less than two weeks post-calving for average yielding cows and probably three weeks for higher yielding animals, which peak later. Ideally no more than 4.5kg of feed should be given in the parlour. The inclusion of 1–3kg of long-chop straw, well mixed with the ration, helps to stimulate rumination, thereby promoting a good flow of saliva and decreasing acidosis. There is evidence that maintaining an ideal dietary cation–anion balance (DCAB) is beneficial (see p. 787). Acidosis can be recognized clinically by loose faeces, an increased incidence of digestive upsets, cud regurgitation and a sweaty coat.

Although high protein diets have occasionally been suggested as a cause of coriosis, most consider protein to be of less importance than other factors. High intakes of poorly fermented grass silage have also been implicated, although this could be due to toxic amines rather than high protein.

Even feeding during rearing influences the incidence of sole haemorrhage, with heifers fed high levels of concentrate being the worst affected. High fibre diets are now recommended for rearing dairy heifers.

Trace elements and vitamins: Many attempts have been made to improve hoof condition by mineral, vitamin and trace element supplementation. The use of zinc, particularly zinc methionine, is often promoted as a feed supplement having beneficial effects. If one of the reasons for the production of poor quality horn at calving is a temporary deficit of sulphur amino acids (see p. 419) then logic would suggest that supplementation with zinc methionine might be beneficial at this time, since methionine is a sulphur amino acid and zinc promotes healing.

Biotin has been shown to influence the differentiation of epidermal cells into hoof horn; it boosts the production of keratin and it stimulates the production of intracellular cementing substance (ICS). ICS is a vital component of non-tubular horn, such as is found in the white line, and this is perhaps why biotin supplementation has a major effect on white line disease. Although

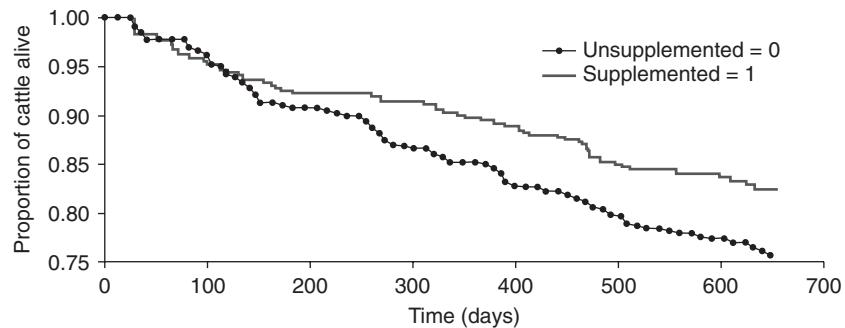

Fig. 31.10 Effect of biotin supplementation on white line lameness in dairy cows. No effect was seen until after 130 days of supplementation (Hedges *et al.*, 2001). Reproduced with permission of the American Dairy Science Association.

one might expect ruminal synthesis of biotin would meet the requirements of the cow, Da Costa Gomes *et al.* (1998) showed that with high concentrate diets producing rumen acidosis, *in vitro* biotin synthesis was reduced from 1.5 to 0.3 µg per day. Herds with significant problems associated with horn quality may benefit from biotin supplementation, although attention to dietary management would also be important.

In a study with 100 first lactation heifers, Midla *et al.* (1998) showed that supplementation with 20 mg biotin/day from calving produced a significant improvement in white line lesions at 100 days of lactation. In a more extensive split herd intervention study involving over 1100 cow lactations in five UK dairy herds, supplementation with 20 mg/day biotin significantly halved the incidence of lameness caused by white line lesions (Hedges *et al.*, 2001). Survival analysis demonstrated that supplementation needed to be given for 130 days before any difference in the two groups was seen (Fig. 31.10). In addition, only 28 per cent of supplemented animals required a repeat treatment in the same digit, compared with 72 per cent of unsupplemented controls (Blowey *et al.*, 2000c).

Hagemeister (1996) showed that animals receiving 10 mg biotin daily had significantly fewer sole ulcers and less heel erosion than unsupplemented controls, and Lischer *et al.* (1996) reported a correlation between biotin supplementation and the rate of healing of claw lesions. New horn formed more rapidly in those cows supplemented with 20 mg biotin/day. A two-year Canadian field study of 265 Hereford beef cows with a high prevalence of vertical fissures (sandcracks) demonstrated that supplementation with 20 mg biotin/cow per day significantly reduced the prevalence of vertical fissures from 29.4 per cent to 14.3 per cent ($P < 0.05$; Campbell *et al.*, 1996).

General management

Many aspects of management have already been discussed in the housing and feeding sections. This section will cover a few miscellaneous points relating to lame-

ness, placing particular emphasis on those factors which might damage the corium, especially in the early lactation animal.

Wet hoof: This is softer than dry hoof and therefore the sole is more likely to become penetrated or the corium bruised if the feet are damp. Cubicle passages should be scraped twice daily and the addition of small quantities of slaked lime to the cubicle beds once a week will help to dry the feet as well as control mastitis (see p. 391).

Floor surfaces: These should not be too rough, stony or have broken concrete, all of which could damage the corium. On the other hand, very slippery surfaces can lead to leg damage. An excellent demonstration that cows do not like walking on concrete is shown in Plate 31.11. A strip of second-hand rubber belting, approximately 1.5 metres wide, has been laid along the centre of a concrete track which runs from a dirt yard to the milking parlour at a dairy in California. Although the cows could walk anywhere they wished on the track, note how they all prefer to walk on the rubber belt. In the UK, if cows are allowed to amble out to a field at their own speed they will usually choose to do so by walking on the soft earth of a grass verge, rather than on stones (Plate 31.12). They even place their feet in exactly the same spot each time, making holes in the ground. This preference for a softer surface has led to the development of specific cow tracks. The ground is excavated to 0.3 cm deep and 1.0–1.5 metres wide and lined with a permeable geotextile road construction membrane which prevents sinkage of the track. A drainage pipe runs along the base, surrounded by a large aggregate, perhaps having fine stone on the top (Fig. 31.11). This is covered with a second special toughened membrane, which allows water to drain through but will not allow mud to rise up through it. Finally a layer of bark stripings, sometimes known as Cundy peelings, 100 mm (4 inches) deep, is placed on top of the upper membrane to provide a comfortable walking surface for the cows. Tractors and other vehicles must

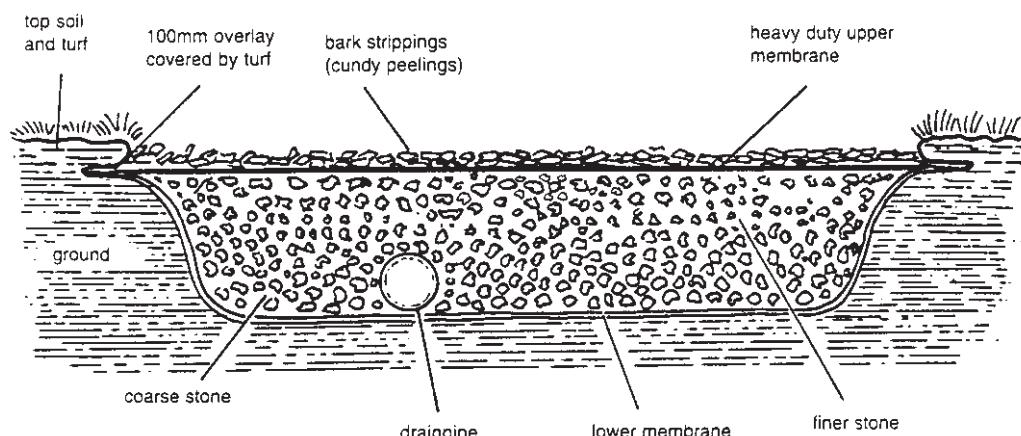

Fig. 31.11 Cross-section of a cow track.

not use the track. Similar tracks may be constructed in gateways, around water troughs and in other areas where the ground gets badly poached. On very well drained land some farmers have constructed a very simple track by scraping away the topsoil and then unrolling a large round straw bale onto the underlying stone. Wet bales, too badly soiled for straw yards, could be used. The straw needs replacing approximately every two or three weeks, depending on the weather, but it makes a good track and is certainly cheaper.

The influence of floor surface on white line disease is interesting. It is commonly stated that cows become lame because of a specific type of stone or gravel in a track, particularly if sharp flints are present. However, beef cattle could probably walk along the same track without stones penetrating their feet. This strongly suggests that it is the weakening of the white line which is the critical factor and not the sharpness of the stones.

Rough handling: This has also been shown to have an effect. A survey of farms showed that cows which were forcibly rushed along farm tracks by a herdsman, dog or tractor had a far higher incidence of lameness than farms where the cows were allowed to walk along at their own speed. This was presumably because in the latter case they chose their own footing, thus avoiding bruising to the sole and corium. Similarly, if heifers are introduced into a highly competitive situation where they are forced to make many sudden turning movements, this both increases hoof wear and forces the wall away from the sole, leading to an increase in white line defects. When walking, cows should be allowed to move at their own pace. Their heads will be down as they look at the ground surface in front of them for a safe and soft footing. If cows are being driven too fast, or if they are too crowded, then their heads will be high, they cannot see their footing and increased lameness may result.

Hoof wear: Both inadequate and excessive hoof wear can cause problems. Heifers reared and housed in totally bedded areas (straw, shavings or sand) may not receive sufficient hoof wear. The toes become overgrown, the foot rotates caudally and the corium may become damaged at the sole ulcer site. The provision of a lightly abrasive concrete feeding area is essential, both to keep the foot in shape and to stimulate sufficient horn production to produce the thick sole that is needed in the postpartum animal. At the other extreme, cows or heifers (and especially fresh calves) that are made to walk long distances on gravel or even concrete roads can wear their soles so thin that they are easily compressed by thumb pressure. This syndrome is common in the grazing systems of Australia, New Zealand and Uruguay. Heifers reared on pasture are often introduced into the dairy herd immediately after calving and expected to walk long distances to and from grazing. This produces maximal wear at a time when hoof growth is minimal, and soft soles with subsequent bruising of the fragile postpartum corium leads to an increase in white line disease and toe ulcers (see 'negative net growth', p. 415). If heifers are exposed to concrete or some other hard surface for a few weeks before calving, this can stimulate an increased thickening of the sole and the severity of the syndrome is reduced.

A similar 'soft sole' syndrome is seen in young bulls introduced to work in a dairy herd, particularly if the bulls are large and do not use the cubicles. The soles of their hind feet, especially at the toe, can wear down to the corium. Ideally, bulls in cubicle systems should be rested in a straw yard, for example cubicles by day and a straw yard by night, or alternate weeks in cubicles and straw yards. On a daily basis bulls soon learn which is to be their period of lying and compensate for the cubicles by lying in the straw yards for long periods of time.

Conformation: Conformation affects the incidence of lameness, which is therefore influenced by genetics and breeding. Bulls should be chosen to give a good depth of heel and a good upright angle of the front wall, as in Fig. 31.3.

Foot trimming: The final management factor that influences the development of lameness is routine foot trimming. If parturition is a major stress period for the development of coriosis, then feet need to be in optimum shape at calving in order to minimize this effect. This is achieved by hoof trimming at drying off, and at any other time when they are overgrown.

Footbaths: The use of footbaths is discussed on p. 430.

Other causes of foot lameness

Hoof disorders:

- Foreign body penetration
- Slurry heel
- Vertical fissure (sandcracks)
- Hardship lines and laminitis
- Horizontal fissure
- Broken toe
- Axial wall fissures

Skin disorders:

- Interdigital necrobacillosis (foul of the foot or footrot)
- Digital dermatitis (hairy warts)
- Interdigital skin hyperplasia (corns, growths or tylomas)
- Mud fever

Bone and joint disorders:

- Pedal bone fracture
- Necrosis of the apex of the pedal bone
- Pedal arthritis

Hoof disorders

Foreign body penetration of the sole

Typical foreign bodies are stones (especially sharp flints), nails (particularly those with flat heads), fragments of wood, glass or tin and occasionally even the sharp root of a cast tooth will penetrate the sole. After removal of the foreign body it is essential to provide drainage by opening the sole at the point of entry and removing all under-run horn.

Slurry heel (heel horn erosion, heel necrosis)

In feet which have been exposed to slurry over a long period of time, the smooth, soft and pliable heel horn often becomes black and pitted and in more extreme cases totally eroded, especially in the axial area (Plate 31.13). Although perhaps not too serious externally, slurry heel causes important internal changes. Removal of weight bearing at the heel allows the foot to rotate backwards, thereby predisposing to sole ulcers. In advanced cases the flexor tuberosity no longer has adequate support and as a result penetrates the horn of the sole. The corium will be pinched as the cow walks and sole ulcers develop.

Deep slurry heel fissures may develop into an under-run sole, which may be further complicated by a secondary digital dermatitis. Erosion of the heel also predisposes to white line defects, and by predisposing to a caudal rotation of the claw, to sole ulcers.

There is no one single cause of heel horn erosion. As it is almost exclusively a condition of housed cattle, simple erosion by slurry seems to be the most probable factor. Others have suggested the involvement of specific bacterial infections such as *Dichelobacter nodosus* (Toussaint-Raven, 1985) or *Prevotella (Bacteroides)-melaninogenicus* (Greenough, 1987). Coriosis/laminitis may also be involved, leading to poorer quality heel horn, which is then more susceptible to the corrosive effects of slurry.

Treatment and control

Deep fissures may need to be investigated to eliminate (and correct) an under-run sole, but if the lesion is relatively superficial it is best left and treated topically. Removal of heel horn is commonly contraindicated, because to do so must inevitably lead to a caudal rotation of the claw and increase the risk of sole ulcers. Hygiene is the best control measure, maintaining the feet in a clean and dry environment, with regular footbaths. Lime, used in cubicles for mastitis control, also acts as a disinfectant and drying agent.

Vertical fissures (sandcracks)

Vertical fissures occur as a result of damage to a small area of the periople and underlying coronary band. Horn formation is disrupted at that point, although the adjacent horn continues to grow. This leaves a gap (the vertical fissure) running down the hoof wall from the point of disrupted production (Plate 31.14). In North America vertical fissures are commonly seen in both beef cattle and older dairy cows kept in sand lots where the combination of age, sand, wind and dry weather removes the protective periople. Vertical fissures can

also be a result of a digital dermatitis infection on the coronary band. A two-year Canadian field study of 265 Hereford beef cows with a 37 per cent prevalence of sandcracks demonstrated that supplementation with 10mg/day of biotin significantly reduced the incidence of sandcracks from 29.4 per cent to 14.3 per cent (Campbell *et al.*, 1996).

For treatment, the full length of the fissure should be opened using the curved tip of the hoof knife. Even a small abscess can cause intense lameness. If the fissure is large, a block should be applied to the sound claw.

Hardship lines

Any disruption in horn formation may leave a groove, sometimes referred to as a 'hardship groove' (Greenough *et al.*, 1997), encircling the hoof wall. These are the result of coriosis/laminitis. Inflammation of the laminae is said to lead to massive pressure under the hoof wall, causing the wall to push forward and the toe to lift. The eventual effect is a concave front wall with numerous hardship lines.

Horizontal fissures (sandcracks)

Animals severely ill, for example with mastitis, metritis or any toxic condition, may undergo a total cessation of horn formation. When horn production resumes, instead of a hardship groove, there may be a horizontal fissure encircling the hoof wall. Initially this may cause no problem, but as the defect moves distally towards the toe it loses its support and attachment at the heel. The protruding 'thimble' of horn is then able to rotate on the underlying corium, causing pinching, pain and lameness. Both claws of all four feet may be affected. The date of the illness can be calculated by measuring the distance from the coronary band to the fissure and dividing this by the rate of horn growth, namely 5mm per month.

For treatment, the loose 'thimble' of horn is removed. If the corium is extensively exposed on one claw, a block should be applied to the other claw if it is sound. However, not all horizontal fissures lead to lameness. Some simply grow to the toe and are shed naturally. It is only necessary to trim the foot if the cow is lame. A cow with one long claw and one short, due to the horizontal fissure fragment having been shed from one claw only, is sometimes referred to as having a 'broken toe'.

Axial wall fissures

The white line junction runs along the abaxial wall from the heel to the toe, caudally along the axial wall at sole level and then passes obliquely in a proximal caudal direction along the axial wall to the coronary band in

the interdigital space. White line lesions running obliquely along the axial wall are often referred to as axial wall fissures (Plate 31.15). Recently there has been an apparent increase in incidence (Vermunt, 1998). The cause is unknown, but wet conditions underfoot have been suggested. Due to their position in the interdigital space they are quite difficult to pare and lesions which damage the coronary band can lead to permanent vertical fissures. Digital dermatitis lesions affecting the coronary band in the interdigital space may be a further factor.

Skin disorders

Interdigital necrobacillosis

(foul of the foot, foot-rot)

This is a bacterial infection of the skin of the interdigital cleft. Two organisms are primarily involved, namely *Prevotella (Bacteroides) melaninogenicus* and *Fusobacterium necrophorum*. Cultural studies have suggested that *P. melaninogenicus* should be further subdivided into *Porphyromonas asaccharolytica* and *Prevotella* species (Berg & Weaver, 1994). *Dichelobacter nodosus* may also be involved. *F. necrophorum* is an obligate anaerobic Gram-negative bacterium found in the intestinal tract of both cattle and sheep and it is widespread in the environment, surviving for up to ten months. The A and AB biotypes produce a potent exotoxin which causes a suppurative necrosis and depresses phagocytosis, and a degree of synergism may exist between *B. melaninogenicus* and *F. necrophorum*. Injury to the interdigital skin may be required to allow entry of infection. This is usually due to stones, stubble, kale stems, hardened dung in the interdigital area, sticks, very dry pasture, rough flooring, etc. Damage will be easier when the skin is soft due to continued wetting. In some instances the damage may be caused by penetration of spirochaete organisms. Reservoirs of infection may exist in wet, dirty areas such as the gateways to fields and around water and feed troughs. It is also possible that mild digital dermatitis or interdigital dermatitis might be the cause of the initial damage.

The condition has a worldwide distribution in both dairy and beef cattle. Usually only one or a few animals are affected at one time. However, the disease appears to be contagious with the incidence increasing in wet humid weather and interdigital skin damage. Epizootics can arise when cattle are moved to a new environment or mixed together. The most probable source of infection is discharge from the feet of infected animals. The same animal can be affected repeatedly and as susceptibility only changes slightly with age, acquired immunity to the bacteria appears to be poor.

Clinical signs

Typically 'foul' is seen as a sudden onset lameness, more commonly in the hind foot, and it is characterized by bilateral swelling above the coronary band of both claws, often with the digits forced apart. Pyrexia is common. Initial erythema of the interdigital skin progresses to a fissure and subsequent slough of the epidermis to expose the underlying necrotic dermis (Plate 31.16). Unless treated, lesions may progress to an infection of the navicular bursa, the flexor tendon sheath or even the distal interphalangeal joint. However, these complications are more commonly associated with the virulent condition known as 'superfoul'.

Treatment

A wide range of parenteral antibiotics including penicillin, oxytetracycline, sulphonamides, tylosin, tilmicin, ceftiofur and cefquinome are all effective. The period of treatment required will vary with the severity of the initial lesion. The foot should always be lifted and examined to remove necrotic tissue and any predisposing foreign body and a topical antibiotic applied. Local treatment must improve the rate of healing and reduce the spread of infection into the environment.

Superfoul

This is a peracute form of interdigital necrobacillosis with a poor response to treatment unless aggressive therapy is instigated in the very early stages (David, 1993). Cultural examinations have indicated that the same organisms are present, although most cases are seen in herds concurrently infected with digital dermatitis. An 'invasive spirochaete', similar to both digital dermatitis and the spirochaete identified in peracute foot-rot in sheep, has been seen in lesions of superfoul. The main difference between foul and superfoul is the speed of onset and the severity of the lesions. Necrosis of the interdigital skin may be seen within 12 hours, with deep necrotic fissures into the dermis within 24 hours. Early and aggressive therapy is therefore essential. The treatments used are similar to conventional foul, but at a higher dose and for a longer period. Some benefit has been reported from the use of local anaerobic therapy such as clindamycin, spiramycin and metronidazole.

Prevention and control: Environmental hygiene and footbathing are the main control measures. If outbreaks occur, passages should be scraped with increased frequency, more bedding can be used, and if cattle are outside, they should be moved to a different paddock. Attention should be given to gateways, areas around water troughs and other gathering points to minimize

physical damage to the interdigital cleft. Frosted ground can also produce damage.

Disinfectant footbaths (formalin, copper sulphate, etc.) provide excellent control and are discussed on p. 432. Antibiotic footbaths have been used in the control of superfoul where digital dermatitis may be involved.

Digital dermatitis

This is a bacterial skin infection that primarily affects the epidermis. First reported in Italy (Cheli & Mortellaro, 1974), digital dermatitis now has a worldwide distribution. Figures of frequency of occurrence vary enormously depending on whether the incidence is recorded as a cause of lameness or whether prevalence of lesions is recorded. Many cows show low-grade lesions. For example, Laven (1999) found a lesion prevalence of 41 per cent in 1810 hind feet examined, although only a few of the cows were lame. Within the UK, digital dermatitis now represents approximately 30 per cent of all cases of lameness, which is probably why the overall incidence of lameness in cattle has not decreased since digital dermatitis was first reported in 1987 (Blowey & Sharp, 1988).

Aetiology

Histological studies were first to implicate spirochaetes (Blowey *et al.*, 1992; Read *et al.*, 1992). These had a predilection for keratinized cells and produced a toxin which is keratolytic. A possible association between *Borrelia burgdorferi* and other Treponemes has been suggested. Digital dermatitis-infected cows had a higher seropositivity to *B. burgdorferi* strain B31 and Treponemes 1-9185MED and 2-1498 than control cows (Demirkan *et al.*, 1999). Other workers have suggested the involvement of *Dichelobacter nodosus* and *Campylobacter faecalis*.

While spirochaetes can often be found in large numbers at the junction of viable and necrotic tissue layers, they are often difficult to culture. However, successful culture techniques have been reported. Two different spirochaetes have now been demonstrated. One is a long, filamentous organism 12 µm long and 3 µm wide and the other a short spirochaete 5 to 6 µm long and 0.1 µm wide. They are also different on enzymatic analysis (Walker *et al.*, 1995). The most probable cause is an organism with characteristics most consistent with the genus *Treponema*. Potential isolates suggested are *T. phagedenis*, *T. vincentii* and *T. denticola*.

Epidemiology

There is considerable confusion in the literature between incidence of disease seen as lameness and

prevalence of lesions, with few studies having examined large numbers of feet at a single point in time. Laven (1999) reported a 41 per cent lesion prevalence but did not relate this to lameness incidence. Hedges *et al.* (2000), in a study of over 1100 cow years in five UK dairy herds, found that digital dermatitis ranked approximately equal to sole ulcers and white line disease, and accounted for around 20 per cent of all cases of clinical lameness examined. Lesions are most commonly seen in housed cattle, especially dairy cows, but heifers and beef animals can also be affected. Lesions in hind feet are more common than in front feet and there would appear to be relatively little immunity, because affected cattle are more likely to have lesions on *both* hind feet (Laven, 1999) and reinfections occur in the same cows year on year, suggesting recrudescence of latent infections. Environmental hygiene is the main factor influencing disease, with the most severe outbreaks occurring in housed cattle in winter, although the increase in lesions and lameness seen in early lactation (Laven, 1999) could also be a reflection of periparturient immune suppression. The highest incidence of disease is seen in the early lactation period and this is associated with animals showing a high prevalence of lesions prepartum. Disease incidence is higher in lactating than dry cows. Suggested causes include lactating cows spending longer standing (for milking, moving and feeding), higher bacterial levels in slurry from higher concentrate diets, faeces are not as dry and stocking density is often higher.

Clinical signs

The earliest lesions of digital dermatitis are seen as a dry, painless, grey encrustation of hyperkeratotic material, often lining the caudal edge of the interdigital pouch. The pouch is most probably the major reservoir of infection in carrier animals, although similar encrustations can be seen along the junction of the heel horn and skin. More advanced lesions, and those sufficiently painful to cause lameness, are typically seen as a moist, light greyish-brown area of exudate, 10–20 mm in diameter, often with matted hairs and encircling the interdigital cleft (Plate 31.13). Cleaning the lesions reveals a red, raw area of epidermitis, very painful when touched and having a characteristic fetid odour and a granular 'strawberry' appearance. Advanced lesions create superficial epidermal erosions and irradiate across the heel bulbs, but ulceration into the dermis is rare: most lesions retain an epidermal covering. Longstanding, chronic lesions have a proliferative appearance, with marked epidermal hypertrophy and hyperplasia (Plate 31.17). These lesions are more prevalent in North America where they are referred to as papillomatous

digital dermatitis (PDD) or 'hairy warts', although they are now becoming increasingly common in the UK.

Although the heel area is the most common site, lesions of digital dermatitis may also be seen in the interdigital space, on the sole following a sole ulcer, white line disease or some other lesion exposing the corium, adjacent to the accessory digits or at the anterior aspect of the interdigital space adjacent to the coronary band. Lesions at this point are particularly significant because they can damage the germinal layers of the hoof wall to produce a vertical fissure. In chronic cases granulation tissue may protrude from the fissure and because the corium is inflamed exostoses develop on the anterior wall of the pedal bone. Vertical fissures resulting from anterior digital dermatitis are currently a common indication for digit amputation.

Treatment

Most lesions regress following cleaning and topical application of antibiotics, although repeated treatments may be necessary. Lameness resolves but it is likely that lesions persist to recrudesce at a later date. A wide range of topical antibiotics have been used including lincomycin, combined lincomycin and spectinomycin, oxytetracycline, erythromycin, tylosin and tiamulin. Concurrent parenteral therapy is indicated for anterior lesions to reduce the risk of vertical fissure development. Frequency of application varies with lesion severity, but ideally the lesion should be cleaned and treated for at least two consecutive days. Severe lesions should be bandaged with topical antibiotics for 3–4 days.

Treatment of PDD (hairy warts) is more difficult because the organism is protected by 10–20 mm of keratinized epidermis. Ideally these lesions should be amputated at lower epidermal level, under local anaesthesia, and an antibiotic dressing applied for three to five days, although an antibiotic dressing alone may be sufficient. Single topical treatments and footbaths are not effective against PDD. Antibiotic and antiseptic footbaths are an important aspect of both treatment and control.

Prevention and control

Environmental hygiene is the most important control measure and factors which produce a cleaner and/or drier foot environment will lower disease incidence. Cubicle and feed passages should be scraped at least twice daily and accumulations of stale slurry such as may be found in cross passages and around water troughs should be avoided. Feet should be kept as dry as possible by good drainage, ample bedding and the use of lime in cubicle beds (which also helps in mastitis control). Footbaths are an important control measure, although antibiotics applied as a foot spray on a whole-herd basis have also been effective.

Interdigital dermatitis (IDD)

Considerable confusion exists in the literature over whether IDD is a separate entity or whether it is a combination of a chronic form of digital dermatitis confused with stages of slurry heel. Many of the lesions attributed to IDD contain the spirochaete of digital dermatitis. It is not generally considered to be a cause of lameness, but large numbers of cattle are said to be affected and this predisposes to other lesions such as digital dermatitis, foul, slurry heel and interdigital hyperplasia. *Dichelobacter nodosus* is said to be a common organism involved, but others dispute whether this organism ever causes problems in the feet of cattle.

Clinical signs

Many cases are mild, leading to irritation and hyperaemia of the interdigital skin, with lesions spreading onto the heel bulb. Fissures and necrosis of heel horn can result, with coronary band lesions said to disrupt hoof wall formation and lead to vertical fissures. The latter is also characteristic of anterior digital dermatitis

Control

Environmental hygiene and regular footbathing with copper sulphate or formalin are said to be effective in control.

Interdigital skin hyperplasia (see p. 182)

Also called corns, tylomas, fibromas and just 'growths', interdigital skin hyperplasia is an overgrowth of the natural skin fold adjacent to the axial hoof wall. There is a fold of interdigital skin adjacent to both the medial and lateral claw, and the hyperplasia may develop from either side. It is an overgrowth of skin with gross hypertrophy of the epidermis. The term 'fibroma' is therefore technically incorrect. The lesion is hereditary in certain heavier breeds of cows, especially beef breeds. In other cases it is secondary to chronic irritation of the interdigital skin, for example due to low-grade foul, digital dermatitis or simply impaction with dirt. Cows walking over rough surfaces, leading to excessive splaying of the claws, may show an increased incidence. Lameness occurs either when the lesion reaches such a size that it is compressed by the claws during locomotion or when it becomes secondarily infected, for example by digital dermatitis or foul.

Mild cases can be treated by removing excess horn from the axial wall and the axial surface of the sole. Many lesions regress spontaneously when they are no longer traumatized during locomotion, although low-

grade digital dermatitis lesions are so common that it is always worth applying a topical antibiotic. Larger lesions require surgical amputation, although many recur. Regular footbathing through formalin is also said to resolve many lesions.

Mud fever

Mud fever occurs following exposure to cold, wet and muddy conditions. The lower leg becomes slightly swollen, with hard, dry and flaking skin. There may be hair loss and even bleeding if the skin cracks.

For treatment, the legs should be thoroughly washed and dried followed by application of a greasy antiseptic ointment or a teat spray which contains a high level of emollient. As the organism *Dermatophilus* may be involved, three days of injectable antibiotic (penicillin) may also help (see p. 886; Blowey & Weaver, 2003).

Bone and joint disorders

Fracture of the pedal bone

Bulling activity, with the mounting cow falling back heavily onto hard or rough concrete, is the most common cause of a fractured pedal bone. Bones weakened by age, fluorine poisoning or a foreign body penetrating the sole of the hoof may be at greater risk of fracture. Typically it is the inner claw of the front foot that is involved and by adopting a cross-legged stance the cow transfers her weight onto the sound lateral claw. However, the stance alone is not sufficient to diagnose fracture of the pedal bone. Cows with ulcers in both inner claws will adopt the same position. Most animals heal well if a block is applied to the sound claw.

Apical necrosis of the pedal bone

In a few cows, what initially appears to be a standard white line abscess at the toe sometimes fails to heal, even though it may have been treated thoroughly. At the second examination there will probably be a characteristic foul odour and even with further extensive removal of under-run tissues the toe fails to heal (Plate 31.18). In such cases the apex of the pedal bone has become infected (osteomyelitis). The negative net horn growth (p. 415) which occurs in the periparturient heifer, leading to erosion of toe horn, can be an exacerbating factor, especially if housing coincides with parturition. A similar condition is seen in weaned beef calves that continually run around the pen when introduced into feed lots.

Treatment must involve removal of all necrotic bone. Some clinicians report success with aggressive debride-

ment of the bone, but this has not been this author's experience. Provided the coronary band remains intact, removal of the necrotic toe and the adjacent wall and sole with an embryotomy wire may result in full resolution. Ideally, a radiograph is needed to identify the extent of the necrosis, and as many pedal bones are already severely eroded (Plate 31.19), total amputation of the digit may be the best option (see p. 1119).

Deep pedal infections

Severe or neglected cases of sole ulcers, white line disease, interdigital necrobacillosis or foreign body penetration can lead to infection tracking into deeper tissues. Complications must be suspected when severe lameness follows treatment of an apparently standard lesion, when swelling appears above the coronary band of the affected digit or when pus can be expressed from a sinus when massaging the digit. In any of these instances it is the author's opinion that immediate and aggressive parenteral therapy should be instigated, for example oxytetracycline (2g twice daily), tylosin or penicillin. If swelling of the coronary band was the only apparent lesion, this may be sufficient to effect resolution.

Deep infections may produce a retro-articular abscess (namely in the heel caudal to the deep flexor tendon), an infection of the navicular bursa, osteomyelitis of the navicular (distal sesamoid) bone or a purulent coronopalmar arthritis. A range of treatment options is available, all of which involve aggressive antibiotic cover, and most will require a block applied to the sound claw, thus minimizing weightbearing on the affected claw (p. 432). The option chosen will depend on the severity of the lameness and the clinician's preference, and includes the following:

- Radical fenestration of the sole or wall to provide drainage, followed by regular flushing of the lesion to prevent overgrowth of granulation tissue which would impede drainage (Blowey, 1990).
- Insertion of a drainage tube, the upper end of which is strapped to the hock to allow ease of flushing at milking (Plate 31.20). The lower end is closed. A practical method of siting this tube is to use a trocar and cannula to follow the sinus tract into the foot and then exit above the coronary band.
- Permanent arthrodesis can be created by drilling through the pedal joint and curettage of the articular joint surfaces.
- A surgical approach, opening the joint from the heel, is also available.
- Digit amputation is relatively simple. It can be performed in the standing animal under regional intravenous anaesthesia and provided that there is no major ascending infection of the flexor tendon it

generally results in a good response. There is an additional requirement to redress the lesion regularly, however, and additional weightbearing on the remaining digit may lead to early culling. If amputation can be performed at drying off, then a single dressing change after two to three days may be sufficient, with the second dressing fully removed three to four days later. Most cases heal remarkably well (see also p. 1119).

General treatment and control of foot lameness

Footbaths

Footbaths are an excellent preventive measure for lameness and cows should be walked through once a week during the winter housing period. Solutions of 5–10 per cent formalin or 2.5 per cent copper sulphate or zinc sulphate have been used, as have a variety of other disinfectants. The main objective of a footbath is both to clean and disinfect the foot and in so doing it should help to reduce the incidence of conditions such as:

- Interdigital necrobacillosis
- Slurry heel and heel erosion
- Interdigital skin hyperplasia ('tylomas' or 'corns')
- Digital dermatitis

Formalin also has a drying action on the foot. However, it is unpleasant to handle and its use is not permitted in some countries. Similarly copper sulphate baths may not be permitted by some environmental authorities because of the risk of pollution. Often two baths are used, the first containing water to wash and clean the feet. There is then a raised concrete strip to drain off excess water before the cows walk into the second bath containing the active chemical, as shown in Fig. 31.12. The liquid in the bath needs to be only 80–100 mm deep, as only the claws need to be immersed. Overfilling, particularly with formalin, can lead to damaged skin on both feet and teats.

For best effects cows should have their heels cleaned by a water spray as they enter the milking parlour. Excess water then drains off during milking, after which the cows should exit through a footbath and into a clean environment, with the whole herd being bathed on the same day to avoid cross-contamination. If done carefully, a single passage through an antibiotic footbath will dramatically reduce the incidence of lameness due to digital dermatitis in as little as 24 hours. Unfortunately it does not eliminate infection from a herd.

A range of antibiotics have been used to treat and control digital dermatitis, and at varying concentrations. In most countries none are licensed for this use. The

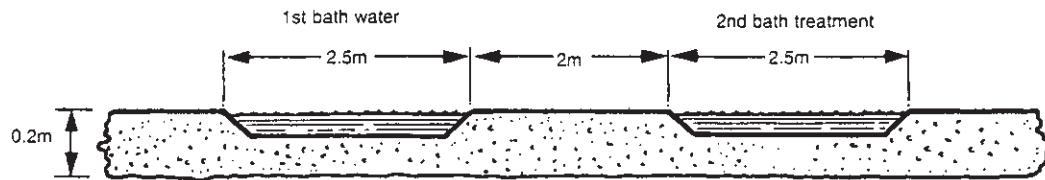

Fig. 31.12 Two footbaths in series.

following are the most common: oxytetracyclines at 4–6 g/litre, lincomycin at 1.0 g/litre, combined lincomycin/spectinomycin at 33 g lincomycin plus 66 g spectinomycin in 150 litres, erythromycin at 0.6 g/litre, tiamulin at 0.5 g/litre and tylosin at 1.3 g/litre. The dosage and frequency of bathing required depends on the severity of clinical signs, with a single or perhaps two passages through a fresh solution once every four weeks originally being the most common recommendation in the UK. (This was not effective on the hairy warts seen in North America, however.) Although this initially appeared reasonably effective, by the late 1990s all antibiotics appeared to be losing their effectiveness and revised concepts of footbathing were considered (Blowey, 2000). At that stage footbaths were instigated only when lameness appeared and usually when a small but significant proportion of the herd was lame. Clearly at this stage lesions have progressed to quite an advanced stage and a single treatment is likely to be less effective.

If footbaths were instigated at an earlier stage, before lesions appeared and especially if dry cows were treated on a preventive basis prior to calving, then it was likely to be more effective. A system of continual daily footbathings in 2.5–5 per cent formalin for periods of two to three weeks (Brizi, 1993; Blowey, 2000) was effective in reducing lesion severity, although even this does not totally eliminate infection from a herd and the treatment has to be repeated after intervals of three to four weeks. Some herds now use footbaths on a continual daily basis. Although formalin and other disinfectants do not penetrate the epidermis as well as antibiotic solutions, regular use eventually leads to drying and sloughing of superficial keratinized tissue. The black debris of hairy warts can be peeled off after two weeks of treatment, although in a proportion of cases characteristic granular areas of active dermatitis may still be visible beneath. Individual severely affected cows can be stood in formalin for 20–30 minutes and this also results in resolution of lesions. The system has also been effective against combined outbreaks of foul and digital dermatitis.

A variety of other footbath chemicals have been used including acidified ionized copper sulphate, hydrogen peroxide/peroxyacetic acid or quaternary ammonium

disinfectants, a beta-ionine terpene compound and a triplex of copper, a peroxy compound and a cationic agent. The latter was found to be at least as effective as oxytetracycline.

Nursing, dressings and footblocks

Nursing

Lame cows obviously find walking difficult. They are much less able to compete with the rest of the herd, especially if they are at the lower end of the social dominance scale, which is commonly the case with lame heifers. In addition, they find it difficult to manoeuvre in and out of the cubicles. Cubicles are not easy to use at the best of times and if a cow is not fully mobile cubicles are even more difficult to negotiate. This results either in lame cows spending longer time standing, which exacerbates the digit lesion, or, when down, they spend a long time lying and do not feed sufficiently, resulting in marked weight loss. Ideally lame cows should be transferred into a straw yard, where it is easier for them to lie down and get up and where there is less competition for food. Many herdsmen have commented that moving lame cows from cubicles into straw yards results in an increase in yield in as little as 24 hours, especially in heifers.

Foot dressings

Opinions vary over the need to apply a bandage and dressing to an exposed corium, for example following the trimming of sole ulcers or white line lesions with under-run sole. There appears to be a minimal risk of infection from the environment penetrating the corium, even if cows with extensively under-run soles are allowed to walk out into the slurry, and it is surprising how quickly the exposed corium becomes covered by a layer of new horn. On the other hand, there are several potential disadvantages in applying a dressing, any of which may retard healing. These include the following:

- Unless changed almost daily, the dressing will absorb infection from the environment and impede drainage. Impeded drainage may allow infection to spread, producing further under-run horn.

- Dressings prevent exposure to air and air often promotes healing.
- The presence of a bulky dressing on the sole means that the affected sole becomes weightbearing. This could make sole ulcers worse and cannot be beneficial in the production of new horn.
- Astringents, sometimes used to reduce granulation tissue from a sole ulcer, may damage the corium and hence discourage the formation of the new horn, which is so badly needed to cover the sole.

Few clinicians now use dressings on uncomplicated sole ulcers or white line abscesses and most consider that this results in improved healing. Dressings are needed following amputation of a digit, amputation of large interdigital skin hyperplasia lesions, treatment of extensive digital dermatitis and occasionally to control haemorrhage.

Footblocks

The use of a block applied to the sound claw is an excellent practice as it both promotes healing and considerably improves the welfare of the cow. A variety of devices are available, for example:

- Tie-on shoes and boots
- Nail-on blocks
- Blocks and shoes which are glued on

Tie-on shoes are the least popular, because they are difficult to fix and by encasing the whole foot keep it damp and can retard healing. They also do not reduce weightbearing on the affected digit as effectively as other methods.

Nail-on blocks are used successfully in skilled hands, although the sole of the claw to be blocked needs to be flat. They are cheap and fast to apply, but they do not remain *in situ* for as long as the glue-on blocks: they may move slightly and occasionally create sole ulcers under the rear edge of the block. The nail holes must also weaken the sound claw.

Wooden blocks, rubber blocks and PVC shoes, all of which can be glued onto the sound hoof, are the most popular products. The PVC shoe (Plates 31.7 and 31.20) gives the best support because it is glued to both the wall and the sole, and weightbearing is therefore transferred to the wall, which is the correct weightbearing structure. The glue also sets more rapidly, thus facilitating ease of application, especially in colder climates. However, on cows with very large feet it may not be possible to push the shoe sufficiently far back towards the heel, and the foot can rotate caudally, leading to discomfort.

For all glue-on blocks, the sound claw should be scraped totally clean and dry with a hoof knife, avoiding even finger contact. Access to the inner wall can be

improved by forcing the claws apart with a small roll of paper towel. With the PVC shoe the glue is mixed in the shoe until it forms a paste. When the paste is just starting to set the shoe should be pushed as far back towards the heel as possible. It is very important that the shoe or block supports the heel, otherwise the cow rotates backwards onto the sound claw, leading to discomfort and very rapid wearing of the block. Although some authors recommend removing blocks after two or three weeks to retrim the sound claw, most clinicians consider this unnecessary. On average, PVC shoes have been shown to remain in place for over two months, allowing ample time for the new sole to reform (Blowey *et al.*, 1999). The PVC shoes can easily be removed by clipping around their outer wall with hoof clippers.

Introduction

Lameness above the foot accounts for only 5–15 per cent of dairy cow lameness, and perhaps twice as great a proportion in beef cattle, for which data are lacking. Economic conditions in the UK and elsewhere in Western Europe have led to an increase in the size of the average dairy herd (see p. 23), but the labour force has been reduced. Additionally, only a minority of farmers have been financially secure enough to improve older dairy units, or to replace them with new accommodation. A personal survey of dairy cattle housing (Weaver, 1997) revealed their construction dates to be 1955 to 1994 ($n = 49$) mean 1976, i.e. over 20 years old. Seven units had undergone structural improvements 5 to 28 years (mean 19 years) later. In the period 1997 to 2000 two units were completely rebuilt, while six stopped operating as dairy farms. The result has been an apparent increase in both minor and more severe injuries in dairy cows. In the worst scenario a routine (herd fertility) visit to a dairy unit can reveal two downer cows, both needing urgent nursing care (see p. 440), while the labour – two or three experienced persons – is not always available immediately to move such cows to straw-bedded boxes.

Non-digital lameness problems due to poor accommodation arise from inadequate size and quality of cubicles, false economy of bedding requirements, over-crowding of cubicles and feeding areas, inappropriate mixing of first lactation heifers with mature cattle (leading to bullying, slipping and trampling of younger stock), and an increasing tendency to push cattle around rather than permit them to move at their own speed.

The results, discussed elsewhere in this chapter, include an increased incidence of skin and subcutaneous problems such as tarsal cellulitis (p. 460), carpal swelling (p. 460), traumatic tendon injuries (p. 451), pelvic damage (p. 446) and hip dislocation following falls (p. 447). Not one of these conditions is new. However, as housing systems in the present economic climate fail to satisfy two of the five freedoms – freedom from thermal and physical discomfort, freedom from fear and stress – there is a renewed obligation to recognize the deficiencies in specific dairy units and to advise on both economic and welfare grounds, the need for radical improvements. The introduction of herd health assurance schemes (p. 52) and increased welfare checks on many farms means that housing conditions for dairy herds are likely steadily to improve.

Economic conditions render many of the treatment and management modalities in this chapter hopelessly non-economic except in valuable pedigree stock. It is therefore all the more important that early and accurate diagnosis (e.g. septic arthritis in neonate, p. 455, tibial fracture, p. 444) is sought and the options are discussed fully with the responsible person on the farm.

Nerve paralyses

Introduction

Nerve paralyses of the forelimb include the suprascapular, brachial plexus and radial. The main hindlimb involvement is with the femoral, obturator, tibial, peroneal and sciatic. The usual common aetiological component is trauma. The typical age of affected individuals varies from neonate to mature cow. The treatment in all forms involves careful nursing and supportive care (e.g. oral fluids), and management of the primary lesion (e.g. fracture). Sometimes multiple nerve injuries occur as in the downer cow syndrome, which is considered separately (p. 439).

Suprascapular paralysis

Aetiology and pathology

The suprascapular nerve originates from cervical 6 and 7 roots. It may be involved in brachial plexus injuries (see below). The nerve supplies the supraspinatus and infraspinatus muscles. It has no sensory component. It is occasionally injured by blunt trauma in calves butted by others at mangers and troughs when the vertical bar barrier bruises the scapular region. Associated injuries can include fractures of the scapular neck or acromium.

Clinical signs and diagnosis

Suprascapular paralysis causes few clinical signs initially. The shoulder joint may be slightly abducted and

the forward phase of the stride shortened. After one week muscular atrophy causes increased prominence of the scapular spine ('sweeney').

Treatment

Treatment is purely palliative. Vitamin B complex may be given systemically. The prognosis is usually good.

Brachial plexus injuries

Aetiology

Trauma, as from sudden caudal and ventral displacement of the shoulder and entire forelimb, together with abduction can lead to separation of any group of the nerve roots C6 to T2. The nerves mainly affected are the radial, median and ulnar. Occasionally, the nerves are damaged by penetrating injury in the axilla with extensive additional damage to the vasculature. More frequently, the plexus is injured during traction in dystocia and severe abduction of the forelimb.

Pathology

The avulsion close to the spinal cord results in a complete loss of motor supply to the forelimb. Occasionally, the cranial segments of the network (supplying the suprascapular and axillary nerves) are spared.

Clinical signs and diagnosis

The forelimb is non-weightbearing and maintained in flaccid extension, with a tendency for the digits to be dragged. Sensation is absent from the level of the elbow distally. Muscular atrophy is evident after seven days.

Differential diagnosis includes radial paralysis (dropped elbow, more localized loss of skin sensation) and humeral shaft fracture with or without radial nerve injury (see p. 444), and forelimb dislocation.

Treatment and prevention

Since brachial plexus avulsion has a very poor prognosis, treatment is not usually justified. In calves with partial avulsion, anti-inflammatory drugs and limb support are suggested. Affected cattle should be confined to a well-bedded stall and care should be taken to avoid the development of decubital damage to the analgesic lower limb.

Radial paralysis

Aetiology and pathogenesis

The nerve (roots C7-T1) is damaged in its distal portion secondarily to humeral shaft fractures, which tend to be

Fig. 32.1 Radial paralysis of right foreleg of six-year-old Friesian cow. Paralysis was present on standing following 120 minutes in right lateral recumbency for surgery of a septic parotitis under general anaesthesia. Total recovery took 48 hours. The classical signs are present: dropped elbow, flexed carpus and inability to extend forelimb for weight bearing.

spiral, comminuted and to have sharp protruding spikes of bone. Radial nerve paresis frequently occurs following a long (one to two hour) period of general anaesthesia in lateral recumbency when the primary damage is a compressed vascular compartment. A dairy cow trapped under the lower horizontal bar of a cubicle division can also, on release, have radial paralysis. While partial paralysis is more common, complete radial paralysis can result from brachial plexus injuries or severe trauma. Cattle entering a crush fast and banging the shoulders against the yoke gate occasionally have a temporary partial radial paralysis.

Clinical signs and diagnosis

The main signs are a dropped elbow due to triceps paralysis, knuckled fetlock and an inability to advance the limb (Fig. 32.1). If the limb is placed in its usual position, the fetlock flexes as an attempt is made to bear weight. Sensory loss can be detected over the elbow and lateral aspect of the forearm.

Differential diagnosis includes humeral fracture with or without radial paralysis.

Treatment and prevention

The prognosis is good if the nerve has not been sectioned by humeral bone fragments. Treatment is supportive, keeping the animal on soft bedding and on non-slip surfaces. The fetlock should be bandaged to prevent iatrogenic trauma. Anti-inflammatory drugs and vitamin B complex may be given systemically.

Cattle maintained in lateral recumbency under general anaesthesia should have soft supporting surfaces and the down forelimb should be extended forwards to reduce the pressure on the vasculature to the lower parts of the limb. Also, the upper foreleg should not be roped tightly down against the table, whereby it would increase pressure on the lower leg.

Femoral paralysis

Aetiology and pathology

The femoral nerve (L4–6 spinal nerve roots) has a short course, ramifying in the iliopsoas and quadriceps muscles. It is liable to damage in the oversized fetus of large-framed breeds (Simmental, Charolais, Holstein) at delivery when presented in the 'hiplock' or 'stifle lock' position, which tends to cause femoral hyperextension as forced traction is exerted. The femoral nerve, usually unilaterally, is drawn against the pubic brim at the pelvic inlet. The injury can occur in either anterior or posterior presentation. The lesion is sometimes a rupture of the nerve, but more frequently involves very severe perineural haemorrhage and oedema. In other cases, the quadriceps femoris muscle is severely stretched and incurs damage to its vascular and nerve supply. The resulting quadriceps atrophy presents with typical clinical signs.

Clinical signs and diagnosis

The animal, usually a neonate, is unable to maintain the stifle in extension due to quadriceps dysfunction. The joint is flexed and the digit rests with minimal weight bearing. Usually, hock and digital joints are also flexed, though the toe is not dragged. A small area of loss of skin sensitivity may be detectable lateral and proximal to the stifle joint. Quadriceps atrophy within 10 to 14 days results in a triangular depression in the lateral cranial part of the thigh. Fibrosis of the remaining quadriceps muscle mass develops later. The stifle joint may become unusually prominent. Differential diagnosis involves dorsal or lateral patellar luxation, septic gonitis, femoral fracture or growth plate separation, hip dislocation and quadriceps rupture.

Treatment and prevention

The prognosis is guarded or poor. Recovery is unlikely in calves with femoral nerve rupture. The recovery time for regeneration was about four months in an experimental study when a 5 mm ($\frac{1}{4}$ inch) length of femoral nerve was resected surgically (Buchthal *et al.*, 1984). Treatment is primarily careful supportive nursing care. Calves should receive colostrum by bottle within 6 hours of birth if the injury has prevented rising to suck.

Clean and dry bedding is essential. The calf should be frequently turned. Analgesics, anti-inflammatories, and vitamin E and selenium preparations should be given.

Obturator paralysis

Aetiology and pathology

Obturator paralysis classically involves unilateral or bilateral damage to the nerve, usually in heifers during dystokia due to fetal oversize or maternal immaturity, when the nerve (L4–L6 nerve roots) is damaged by fetal pressure on its course along the medial aspect of the ileum or along the pelvic floor. Experimental section of the nerve, which innervates the adductor muscles (gracilis, pectenous, adductor and external obturator), has caused mild abduction of one or both hind limbs but experimental animals have been able to rise without difficulty (Vaughan, 1964; Cox, 1981). A common synonym for obturator paralysis, ‘calving paralysis’, is considered a misnomer since the latter is usually associated with the ‘downer cow’ syndrome (Cox & Onapito, 1998) (see p. 439). Many clinical cases of so-called obturator paralysis have a more complex aetiology involving branches of the sciatic nerve or primary muscle damage.

Clinical signs and diagnosis

Abduction of the hindlimb (unilateral) or a straddled gait (bilateral) are the classical signs. Confusion clinically may result from the stance adopted by a heifer with an oedematous and overstocked udder and with pelvic fractures. Rectal and vaginal examination may reveal minor pelvic damage associated with the paralysis. Some cattle are recumbent and such recumbency is rarely due to simple unilateral obturator injury. Cattle are liable to slip with gross hindlimb abduction, giving rise to hip luxation. Skin sensation remains unimpaired. Diagnosis is based on the history of possible injury at parturition and on the characteristic stance and gait.

Treatment and prevention

The animal should be kept on non-slip surfaces to avoid possible hip luxation or femoral neck fracture. Sand on the concrete floor of a calving/isolation box, overlaid with plenty of straw, is ideal. The hocks and hind feet should be kept close together by a figure of eight pattern of rope above the hocks or fetlocks. The distance between these joints should not exceed 30 cm (12 inches), which permits the animal to rise. Supportive care should be continued for several days. Breeding

management should be reviewed to avoid a high incidence of dystokia in heifers and to prevent damage during forced extraction of the fetus.

Tibial paralysis

Aetiology and pathology

Tibial paralysis is rare. It is associated with iatrogenic damage following deep infections in the caudal thigh musculature or lacerating injuries in the medial aspect of the hock with associated damage to related tendons.

Clinical signs and diagnosis

Tibial paralysis results in hock flexion from inability primarily to cause gastrocnemius contraction, which would result in hock extension. It also causes hyperextension of the digits in that the weight is borne more on the heels. Skin sensation is absent over the caudal aspect of the metatarsus and digits. Differential diagnosis includes peroneal paralysis and gastrocnemius and flexor tendon rupture.

Treatment and prevention

Treatment is symptomatic, involving confinement and vitamin B complex injections.

Peroneal paralysis

Aetiology and pathology

As with the tibial nerve, the peroneal nerve is a major branch of the sciatic nerve (L6–S2 nerve roots). Its common site of damage is over the lateral aspect of the stifle joint where the nerve lies relatively close to the skin surface. It is liable to injury following sudden (falls) or chronic pressure (prolonged recumbency).

Clinical signs and diagnosis

The hock is hyperextended, and fetlock and digits are flexed (knuckled over) (Fig. 32.2). The foot can be placed in its normal position. Skin sensation is lost dorsally from the fetlock distally to the coronary band. Diagnosis is easily made on the clinical signs and sensory loss. Differential diagnosis involves tibial paralysis and painful digital diseases.

Treatment and prevention

The prognosis is good with recovery usually evident in a few days. Self-induced trauma to the fetlock is minimized by application of a soft bandage or a light resin cast to the fetlock.

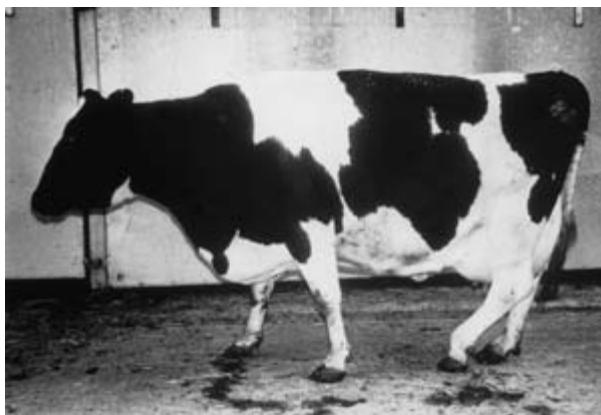

Fig. 32.2 Peroneal paralysis in six-year-old Friesian cow showing extended hock and knuckling of fetlock. Two days previously the digit had also been flexed. Some weight is now borne on claw normally. Total recovery took another three days.

Sciatic paralysis

Sciatic nerve paralysis involves the nerve that originates from three ventral roots (L6, S1–2). Damage to L6 root may be an important component of ‘calving paralysis’ or obturator paralysis (Cox, 1981) (see p. 438). The sciatic nerve is liable to damage unassociated directly with parturition but in prolonged unilateral recumbency. The site is usually close to the medial aspect of the femoral greater trochanter and may be associated with struggling. Such circumstances can involve partial recovery from milk fever or postparturient hypocalcaemia, as the cow struggles to rise on a slippery surface (e.g. concrete) (Cox & Onapito, 1998). Rarely, sciatic paralysis is secondary to femoral neck or pelvic fracture (pubis, ischium), or iatrogenic in origin from septic infection arising from intramuscular injections.

Clinical signs and diagnosis

The limb is entirely non-weightbearing. Sensation is lost from the limb distal to the stifle except for a strip on the medial aspect of the thigh distal to the mid-metatarsal region, which is supplied by the saphenous branch of the femoral nerve. Differential diagnosis should include femoral fracture, the signs of which will include crepitus, possibly swelling and abnormal mobility, and septic gonitis and tarsitis.

Treatment and prevention

The prognosis is usually hopeless. Many cases are presented as ‘downer cows’. It is vital that this paralysis be recognized early, so that long-term nursing measures will not be instituted. Early slaughter is advisable.

Downer cow syndrome (see p. 797)

Defined as ‘a cow down in sternal recumbency for unknown reasons’, the syndrome usually affects high-yielding dairy cows in the first 48 hours postpartum. In the UK the incidence appears to be increasing as a result of overcrowding in cubicle houses (see p. 43). Veterinary attention may not be sought for 24 hours, as a response to calcium borogluconate therapy is awaited. The condition has a multiple aetiology including traumatic, metabolic, neurological and toxic infectious causes. The following are examples:

- Traumatic: sacroiliac luxation and subluxation, bilateral or unilateral coxofemoral luxation, rupture of gastrocnemius muscle, pelvic fracture, massive blood loss (profound anaemia).
- Metabolic: non-responsive hypocalcaemia, hypokalaemia.
- Neurological: lymphosarcoma infiltration into thoracic or lumbosacral spinal canal, bilateral peroneal paralysis, complications of obturator paralysis.
- Toxic infectious: septic metritis, acute coliform mastitis (pp. 334, 519).

The primary recumbency, whether due to dystokia (46 per cent of cases), milk fever (38 per cent), or other causes (16 per cent) (Chamberlain, 1987), is followed by secondary recumbency. The usual explanation for the development of a downer syndrome in a cow, which is unsuccessfully treated for clinical signs diagnostic of hypocalcaemic parturient paresis or milk fever, is that the hypocalcaemia has been treated too late and that unrecognized traumatic injury has already taken place. Half of all ‘downer cows’ develop within 24 hours of parturition. They tend to be high producers. The incidence is higher in winter. Survey data indicate a considerable range (3.8–28.2 per cent) in the incidence of downer cows as a percentage of cases of milk fever. One study revealed that 33 per cent of downer cows recovered, 23 per cent were slaughtered, and 44 per cent died or were euthanized.

Pressure damage causes ischaemia of muscles and nerves. Following a variable period of struggling, further skeletal injury such as gastrocnemius muscle rupture may occur. The differential diagnosis is often difficult since frequently a non-responsive milk fever cow does not appear to have any further specific abnormality.

The aetiology of this pressure damage involves effects resulting from the ‘compartment syndrome’ (Cox & Onapito, 1998). Increased pressure develops within an osteofascial compartment following external pressure or internal filling of the compartment with blood or oedematous fluid, or both. External pressure

results in ischaemia, 'leaky' vessels, and a postcompression swelling. The effects of the crush syndrome, which refer to the systemic results or muscle damage, involve largely the absorption of muscle breakdown products.

One specific cause of the downer cow syndrome is pressure damage to the hindquarters following a period of prolonged recumbency (3–6 hours or more), resulting both in extensive muscle damage and reversible or irreversible changes in the sciatic nerve caudal to the proximal end of the femur and to the peroneal nerve.

Consideration of the aetiology and pathology of traumatic factors is reviewed in other sections (see Fractures, p. 441; Dislocations and subluxations, p. 447; Muscle and tendon injuries, p. 451).

Clinical signs and diagnosis

By definition the animal is recumbent. The cow is usually alert, eats, and can defecate and urinate. Affected cows make little or no attempt to rise in the hindlimbs. Some alert cows move around using the forelimbs and have been termed 'creeper cows'. Cows confined to a stanchion do not have facilities to demonstrate this movement, which may appear after the animal is transferred to a well-bedded stall or box. Dull or comatose and anorectic cows may be 'downers' due to systemic toxic factors (coliform mastitis, severe metritis). Occasionally, downer cows are hyperexcitable due to hypomagnesaemia or hypocalcaemia (see Chapter 46).

Rectal palpation is crucial to evaluate various traumatic aetiologies: sacroiliac (sub)luxation, pelvic fracture, severe, intrapelvic, soft tissue injury and coxofemoral luxation, as well as to check the state of the uterus (puerperium). External assessment includes palpation of the spine for abnormal angulation, swelling, or crepitus (fracture), musculature of the hindlimbs, especially the adductor group medially (muscle rupture), manipulation of the upper hindlimb and pelvis for evidence of fracture or dislocation, and determination of possible loss of skin sensation. The possibility of acute coliform mastitis should be investigated. The cow should be turned to the opposite side for similar examination of the other hindlimb. Cows usually prefer to lie with the more painful hindlimb uppermost.

Downer cows have variable changes in blood mineral levels, some showing a persistent hypocalcaemia, hypophosphataemia, and possible hypomagnesaemia. The role and significance of hypokalaemia is disputed. The release of potassium from damaged muscle cells does not necessarily cause hyperkalaemia because the usual coexisting hypocalcaemia has a tendency to cause hypokalaemia. All cases show an elevated creatine kinase (CK), which is specific for muscle injury. In one

study (Chamberlain, 1986), CK peaked at 24 hours after onset of recumbency in cows that recovered to stand, and at 48 hours in cows that became permanent 'downers'. Plasma or serum CK values reflect the total mass of injured muscle, but CK half-life is such that it is of doubtful value as a prognostic indicator several days after initial recumbency, when little further active muscle damage may be occurring.

Plasma aspartate aminotransferase (AST) is elevated in animals with muscle damage. This enzyme is also released in cardiac myopathies, but postpartum increases in downer cows are almost invariably related to the muscle component.

In cows recumbent for over 48 hours (at the time of second clinical examination), clinical pathology can be reassessed. Urinalysis may now reveal proteinuria indicative of myoglobinuria (from muscle breakdown), ketonuria and bilirubinuria (from partial anorexia).

If the aetiology of the persistent recumbency remains in doubt, a repeat complete clinical examination should bear in mind less common causes (e.g. infiltration of lymphosarcoma into the spinal canal). A careful recheck of the history may aid diagnosis at this stage.

Treatment and prevention

The downer cow should be moved to a well-bedded loose box not later than 24 hours after the onset of recumbency. Ample food and water must be provided in low, wide-based containers.

The primary aim is to raise the cow. Any attempt should be made on a relatively non-slip surface. Personnel should be ready to assist with tail support following provocative stimulation (e.g. electric goad). Hip clamps, e.g. Bagshaw hoist, may be applied to the wings of the ilium for a maximum of 20 minutes. Usually, the ability of the cow to bear weight is obvious. While slung in this manner, the hindquarters should be checked for symmetry and the opportunity taken to flex and extend each hindlimb to check for fractures. Other devices for elevation include air cushions or bags, webbing slings and water flotation tanks (Smith *et al.*, 1997). Some cows that can stand following hoisting require to be hobbled above the hocks or hind fetlocks to prevent abduction of the hindlimbs.

Hip clamps may be repeatedly applied for a few minutes of forced elevation of the hindquarters to improve circulation. When lowered, the cow should be placed with the previously dependent side uppermost.

The most important component of treatment is good nursing. The cow must be made comfortable. Owners should be observant for the possible development of a toxic (e.g. coliform) mastitis during recumbency. Rapid loss of weight, signs of systemic toxicity, and anorexia

are grave prognostic indicators. Soft bedding is essential for effective nursing in all downer cows, which should be turned several times daily.

Fresh water should be available alongside a bucket containing a commercial electrolyte solution. Parenteral treatment includes repeated injection of solutions containing calcium–phosphorus–magnesium with glucose and potassium. Additional potassium should only be given by stomach tube (e.g. 50g KCl daily). Tripelennamine hydrochloride given as 12ml solution i.v. is an effective stimulant and antihistaminic that makes a downer cow appear more alert (Chamberlain, 1987). Analgesics such as phenylbutazone, flunixin meglumine and ketoprofen should be restricted to cows with obvious signs of pain.

The prognosis is good in well-nursed ‘creeper cows’ with some voluntary hindlimb movement and cows that are capable of a short period of weight bearing when hoisted or slung. The prognosis is poor in animals with no hindlimb movement. Proprioceptive reflexes should be repeatedly checked in such cows.

Generally, excellent nursing, a consistently good appetite, and some spontaneous movement should encourage owners to persist and practise patience.

Valuable prognostic indicators for survival in a limited British survey of 64 downer cows were as follows.

- On day 2 of recumbency: body condition score, quality of nursing care, absence of hypocalcaemia, relative hypomagnesaemia, and lower AST and CK enzyme levels.
- On day 4 of recumbency: survival was associated with little further rise of CK and with continued good nursing.

A US survey of 15 veterinarians' experience with slings used on 145 cows showed a recovery rate of 52 per cent.

Prevention depends primarily on the avoidance of parturient paresis associated with milk fever (see Chapter 46). Calving should take place in properly designed areas with good footing. Many farms will benefit from stalls with 30cm (12 inches) clean sand as bedding. On problem farms, successful reduction of the incidence of downer cows has been primarily attributed to improved observation for the initial signs of milk fever and its prompt treatment.

Periparturient cows should be placed onto a minimal slip surface and sand is excellent for this purpose if straw-bedded calving boxes are not available.

A high incidence of downer cows in first-calf heifers, where hypocalcaemia can be ruled out, may be due to dystokia. Breeding policies may require modification such as use of a smaller breed bull or later first service dates for heifers.

Prevention of the downer cow syndrome is particularly vital today since treatment is very labour-intensive and repeated veterinary involvement is too costly for the minimal profit margins of many dairy farms.

Fractures

Introduction

In the assessment of bovine fractures, several factors require consideration in each clinical situation.

Economics

With some exceptions, economic consideration is a vital factor. Many cattle not used for breeding, e.g. steers, are best slaughtered at once, since treatment would be costly. Young potentially valuable breeding stock fall into a different category, where slaughter value is negligible in comparison with the potential value following fracture healing.

Size, age and sex

Young cattle respond well to restrictions imposed during fracture immobilization. They tend to rise easily despite external fixation and to be less liable to develop decubital lesions. The soft thin cortices of long bones in calves make plate and screws generally an unsuitable means of internal fixation. Calves have a remarkable ability rapidly to produce a fibrous response at a fracture site and early callus formation.

Disposition

An advantage of fracture healing in cattle compared with horses is their tolerant disposition making handling easier.

Location and character

Generally, the more proximal the fracture, the more difficult is its anatomical reduction and rigid fixation. Thus humeral and femoral fractures have notoriously low recovery rates, while metatarsal and metacarpal fractures usually heal well. Fracture of the distal phalanx, in which displacement is minimal, is discussed elsewhere (see Fracture of distal phalanx, p. 429).

Comminuted fractures are the rule in cattle. Many fractures are closed initially but become open following inappropriate handling such as movement to a stall. The prognosis for open fractures, especially proximal fractures (humerus, tibia, femur), is guarded. Soft tissue damage is often limited to haematoma and oedema

formation resulting from the original insult and movement of the fractured bone ends. In certain instances, significant nerve damage (e.g. to radial nerve in a spiral humeral shaft fracture) may be an important consideration in the prognosis.

Most fractures tend to be oblique or spiral in cattle. Maintenance of reduction while external or internal fixation is applied tends to be more difficult than with transverse fractures.

Duration of fracture

Unlike small animals and horses, the duration of a bovine fracture before presentation can often be 12–24 hours, a consequence of the relatively casual methods of husbandry practised on some farms. The result is invariably a greater degree of soft tissue injury than in a freshly presented fracture. One effect of a longer duration of movement at a fracture site is an open fracture.

First aid

Fractures should be immobilized on the farm premises as soon as possible. Suitable materials include padding with old towels or sheeting, and splinting with polyvinyl chloride tubing, or stiff rods such as broomsticks placed at 90° to each other (e.g. cranial and lateral surfaces of the forelimb to stabilize metacarpal fracture) and fixed in position with duct tape. The joints above and below the fracture should be immobilized. This technique is impossible in femoral, tibial and humeral fractures. In tibial fractures, a Robert Jones bandage comprising layers of cotton wool firmly bound by cotton bandage can achieve adequate immobility if sufficient bulk is applied.

Fracture repair

In certain fractures (e.g. rib) spontaneous healing is the rule. In others (e.g. external angle of ilium) repair usually takes place but a sequestrum may form. The sequestrum generally is only a cosmetic blemish but sometimes becomes infected and then requires removal.

Most fractures require treatment by methods of external or internal fixation, or both, if recovery is to take place.

Long bone fractures: external fixation

External fixation of fractures is usually satisfactory if the site is distal to the humerus or proximal tibial meta-

physis. A minimum of equipment is required, and extensive experience is unnecessary. External fixation is unsuitable for more proximal sites, in open fractures with gross contamination and fractures occurring in two limbs simultaneously. Young cattle develop osteomyelitis following open long bone fractures more frequently than older cattle. Careful examination of the fracture site, preferably after clipping of the skin, is essential to avoid missing an open fracture. External fixation alone may be contraindicated in very heavy animals.

Choice of materials and technique for external fixation

Immobilization techniques include the splint or cast, the modified Thomas splint, and both methods together.

Casting materials available today include plaster of Paris (one form of which is rapid-setting), thermoplastic polyester polymers (Hexcelite), and polyurethane resin incorporated into woven material of polyester (Cuttercast, Baycast) or fibreglass (Deltalite/Scotchcast). Casts should always be applied over a layer of padding. The depth of padding should be considerably greater if soft tissue swelling is anticipated at the fracture site and also should be generous over bone prominences. The padding should extend beyond the intended proximal point of the cast. The cast should immobilize the joints proximal and distal to the fracture site. Thus, in a one-month-old calf with a distal metacarpal shaft fracture, the cast should extend at least 8 cm (3 inches) proximal to the radiocarpal joint and similarly distal to the fetlock.

Positioning is very important in applying a cast. General anaesthesia is rarely necessary; xylazine is usually adequate for restraint and analgesia. The limb must be forcibly extended for fracture reduction and then maintained immobile until the cast has set. Traction on the distal part of the limb may be aided by inserting wire through holes drilled in the toes.

The advantages of a lightweight cast include increased comfort and ease of rising, and are achieved by fibreglass (e.g. Vetcast, Deltalite, Scotchcast), which has a strength five times greater than plaster of Paris. Weight reduction is also possible using several layers of plaster overlaid by fibreglass casting tape, once the plaster has hardened. Strength combined with lightness is the result.

Some fractures require radiography before reduction and immobilization to determine the extent and severity of bone damage. Fractures may also be radiographed two to three weeks after immobilization to assess the degree of healing. Removal of the cast at this time is often unnecessary. The radiolucency of cast materials varies, plaster of Paris being poor,

Deltalite/Scotchcast fair with some mottling, and Cuttercast/Baycast is excellent.

Extension bars have sometimes been incorporated into external casts. These U-shaped metal stirrups have the curved part of the U distal to the toes, so that weight is borne by the bar and transferred proximally to the cast, into which the two arms of the extension bar are buried during cast application. Such a device is only useful if there is a specific indication to avoid weight bearing by the digits. The effective increase in limb length makes standing up and ambulation more difficult. A modification is the hanging cast. This device comprises one or more intramedullary pins that are drilled through the proximal fracture fragment, and onto which a U-shaped bar is fitted after the usual external immobilization has been applied. When weight is borne, it is transferred proximally to load bearing by the proximal fracture site, so that the fracture site is not stressed.

Thomas extension splints may be put on either fore-limb or hindlimb. Good padding is essential both at the points (axilla, inguinum) where maximal pressure will be applied, as well as at any contact points more distally. The Thomas extension splint must be 'made to measure' for the individual case (e.g. circumference of proximal and distal rings, length of cranial and caudal longitudinal bars). In growing stock the length should be slightly greater (e.g. 5 cm or 2 inches) than necessary, to permit growth. Some devices have expansion clamps or rings on the longitudinal bars to allow continual modification.

The bottom ring should be wired to the foot to maintain the leg in extension. Bandages and padding should be placed around the limb at potentially exposed areas before they are taped to the longitudinal bars. In the hindlimb, the metatarsus may be fixed to the caudal bar, the tibial (gaskin) area to the cranial bar. The extension splint should be checked carefully for fit and effective immobilization of the fracture site before release of the patient. Many cases will benefit from combination of an external cast (e.g. fibreglass) and a Thomas extension splint.

Cattle up to 350 kg (800 lb) will generally adapt well to Thomas splintage. Patients should be confined to a stall with relatively little straw bedding. Assistance to rise may be needed initially. The cast or splint should be checked daily for skin abrasions, cast fracture or slackness.

Neonatal and other calves less than a month old with simple fractures and rapid callus formation may require external support for two weeks only (Fig. 32.3). Other young cattle should be checked for progress at three weeks by removing the cast with an oscillating saw. Sometimes the same splint may be reapplied (e.g. with Deltalite, Cuttercast).

Fig. 32.3 Bilateral distal metacarpal fractures in a one-day-old Saler calf. Circular lesions result from pressure of obstetrical chains applied during forced extraction. In the absence of percutaneous infection (seen here) external immobilization from mid metacarpal to coronary level is indicated.

Humeral fractures in cattle aged two and a half months to three years can heal four to six weeks following Thomas splintage (Wintzer, 1961). In other cases, immobility has been unsatisfactory and non-union has resulted despite massive callus formation.

Open fractures, at sites where external fixation is practical, require particular attention. The presence of skin perforation should carry the presumption of an open fracture even if bone cannot be seen or palpated through the injury. The wound is cleansed and carefully explored. Any free bone fragments should be removed. Larger wounds require debridement. It may be useful to take tissue samples or a blood clot for microbiological culture in the case of valuable cattle. Wounds should be copiously irrigated with a polyionic solution (isotonic balanced electrolyte with neutral pH). The value of adding a 0.1 per cent povidone-iodine solution (1:100 dilution of povidone-iodine 10 per cent solution) has not been established in cattle.

Antibiotics should be given parenterally in all open fractures in cattle. Natural and synthetic penicillins are the first choice. Systemic antibiotics should be

continued for seven to ten days. Antibacterial sensitivity patterns may be checked via samples taken at an early stage and before antibiotics are given. Samples should preferably be taken from infected bone at surgery rather than from discharging sinus tracts where contamination with surface pathogens will complicate interpretation of laboratory results. Antibiotic therapy should be instituted as soon as possible following identification of an open fracture. Small wounds may be covered with a sterile protective dressing, but any external support of the fracture site should be removed after three to five days to permit quick assessment of the wound. Young cattle develop osteomyelitis following open fractures more frequently than adults. The reason may be a richer blood supply in the damaged area.

Long bone fractures: internal fixation

Introduction

Economic factors are often important in considering internal fixation of bovine long bone fractures. Expertise in the discipline is also essential for successful reduction and rigid support under aseptic surgical conditions.

Anatomical factors mean that long bone repair by internal fixation is most frequently required in humeral, femoral and tibial fractures. Young calves have very thin cortical bone and screws are liable to loosen or be stripped during insertion. Failure is the common result. Both access to the fracture site and reduction are much simpler in the calf than adult.

In adult cattle, where the cortex is thick and dense, the major problems are associated with general anaesthesia (e.g. regurgitation, rumen tympany, compromised ventilation), the soft tissue mass through which the fracture site is approached, and the initial difficulty of anatomical reduction, when muscle spasm compounds the degree of overriding of the fragment ends.

Specialist texts should be consulted for details of internal fixation of specific bovine fractures (Ferguson, 1997).

Humeral fractures

Animals up to yearling size (e.g. 250kg, 550lb) are amenable to internal fixation unless the fracture is severely comminuted. Such fractures are usually mid-shaft oblique and spiral. The radial nerve is often involved (p. 436). There is often severe overriding, making reduction difficult. Intramedullary pinning (or stack-multiple-pinning) combined with cerclage wiring is often the technique of choice.

Humeral fractures are difficult to plate due to their short length and spiral configuration. Multiple bone fragments often necessitate the use of lag screws.

In older and heavier cattle, internal fixation is less successful due to greater mechanical forces. Often long-term Thomas splintage is adopted.

Femoral fractures

Femoral shaft fractures are relatively common in calves. Most have a history of forced extraction. The existence of concurrent disease should be evaluated (e.g. colostrum intake). No form of external immobilization is helpful. Internal pinning (Steinmann) rarely achieves sufficient immobility of the fracture site. The technique of choice is usually plate and screws, possibly double plating, with two plates placed at about 90° to each other (lateral and cranial).

Similar techniques may be attempted in older cattle. Reduction may present major problems. The huge mechanical force acting at femoral fracture sites makes bending of the plates or loss of screws common. Some femoral shaft fractures eventually heal with some months of stall rest alone.

Tibial fractures

Tibial shaft fractures are amenable to a variety of fixation techniques since exposure is relatively easy. Problems arise with severely comminuted or multiple fractures extending into the proximal and distal metaphyses. As alternatives to plate and screws, and additional support by a Thomas splint, some tibial fractures may be immobilized by cerclage wire with external support. Others best lend themselves to transfixation pinning. In this method two or three 6mm Steinmann pins are placed through both cortices of both proximal and distal segments under strict asepsis, the protruding ends are cut to protrude about 2.5–5cm (1–2 inches) from the skin, and a resin (methylmethacrylate) bridge is placed over these protrusions to immobilize the fracture site. The sites of skin puncture should be carefully covered with dressings to reduce the chance of infection tracking along the pins and causing osteomyelitis, which is the primary complication of this technique. Conservative treatment often fails to result in acceptable fracture resolution due to insufficient stabilization of the break. This often results in the development of severe lateral deformity of the limb with associated weight loss.

Growth plate and other injuries

Separation of the growth plate is a common complication of forced traction in dystokia. The usual site is the

Fig. 32.4 Separation and displacement of distal metacarpal growth plate in 15-month-old Limousin bull. Complete recovery followed manipulation and traction reduction (over 1000 kg pull) and four weeks immobilization in resin cast.

distal metacarpus or metatarsus (Fig. 32.4). Non-weight bearing swelling and crepitus are major clinical signs. Cases must be distinguished from distal metacarpal/metatarsal shaft fractures and fetlock dislocation or subluxation. Most cases respond to manual reduction and some weeks' immobilization in a cast.

Other sites of growth plate separation include the distal femur, distal tibia and distal radius. Apart from external support, cross and Rush pinning are suitable methods of immobilization. The pins in the first method traverse the epiphysis obliquely to emerge through the opposite metaphysis. In Rush pinning, the pin is directed from the epiphysis to slide in a sledge-runner fashion proximally along the internal surface of the opposing diaphysis. Although such pins are liable to displace rather easily, healing is rapid and the success rate is high.

A specific and difficult orthopaedic problem is fracture of the femoral neck and separation of the proximal femoral epiphysis. Most cases result from dystokia. Diagnosis is difficult as precise localization of the fracture requires radiography. The differential diagnosis includes proximal femoral shaft fracture and pelvic

fracture involving the acetabulum. The simplest method of treatment is confinement, which has a low success rate. Alternatively, the femoral head may be resected to permit development of a pseudoarthrosis, but lameness usually persists along with obvious muscle atrophy and compensatory conformational changes in the contralateral limb. Finally, internal fixation by Knowles pins or lag screws has been successful but requires intraoperative radiography to ensure the correct direction of insertion from the lateral aspect of the greater femoral trochanter.

Vertebral fractures

Aetiology and pathology

Elsewhere in this chapter, reference is made to long bone fractures and growth plate separation (p. 444) resulting from excessive traction during dystokia. But vertebral fractures due to forced traction, usually in an exotic beef breed such as Charolais, can lead to fracture and/or luxations in the caudal thoracic or cranial lumbar region (preferentially T12–L3). The common form is a fracture of the caudal physis of T13 (Schub & Killeen, 1988).

Postmortem changes include perirenal and perivertebral haemorrhage, fractured ribs, cord compression, severed cord, subdural haemorrhage, and myelomalacia.

Clinical signs and diagnosis

The calf is alive before traction is applied in dystokia, but following delivery the calf is weak, usually recumbent, with a swollen head, dyspnoea, and spinal deviation. These calves usually die within 24–48 hours from neurogenic shock (pain, trauma, hypoxia).

The normal rigidity of the spine in the affected thoracolumbar region invariably cannot tolerate the spinal curvature induced during typical traction on forelimbs of a fetus in anterior presentation when these dorsal structures become stretched and convex. When fetal hips lock on entering the maternal pelvis, the thoracolumbar region is approximately level with the maternal vulva. If the fetal body is then twisted and bent from side to side, acting as a pivot, a considerable risk of excessive shearing or traction forces can develop.

Treatment and prevention

The magnitude of traction forces in dystokia should be appreciated. Two men can exert a 350 kg pull for 30 seconds. A calf-puller device can produce over 500 kg traction. Adequate lubrication of the birth canal and an instinctive reluctance to use more than manual pressure

are the two most important preventive measures, since treatment is useless. A greater willingness to adopt caesarean section in oversized viable fetuses will help prevent further accidental injuries (see p. 1115).

Pelvic fractures

Aetiology and pathology

Severe pelvic fractures are rare in cattle. Trauma is almost always involved. The most common pelvic fracture involves the tuber coxae, which is damaged during passage through a narrow doorway or in a sudden fall laterally onto hard ground (Fig. 32.5). Unlike other pelvic fractures, the tuber coxae fragment may be pulled ventrally by the fascia lata, becoming a sequestrum from an inadequate blood supply and may develop a septic draining tract to the exterior.

Another specific condition is separation of the pubic symphysis, resulting from excessive traction on a fetus in the pelvic canal of an immature heifer.

Fig. 32.5 Fracture of right wing of ilium in adult cow, showing asymmetry relative to the greater femoral trochanter and ischial tuberosity.

Osteoporosis is a predisposing factor to pelvic fracture in some high-yielding dairy herds.

Other pelvic fractures involve the wing or shaft of the ilium, tuber ischii, and the acetabular margin. The ilial fractures usually involve massive trauma, such as falls down cliffs. Tuber ischii damage may result from road traffic accidents in which the impact is caudal. Acetabular margin fracture chips often involve traumatic hip luxations.

Clinical signs and diagnosis

The degree of lameness varies considerably from nil (tuber coxae) to severe and even to recumbency (pubic and ilial shaft fractures). The external bony landmarks are frequently asymmetrical. Crepitus may be obvious as the animal walks. Rectal palpation will often permit localization of the crepitus and an appreciation of surrounding soft tissue injury. One useful technique is palpation during lateral rocking of the hindquarters. Fractures of the ilial shaft, pubis and cranial ischium can be appreciated on such rectal exploration. Vaginal palpation should be performed in mature cows and recently calved heifers.

Clinical diagnosis of acetabular fractures, which tend to involve the dorsal rim, is difficult as the localized crepitus must be distinguished from coxofemoral dislocation (in which the greater femoral trochanteric position is abnormal) and femoral neck or physeal fractures (which may be suspected from the increased mobility of the hip region in the affected limb). Radiography is essential for diagnosis in some cases, but, due to size and equipment constraints, is rarely feasible.

Other differential diagnoses include pelvic bruising leading to haematoma formation and pelvic abscessation. Haematomas rarely cause lameness, while abscesses tend to have a more gradual onset and a protracted course. Several sites of pelvic fractures can lead to nerve trunk (sciatic, femoral, obturator) and blood vascular damage (middle uterine artery, internal pudendal, internal iliac arteries and veins).

Fractures of the bodies of the ischium and pubis invariably involve the obturator foramen, usually also the obturator nerve, and are serious in that marked pain and discomfort tend to cause prolonged periods of recumbency and a reluctance to stand. Commonly, both bones are fractured, making the pelvis unstable, and healing is then unlikely. In some cases, healing is liable to be accompanied by excessive callus formation. This sometimes extends to produce hip osteoarthritis and a persistent lameness.

Degenerative osteoarthritis of the hip in the older bulls and cows leads to considerable peripheral new bone formation. Sometimes, following minor trauma,

small portions of the new acetabular dorsal rim are chipped off (pathological fractures), leading to a sudden increase in severity of the lameness. Often such fracture chips will heal by fibrous tissue, but lameness persists.

Treatment and prevention

Surgery is indicated in few cases of pelvic fracture, e.g. tuber coxae sequestrum. The only useful treatment is generally rest in a well-bedded stall. Use of hip clamps (e.g. Bagshaw hoist) to raise animals is contraindicated. Few cattle become acclimatized to slings, which may increase the discomfort caused by the fracture. Cases of pelvic fracture should be reassessed after three to four weeks of good nursing, and, in the absence of obvious improvement, most cases should be salvaged.

Dislocations and subluxations

Hip joint

Aetiology

Coxofemoral luxation is sporadic, occurring mostly in two to five-year-old cattle. It has an association with parturition and the early postpartum period. At this time, ligamentous relaxation is maximal and obturator or other nerve injury during dystokia may predispose cattle to abduct the hindlimbs and to slip the feet laterally resulting in a splayed-leg collapse.

Hip dislocation can occur in various directions, craniodorsal being most frequent (about 80 per cent of total), and cranioventral and caudoventral being less common.

Pathology

The gross pathological changes in luxation include rupture of the joint capsule and of the ligament of the femoral head (teres ligament), loss of articular cartilage and surrounding soft tissue, haemorrhage and oedema.

Clinical signs and diagnosis

A sudden onset of lameness is the only consistent sign. Other so-called typical signs refer only to the common craniodorsal luxation, when the leg is held rotated outwards, the hock medial, and stifle more lateral than normal. The leg may appear shortened and the greater femoral trochanters are asymmetrical, the affected side being relatively more dorsal. Movement of the limb is somewhat restricted and painful. Crepitus may be

appreciated on limb abduction and flexion. Rectal palpation aids localization of crepitus to the hip. It will also help to differentiate the less common directions of luxation. In cranioventral luxation, abnormal movement may be appreciable cranial and lateral to the pelvic inlet when the cranial border of the pubis is followed. In caudoventral luxation into the region of the obturator foramen, movement may be noted as the leg is abducted, flexed and extended, released, taking the femoral head out of and back into the margin of the foramen.

Diagnosis may be confirmed in smaller cattle on ventrodorsal radiographs. Differential diagnosis includes femoral neck fractures, physeal separation, pelvic (acetabular) fractures, and greater femoral trochanteric fractures.

Treatment

Manipulative reduction should be attempted in all uncomplicated cases of craniodorsal luxation seen within 24 hours of the onset. The chance of successful manual reduction decreases markedly thereafter. Cases of caudoventral dislocation, which are often recumbent, perhaps due to additional obturator damage, have a poorer prognosis.

The common craniodorsal luxation is treated by careful positioning of the patient so that the body is fixed while the affected upper leg can be extended in various directions. Deep sedation (xylazine) is advisable. The leg is forcibly circumrotated in ever-increasing circles by an assistant to loosen up the periarticular soft tissues, which may be in spasm. A large, firm block is placed between the ground and the medial femoral region to act as a fulcrum when inward pressure is exerted on the stifle, tending to cause hip abduction. The limb is subject to controlled traction along the longitudinal axis of the limb. The veterinarian should concentrate on distal pressure on the greater trochanter. The amount of femoral head movement usually increases with time, and manipulation should not be quickly abandoned. Reduction is usually very obvious, and traction should be stopped at once, otherwise a caudoventral luxation may be produced. Once replaced, the limb is circumrotated slowly and carefully in an attempt to remove blood and other debris from the acetabulum. The animal should not be permitted to stand at once, since spontaneous relaxation is liable. The hindlimbs should be shackled above the hocks or fetlocks for 24–48 hours. A good non-slip surface should be beneath the cow when standing up and, if available, a hip hoist is a useful aid.

A high success rate has followed open surgery for reduction of hip dislocations (Tulleners *et al.*, 1987). In

this series few cases responded to manipulation. As experienced by others, caudoventral and cranioventral dislocations present special problems since limb traction cannot be exerted in the correct direction. The standard surgical approach is medial and cranial to the greater trochanter through the gluteal musculature. Care should be taken to avoid the sciatic nerve. The femoral head is mobilized and moved appropriately with a combination of manipulation by a non-sterile assistant handling the hock, which can be easily rotated slightly or, at will, abducted, and moved by appropriate instrumental leverage. Toggling through the femoral head and acetabulum to produce an artificial intra-articular ligament was unsuccessful in a long-term study.

Recumbency following hip dislocation and for a period after successful reduction necessitates a careful watch for the possible development of acute severe mastitis, since many cases have recently calved. Excellent nursing in good comfortable surroundings is essential for recovery.

Apart from a surgical series (Tulleners *et al.*, 1987) in which many animals were immature and, therefore, better surgical candidates, most cases have a guarded prognosis for craniodorsal dislocation and a poor prognosis for any other direction. Recumbency at presentation makes recovery less likely.

Hip dislocation is the clinical diagnosis in some 'downer cows' (see p. 439).

Sacroiliac luxation and subluxation

Aetiology

Sacroiliac displacement involves a partial or complete separation of the fibrocartilaginous joint surfaces. The aetiology usually involves excessive ligamentous flaccidity around parturition, when most cases occur. Some cases involve a degree of dystokia. A condition of sacroiliac distortion is recognized when there is no displacement, but excessive mobility of the joint surfaces is detectable. In true luxation considerable haemorrhage and soft tissue damage occurs in the joint space and peripherally (haematoma formation).

Clinical signs and diagnosis

Signs of sacroiliac luxation are characteristic. The lumbosacral spine is dropped relative to the sacral tuberosities of the ilium, which are correspondingly prominent. Cows initially prefer recumbency and show slight ataxia, hindquarter weakness, and some knuckling of the hind fetlocks. These signs are attributed to associated bruising of the ventral nerve roots of L5–S2. Crepitus can be easily elicited from the sacroiliac

region. The dropped spine may develop over two to three days and be preceded by evidence of localized pain. Rectal palpation of luxation reveals the sacral promontory has been pushed caudally and depressed, so reducing the dorso-ventral diameter of the pelvic inlet. Very severe cases may be unable to stand as a result of spinal nerve trauma.

In cases of subluxation and distortion, the signs are relatively mild. Some hindlimb ataxia and weakness may appear. Crepitus may be noted during rectal palpation as the cow is walked forwards, and localized swelling over the ventral part of the joint is diagnostic when the history indicates a sudden onset.

Differential diagnosis includes coxofemoral osteoarthritis, pelvic fractures, obturator or other nerve damage, lumbar spondylitis and progressive hindlimb paralysis (spinal abscess, lymphoma).

Treatment and prevention

The prognosis is favourable for cases of distortion and subluxation that are confined to a well-bedded stall for a few days. More severe, recumbent cases of luxation or subluxation have a guarded or poor prognosis. A sacroiliac luxation never undergoes spontaneous repossession and manual reduction is impossible. However, some cows can survive for years with sacroiliac luxation despite the bizarre appearance of the hindquarters.

In nursing affected cows, no forcible attempt (hip clamp, electric goad) should be made to make them stand. Analgesics (phenylbutazone) every second day for one week may increase comfort.

Stifle joint: femoropatellar

Aetiology and pathology

Patellar luxation may occur dorsally, medially and laterally. Dorsal displacement (fixation) is seen in mature cattle as an intermittent condition, unassociated with any known trauma. Medial patellar displacement is rare and is usually congenital. Anatomical defects predisposing to medial luxation have not been clearly identified, though in newly calved heifers with large udders the abducted hindlimb posture may lead to temporary medial patellar luxation.

Lateral patellar luxation is occasionally seen as a specific entity in mature cattle and young calves. This luxation in calves may sometimes be secondary to quadriceps atrophy resulting from femoral paralysis (see p. 437). In calves that first show signs at three months (Weaver & Campbell, 1972) without a history of femoral paralysis, no predisposing factors have been identified.

Fig. 32.6 Upward patellar fixation in 15-month-old Canadian Holstein heifer. The degree and duration of caudal extension were unusual. Heifer recovered following medial patellar desmotomy.

Clinical signs and diagnosis

In dorsal patellar luxation or fixation, the first sign may be initial hindlimb stiffness followed by a jerky action in which the limb remains extended caudally longer than usual, and is then pulled forwards and upwards in a movement resembling equine stringhalt (Fig. 32.6). This action may be intermittent and separated by several normal strides, or it may be repeated. If the animal is pushed backwards, the hindlimb may become fixed temporarily in extension. This extension may persist, whereby the foot is dragged along the ground (permanent upward fixation). Palpation reveals the patella to be more prominent and dorsal than usual, and the patellar ligaments are unusually easily felt. The patella is now resting partly in the supratrochlear fovea, while the medial patellar ligament is felt to be fixed around the medial trochlear ridge.

Both medial and lateral patellar fixation are associated with a characteristic posture. The stifle is markedly flexed, and the limb collapses on weight bearing, exactly as in femoral paralysis (p. 437). Bilaterally affected calves prefer recumbency. The patellar position is obvious visually and on palpation. It can usually be replaced on to the femoral trochlea but may immediately relaxate. Radiography can confirm the abnormal position but is a superfluous procedure. Differential diagnosis includes femoral nerve paralysis, quadricep muscle rupture, gonitis and distal femoral epiphyseal separation.

Treatment and prevention

Dorsal patellar luxation should be treated by medial patellar desmotomy if signs persist for more than a

week. Surgery is preferably carried out in the standing case as an aseptic procedure following sedation and local analgesia. A large udder or a difficult temperament makes recumbency (affected side down) necessary in some cases. The surgical site is superficial to the most distal palpable point of the medial patellar ligament, close to its insertion into the tibial tuberosity. A 4 cm (1½ inch) long vertical skin incision is made cranial to the ligament. A tenotomy is inserted just deep to the ligament with the blade in a vertical position. A Hey Groves knife, with a blunt rounded point, is ideal for this surgery. The conventional disposable scalpel blade and (Bard) handle are unsuitable since slight movement easily results in breakage and loss of the blade. The cutting edge is rotated through 90° towards the skin and the medial patellar ligament is sectioned without damaging or entering the joint cavity. A single non-absorbable skin suture achieves adequate wound apposition. The operated cow should walk normally at once. No deleterious long-term pathology has been reported in operated cattle.

Both medial and lateral patellar luxation are treated by a joint overlap procedure. In lateral luxation the femoropatellar joint is incised longitudinally about 1 cm (½ inch) medial to the patella, which is replaced in the trochlea. The capsule is closed by vertical mattress sutures in a joint capsular overlap procedure. Sometimes this technique fails to maintain the patella in position. The fascia of the thigh may then be split dorsally to permit replacement. Bilateral cases should be operated with a one week interval (Husband & Weaver, 1995). In medial patellar luxation, the overlap procedure is carried out lateral to the patella.

Stifle joint: femorotibial

Aetiology and pathology

Complete femorotibial luxation is rare and incurable. Subluxation is relatively common and is typically seen in the mature cow or bull as a result of primary cranial cruciate injury (see p. 455). Predisposing factors include heavy weight and sudden twists and falls as when mounting or being mounted by cows in oestrus. The cranial cruciate ligament is partially or completely ruptured (Fig. 32.7). Damage to the caudal cruciate is less likely. One or both tibial menisci are often torn and displaced at the time of rupture (Fig. 32.8). Secondary osteoarthritic changes quickly develop with initial loss of articular cartilage from the femoral condyles, followed by exposure and erosion of subchondral bone and peripheral osteophyte proliferation at the joint margins.

Detachment of the medial meniscus has been reported in young (1 month to 1 year) dairy cattle

Fig. 32.7 Degenerative osteoarthritis of stifle of aged beef cow showing ruptured cranial cruciate ligament, massive osteophyte proliferation along margins of femoral trochlea and cartilaginous loss on femoral condyles.

following injury to the medial collateral ligament. Mounting activity has been postulated as a major aetiological factor (Nelson *et al.*, 1990).

Clinical signs and diagnosis

A sudden onset of a medium degree lameness is characteristic of femorotibial subluxation due to cruciate injury. There is generalized soft tissue swelling and crepitus may be spontaneous or may be induced by rotating the point of hock laterally and medially to produce some rotation of the tibial joint surfaces. The tibial tuberosity may be unusually pronounced and a 'drawer-forward' sign may be demonstrable initially. The animal, placed in lateral recumbency with the affected limb uppermost, has the stifle put into moderate extension. The clinician then attempts to move the proximal tibial region cranially, relative to the femoral condyles. Sometimes this movement is even appreciable as the animal walks. If not diagnostic on palpation,

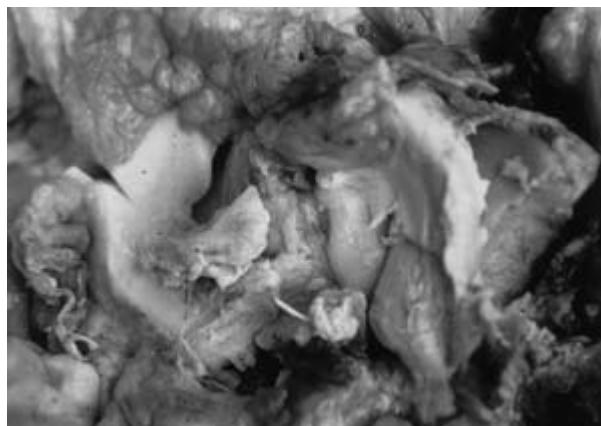

Fig. 32.8 Degenerative osteoarthritis of stifle joint of aged cow exposing damaged menisci and tibial condyles. Menisci are eroded and partially detached, allowing partial eburnation of the underlying tibial condyles. Surrounding musculature is pale due to extensive fibrosis.

and if radiographic facilities are available, lateral views of the stifle may demonstrate significant (approximately 2.5 cm (1 inch)) cranial displacement of the tibial plateau relative to the femoral condyles. In some cattle, arthrocentesis is advisable to rule out septic gonitis and to demonstrate the presence of cartilaginous debris and blood in the femorotibial joint. Other differential diagnoses include collateral ligamentous injuries, patellar fracture, and, in young cattle, proximal tibial epiphyseal separation.

Treatment and prevention

Radical surgery involving replacement of the ruptured cranial cruciate ligament by skin or synthetic material has occasionally been successful. These cases have either been experimental animals in which the ligament has been sectioned, or smaller animals in which surgery has been done very soon after the original injury. Most cases have lacked adequate long-term follow-up studies.

Fetlock joint: metacarpophalangeal and metatarsophalangeal

Aetiology and pathology

Dislocation is rare. It invariably involves rupture of both collateral ligaments as well as the intra-articular structures. Trauma is usually so severe that massive soft tissue injury exposes the joint surfaces. Subluxation either in a medial – lateral or cranial – caudal direction is seen sporadically.

Clinical signs and diagnosis

Clinical signs include a non-weight bearing stance, swelling, obvious gross displacement and crepitus on manipulation of the distal extremity. Diagnosis is usually easy. Differential diagnoses include epiphyseal separation in calves, and distal metacarpal, metatarsal and proximal phalangeal fractures. Subluxation presents with similar signs of gross swelling but crepitus may be hard to elicit. Subluxations can be successfully reduced following sedation and extension. A support bandage or cast should be applied subsequently.

Treatment and prevention

Treatment is usually hopeless. If the joint surfaces can be replaced to be congruent, a synthetic collateral ligament may be inserted by utilizing steel wire anchored to screws drilled into each epiphysis. Alternatively, the ligaments may be replaced with polypropylene material. It is usually impossible effectively to suture together the ruptured ends. In young calves the synthetic material may require later removal to permit normal growth of the epiphysis, otherwise the material is left *in situ*. Meniscopexy was successful in treatment of 20 out of 27 young cattle with medial collateral ligamentous and medial meniscal injury (Nelson *et al.*, 1990).

Muscle and tendon injuries

Introduction

The muscles most liable to rupture include the gastrocnemius, the adductor group and the cranial tibial (peroneus tertius). All three are particularly liable to damage when a heavy cow is struggling to rise postpartum (see Downer cow syndrome, p. 439).

Specific muscles

The gastrocnemius is particularly exposed to damage as a primary extensor of the hock. Prolonged recumbency, excessive weight, and possibly mineral imbalance leading to a degree of osteomalacia can predispose to gastrocnemius rupture.

The common site is the tendon–muscle junction. The rupture is usually complete and leads to considerable swelling due to extravasation of blood and the development of oedema. The hock is dropped and weight bearing is minimal. Diagnosis is rarely in doubt since the clinical picture is typical.

Gastrocnemius muscle rupture is treated by stall rest and maintenance of the hock in extension by means of a Thomas splint. In yearling animals, compression

screws can be drilled from the caudal surface of the calcaneus into the distal portion of the tibial shaft to immobilize the tarsus for some weeks so that fibrous repair at the rupture site can take place.

Cranial tibial (peroneus tertius) rupture is also traumatic, resulting from falls or from excessive traction upwards of the hindlimb by ropes strung over an overhead beam and followed by severe struggling. The animal has a characteristic gait. While the hock is abnormally extended, the stifle remains flexed, in other words the reciprocal stifle–hock action is lost. When standing, any abnormality may be hard to detect, but the limb can be extended caudally so that the metatarsus and tibia form a straight line while the stifle remains flexed. The gastrocnemius tendon is then slack. The site of muscle rupture varies from its origin in the extensor fossa of the femur to the insertion and to the muscle belly itself. Some area of painful swelling is apparent and most cases respond to stall rest over a period of one to four weeks.

Adductor muscle damage has been briefly discussed under downer cow syndrome (see p. 439).

Ventral serrate rupture is spectacular due to loss of its normal anatomical function of supporting the chest in the form of a sling between the forelegs. The scapular cartilage projects above the level of the thoracic spine and is readily palpated subcutaneously. The prominence varies in degree, being more obvious when weight is borne and less obvious in the forward swing of the limb. Colloquially termed ‘loose shoulder’, Channel Island breeds, especially the Jersey, appear to be predisposed. This feature may reflect a smaller muscle mass relative to body weight. The aetiology in young cattle is possibly related to muscular dystrophy (vitamin E and Se deficiency; see page 258). Cases may be associated with turn-out to pasture. Pathological examination of chronic cases in adult cattle reveals severe muscle degeneration, fibrous tissue proliferation and serous infiltration. While mild cases may recover completely, complete rupture is incurable, but animals move around well, remain productive and emergency slaughter is rarely necessary.

Contracted flexor tendons

Aetiology and pathology

Contracted digital flexor tendons are the commonest congenital abnormality in cattle. The name ‘contracted tendons’ is a misnomer, as the primary abnormality is an arthrogryposis or articular rigidity, usually in flexion (Fig. 32.9). Most cases are mild and self-correcting as the calf moves around to an increasing extent. Some are more severe and sometimes associated with

Fig. 32.9 Contracted flexor tendons (forelimb) and flexed hocks in a neonatal Holstein calf, which was unable to stand. Synonyms: arthrogryposis or articular rigidity.

other congenital defects such as cleft palate and arthrogryposis (see p. 177).

Contracted tendons usually affect both deep and superficial flexors, and sometimes the suspensory ligaments (see p. 178). The condition is bilaterally symmetrical in the forelimbs. The hindlimbs may have abnormal hock extensor rigidity and fetlock flexion.

Some breeds (e.g. Belgian Blue) have a very high incidence in which a relationship is suspected between relatively excessive fetal size and abnormal intrauterine posture. Dystokia is almost invariable in such cases. Akabane virus and the ingestion of various toxic plants (e.g. *Lupinus* species and locoweed) have been alleged in other high incidence outbreaks.

Clinical signs and diagnosis

Mild cases show about 10–20° excessive flexion of the carpus and fetlocks. Forced extension discloses the tautness in the flexor tendons and suspensory ligament. The abnormality is generally symmetrical. Some calves may have a split palate and arthrogryposis of the carpi and tarsi. Joints are not swollen and extension is not unduly painful. When moved, mild degrees of abnormal flexion will result in calves moving on the pastern, but, in severe cases, the calf is totally recumbent or will walk on the distal skin of the fetlock and rapidly develop abrasions and cellulitis, perhaps allowing secondary infection to establish itself and bring the risk of a septic arthritis.

Treatment and prevention

Some cases resolve but in others splinting of the leg is normally sufficient. A half-section of a 5cm (2 inch)

diameter polyvinyl drainpipe may be placed on a well-padded limb to immobilize the flexed joints in maximum extension. Such a splint in a neonatal calf must be checked by weekly removal and replacement. The toes should be left exposed to encourage weight bearing and walking. If the stance is not corrected in four weeks, surgery is indicated.

More severe cases will only respond to desmotomy, which should be undertaken at two to three weeks old, after the immediate neonatal stress period. Correction of carpal flexion is possible at the mediopalmar side of the carpus by an initial longitudinal incision through the retinaculum flexorum, exposure of the superficial part of the superficial flexor, and by complete transection of the retinaculum flexorum, which also involves section of the radial carpal flexor. If normal extension is not achievable, the deep flexor and deep part of the superficial flexor are transected, preserving carefully the neurovascular bundle of median artery, vein and nerves. Finally, the palmar carpal ligament may be sectioned. Exceptionally, with a radius–metacarpus angle <100°, it may be preferable to perform radiocarpal arthrodesis with resection of one or both carpal rows. The wound is closed by sutures and then bandaged and cast for five weeks.

Correction of fetlock flexion is similarly a multistep procedure. The skin incision is at the mediopalmar aspect of the metacarpus, and the superficial portion of the flexor tendon is transected. The deep flexor and deep part of the superficial tendon may be sectioned similarly for adequate extension. Small stab incisions may be made in the suspensory ligament. Bandaging and cast immobilization of the limb are again necessary.

Surgery is likely to be unsuccessful in very severe cases of contracted tendons where abnormal flexion creates an angle of <90° between radius and metacarpus.

Prevention of the primary aetiological stimulus is difficult as arthrogryposis leading to contracted tendons may result from infectious agents (bovine virus diarrhoea (BVDV), akabane virus) or toxic plant material.

Traumatic flexor tendon injuries

Sporadic traumatic injuries occasionally affect the flexor tendons and often result from contact with farm machinery. Adult cows may injure both deep and superficial flexor tendons in the metatarsal region, and an open infected wound results. Careful debridement under IVRA is indicated. A septic tenosynovitis necessitates pressure lavage with sterile isotonic saline b.i.d. for several days and systemic antibiotic cover. Selected cases of complete transection of both flexor tendons may heal following tenorrhaphy (e.g. carbon fibre or polyamide) and application of a limb cast. Despite

prolonged convalescence most cases continue to be lame and the prognosis is guarded (Anderson *et al.*, 1996).

Joint diseases

Osteochondrosis

Aetiology and pathology

Osteochondrosis (OCD) is seen in young fast-growing beef cattle on a high calorie intake. Recently an American series of 29 cattle with osteochondrosis was dominated by dairy breeds, primarily mature males (Trostle *et al.*, 1997). Normal endochondral ossification is disturbed at the cartilaginous endplate of the epiphysis and at the metaphyseal growth plate, and is associated with a failure of vascular invasion. The thickness of articular cartilage increases as a result of continued growth and lack of wear, whereupon the failure of adequate nutrient diffusion causes a degeneration of the chondrocytes. The result is a characteristic cleft formation, producing cartilaginous flaps that undergo endochondral ossification (osteochondrosis dissecans). Another process is the formation of subchondral cyst-like lesions.

It is not yet known to what extent the changes are generalized, as most surveys have only examined specific joints (e.g. stifle, carpus or atlanto-occipital). Changes tend to be symmetrical. Sometimes the joint surfaces of several forelimb bones are normal, while significant changes occur in their physes. Osteochondrosis has been reported in the coxofemoral, femoropatellar, femorotibial and tibiotarsal joints of the hindlimbs, and in the scapulohumeral, humororadial, radiocarpal, and metacarpophalangeal joints of the forelimbs.

Clinical signs and diagnosis

Steers and young bulls are predominantly affected. Some lesions cause no clinical signs, while others produce a mild progressive lameness. Some lesions heal following production of fibrocartilage. This accounts for the larger percentage of lesions in autopsies than in clinical series of lame cattle. Other lesions progress to become a secondary degenerative osteoarthritis or degenerative joint disease (DJD). Exacerbations of a mild slight lameness have been attributed to additional joint trauma. If warranted, a doubtful case may be radiographed, but cartilaginous defects are unlikely to be demonstrated unless pneumoarthrography is performed. Suspicious evidence of osteochondrosis is the presence of a free calcified body within the joint ('joint mouse').

Treatment and prevention

Theoretically, as in the horse and dog, removal of the cartilaginous flap and curettage of the underlying bone is indicated. Surgical treatment has, however, not been adopted in cattle for economic and anatomical reasons. Management measures in high-incidence situations include a more restricted calorie intake and transfer to a softer bearing surface to reduce concussion. Lame steers should be confined. Osteochondrosis in a bull should stimulate consideration of its conformation as a possible predisposing factor.

Hip dysplasia

Aetiology and pathology

Hip dysplasia is seen in bulls of various fast-growing beef breeds, predominantly the Hereford and Aberdeen Angus, though isolated cases have been reported in numerous other breeds. In the Hereford breed, particular families have been alleged to have a high incidence. The condition is probably a sex-linked heritable characteristic. Although some cases are observed in the neonate, most develop in calves four to twelve months old with erosion of the acetabular cartilage close to the attachment of the accessory cartilage, which normally functions to extend the effective articulating surface (Fig. 32.10). The femoral articular cartilage usually undergoes a shallower but more extensive erosion.

Later changes include traumatic synovitis, fraying of the intra-articular ligament, and a tendency to subluxation. Secondary degenerative joint disease follows in a few weeks.

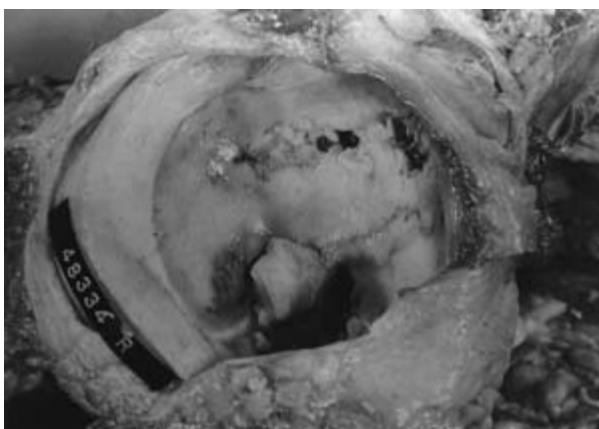

Fig. 32.10 Severe hip dysplasia seen in right acetabulum of nine-month-old Hereford bull. Severe fissuring and loss of cartilage and erosions in subchondral bone.

Fig. 32.11 Severe hip dysplasia evident in ventrodorsal radiograph of pelvis of five-month-old Angus bull that had experienced progressive hindlimb lameness for two months. Both femoral heads are subluxated and severe secondary osteoarthritis affects the acetabular rims.

Clinical signs and diagnosis

Lameness develops slowly and is preceded by a period in which abnormal lateral swinging of the hindquarters is seen. The bull calf spends increased periods in recumbency. Feed intake is reduced and hindquarter atrophy starts. Unilateral or bilateral crepitus is detectable in the hip region and may be localized more precisely if rectal palpation is feasible. The development of subluxation is recognizable from demonstration of the Ortolani sign: with the hand resting on the skin over the greater femoral trochanter, when weight is taken off the hind leg, a distinct 'plop' is felt as the femoral head drops into the acetabulum from its previous position on the dorsal acetabular rim.

In smaller calves, ventrodorsal pelvic radiographs may demonstrate secondary joint changes and a tendency to subluxation (Fig. 32.11). Any radiographic suggestion of shallowness of the acetabulum is usually the result of the secondary changes and not a primary anatomical feature.

Differential diagnosis is important in apparently unilateral cases. Stifle disease, acetabular and other pelvic fractures, hip luxation and slipped femoral epiphysis are all to be considered. A confirmed bilateral hip lameness in young bulls is usually diagnostic of hip dysplasia.

Treatment and prevention

No successful treatment has been reported. Affected bull calves and yearlings should be slaughtered. The hip joints should be retained for pathological confirmation of the clinical diagnosis.

Degenerative arthritis

Aetiology and pathology

Degenerative arthritis (degenerative joint disease, DJD) is attributed to a 'wear-and-tear' phenomenon. This chronic non-infectious disease involves primary degeneration of articular cartilage, generally accompanied by secondary sclerosis and eburnation of subchondral bone, peripheral osteophyte formation and surrounding soft tissue proliferation.

Though a common incidental finding at slaughter, its primary clinical significance is as a cause of progressive debilitating lameness involving major weight-bearing joints. In one study of the stifle and hip joints of cattle disease, atrophy frequently led to partial condemnation at slaughter (Weaver, 1977). A recent US study in 21 processing plants revealed that 11.9–16.5 per cent of beef and dairy cows and bulls had stifle arthritis ('stifled') or a broken leg. The stifle injury resulted in the loss of 17.9 kg tissue from trimming (\$9.72 per carcass) (Roeber *et al.*, 2000). Other studies have shown the frequent involvement of the hock and carpal joints. Overweight and straight-legged cattle may be predisposed to early DJD but control studies are lacking. An inherited DJD of the stifles of Holstein cattle has been reported (Kendrick & Sittmann, 1966). Nutritional imbalance leading to osteochondrosis (see p. 453), which can lead to secondary DJD, is another aetiological possibility.

Subchondral bone cysts were the most frequent cause of stifle lameness in a Canadian survey (Ducharme *et al.*, 1985). The lateral tibial condyle was most frequently affected, followed by the opposing femoral condyle. The age range was six to eighteen months.

Early fibrillation of articular cartilage leads to necrotic and degenerative chondrocytes, which results in decreased proteoglycan production in the cartilaginous matrix. The cartilage becomes soft and somewhat yellowish. Chondrocyte destruction causes release of lysosomal enzymes, especially cathepsin D. Fibrillated cartilage withstands stress relatively poorly, and fissuring, thinning, or cartilaginous erosion follows.

Pain in DJD originates from the exposed subchondral bone and from the associated capsulitis and synovitis. Clinically, the joint enlarges as a result of the increased volume of synovia and soft tissue proliferation.

Clinical signs and diagnosis

A progressive lameness with gradual muscle atrophy and weight loss is commonly seen. The affected limb, usually hind, tends to be dragged as flexion of the affected joint is reduced. Movement of the stifle or hock results in palpable joint enlargement. In the stifle,

proliferative changes (osteophyte formation, periarticular fibrosis) affect both femoropatellar and femorotibial compartments, and crepitus may be noted. Some cases of stifle DJD reflect a secondary response to cranial cruciate rupture or meniscal injury. In the hock, major changes are usually seen craniomedially, affecting the intertarsal and tarsometatarsal joint space (similar to equine 'spavin'). Relatively rarely do changes extend proximally to the tibiotarsal joint. Degenerative joint disease of the hip can be suspected in older cows when the more distal parts of the limb are normal clinically and where crepitus can be detected over the gluteal region and confirmed on rectal palpation.

Subchondral bone cysts can only be diagnosed on radiographic examination. Cases of DJD, ligamentous rupture and septic arthritis show ranging radiographic features. Degenerative joint disease of the stifle and hock shows the extent of the proliferative reaction. Lateral radiographs of the stifle in rupture of the cranial cruciate ligament have the 'drawer-forward' features seen in dogs. Septic arthritic cases on radiography demonstrate soft tissue swelling and distension of the joint capsule in early cases and, when more advanced, the radiographic changes include loss of subchondral bone.

Synovial fluid analysis is only justified when the differential diagnosis includes infectious arthritis or when fluid is withdrawn prior to injection of a local analgesic solution to assess whether lameness is lessened. Synovia in DJD is clear or slightly turbid, increased in volume, does not clot, has a low (<15 per cent) polymorphonuclear lymphocyte count, a normal protein (<2 g/dl), and a near-normal mucin precipitate (Weaver, 1997).

Differential diagnosis, apart from infectious forms of arthritis, includes fluorosis as a primary cause of DJD, osteoporosis, rickets and osteoarthritis deformans, all three of which occur in young growing animals, and osteomalacia. A sudden onset of lameness sometimes represents an exacerbation of a non-clinical DJD following a periarticular fracture (e.g. caudal surface of tibia in femorotibial DJD).

Treatment and prevention

Treatment is purely palliative. Affected cattle should be rested. Ketoprofen (10 per cent solution iv or im) has recently been shown to have analgesic properties in lame cattle. Phenylbutazone may be given (initially 5 mg/kg orally daily, then 5 mg/kg every second day) for its analgesic and anti-inflammatory properties. Aspirin (100 mg/kg orally b.i.d.) is an alternative regimen. Flunixin meglumine has few obvious advantages over either phenylbutazone or aspirin for arthri-

tides and is considerably more expensive. Prolonged low-dosage therapy with phenylbutazone in cattle with painful arthritides has not led to any demonstrable deleterious effects such as gastrointestinal ulceration or renal papillary necrosis. Corticosteroids and dimethyl sulphoxide (DMSO) have also been advocated. The majority of young cattle with stifle lameness due to subchondral bone cysts formation recovered following conservative treatment (Ducharme *et al.*, 1985). Preventive measures include attention to the conformation of further breeding stock, especially bulls, to avoid a hindlimb conformation that is liable to lead to excessive concussive forces in progeny.

Infectious (septic) arthritis

Introduction

Infectious arthritis in this context is synonymous with septic arthritis. The rare primary septic arthritis develops from direct joint penetration by a contaminated foreign body. This section considers secondary septic arthritis resulting from spread of pathogens from an adjacent localized focus, and tertiary septic arthritis resulting from systemic or haematogenous spread from a focus elsewhere in the animal.

Septic arthritis: joint ill in neonate (see p. 249)

Aetiology and pathology

Joint ill in calves is classified as a tertiary septic arthritis. The primary infection is in the umbilicus, often as an umbilical abscess with extension along the umbilical veins towards the liver. Otherwise, spread is from a primary enteric infection. Common pathogens isolated are *Escherichia coli*, *Streptococcus* and *Staphylococcus* spp., *Arcanobacterium pyogenes*, *Erysipelothrix insidiosa* and *Salmonella* spp. Usually, more than one joint is affected, commonly the carpus, tarsus and femorotibial joints. The route of haematogenous spread is through metaphyseal or epiphyseal vessels or, alternatively, the synovial membrane. Establishment of foci of infection is naturally favoured by the slowed flow rate of blood through a network of venous sinusoids in the metaphyseal vessels.

Pathological changes start with an intense polymorphonuclear inflammatory response in the synovial membrane, the permeability of which is increased, permitting protein leakage into the synovial fluid. Later release of lysosomal and other enzymes into the synovia causes degeneration of the articular cartilage, which is weakened by defective nutrition due to an overlying fibrin deposit. The result is extensive loss of articular cartilage, acute synovitis, thickening of the

Fig. 32.12 Extensive soft tissue swelling of lateral aspect of left carpal region in a six-month-old Hereford calf. Bone lysis is evident in the distal part of the radial carpal and fused second and third carpal bones. Lysis resulted from transverse fracture of the proximal surface of the distal component of the joint. Recovery followed removal of the bone fragment, curettage and irrigation.

joint capsule, and sepsis in the growth plate and metaphysis (particularly associated with salmonella infection).

Clinical signs and diagnosis

The first sign is lameness. Later, joint swelling (Fig. 32.12) and pain are apparent. The joint capsule may be distended from an increased synovial volume. The presence and physical nature (serous, fibrinous or purulent) of such synovial effusions can be readily detected on ultrasonography (7.5 mHz linear transducer) in carpal, stifle and hock disorders (Kofler & Martinek, 2000). The polyarthritis is rarely symmetrical. Not all cases are associated with either gross umbilical sepsis or with severe enteritis. Calves that are immune depressed as a result of low gamma globulin levels (inadequate

colostral intake) are at higher risk. Lameness becomes severe after a few days.

Radiology is not a great aid to diagnosis, as the only initial abnormality is the soft tissue swelling. After two to three weeks, changes suggestive of joint destruction are apparent.

Arthrocentesis is a more valuable aid to diagnosis in early cases. Apart from an increased volume, synovial fluid in a calf with joint ill is turbid, clots, and has a loose flaky character in the mucin precipitate. The protein content is >5 g/dl and a Giemsa smear reveals an almost pure (98 per cent) and massive population of polymorphonuclear lymphocytes. Taken aseptically, synovial fluid may be submitted for culture, but is often problematical with this particular material (see p. 457).

Differential diagnosis must be made from physeal and intra-articular fractures.

Treatment and prevention

Early and vigorous treatment is essential in joint ill. High therapeutic levels of systemic antibiotics should be given for two to three weeks. Intra-articular antibiotic medication is usually contraindicated, as the blood supply ensures adequate concentrations are obtained in synovia following systemic injection. Suitable antibiotics include penicillin, ampicillin and tetracyclines.

Joint lavage with a sterile polyionic solution or physiological saline is helpful. Generally, an in-out, through-and-through system using two 14 gauge needles is effective. Open arthrotomy with removal of the fibrin clots and purulent material along with curettage of the articular surfaces has been successful in some series. It appears more useful in less complex joints such as the stifle and fetlock rather than in carpus or tarsus.

Recently intra-articular therapy with gentamycin-impregnated polymethylmethacrylate beads has proved useful in neonatal septic arthritis with concurrent osteomyelitis. Such beads must be removed at a second surgery. Use of gentamicin-impregnated collagen sponges (Garamycin, Essex Chemie, Lucerne, Switzerland) which do not need later removal appear more promising, and further larger studies are awaited (Steiner & Zulauf, 2000).

Supportive care is important. Casting for three weeks of joint immobility (e.g. in fetlock) followed by bandaging for support reduces discomfort and so maintains the appetite. Low level oral dosage with phenylbutazone can improve the general attitude (p. 1050). Some calves also require management of the enteritis by fluid therapy (see pp. 195, 209) and others require drainage of an umbilical abscess. Inadequate levels of gamma globulins may, with difficulty due to the large volumes, be corrected by giving intravenous plasma.

Septic arthritis: older cattle

Aetiology and pathology

The main site of septic (infectious) arthritis in mature cattle is the distal interphalangeal joint resulting from secondary spread from a focus in the sensitive solar laminae or from complications of interdigital necro-bacillosis (see pp. 420 and 426).

Septic digital arthritis is fully discussed elsewhere (p. 455). Other joints liable to be affected by septic arthritis include the fetlock, either by extension along the digital flexor sheath from a digital focus, or by direct trauma from a deep wound (Fig. 32.13). The major hindlimb weight-bearing joints, the tarsus, stifle and hip are occasionally involved as a result of haematogenous spread such as pyaemic vegetative endocarditis (e.g. from primary reticuloperitonitis) or in the tarsus from contiguous spread from an infected subcutaneous bursitis.

Organisms commonly recovered from septic arthritis in adult cattle include *A. pyogenes*, *E. coli*, *Staphylo-*

coccus and *Streptococcus* spp. *Fusobacterium necrophorum* and *Bacteroides melaninogenicus* (anaerobe) have occasionally been reported. The major problem is *A. pyogenes*. Once infection is in the synovial fluid, joint destruction involves the same processes as described for DJD. The difference lies in the speed of destruction. The synovia is usually turbid or frankly purulent.

Some reports from the UK (Bracewell & Corbell, 1979; Wyn-Jones *et al.*, 1980) and USA (Madison *et al.*, 1989) noted an idiopathic, acute suppurative gonitis with severe lameness and synovitis. Articular erosions were evident radiographically on the lateral tibial plateau. Much evidence indicates the likelihood that *Brucella abortus* vaccination may have been the cause.

Clinical signs and diagnosis

Septic arthritis in a major weight-bearing joint causes a rapidly progressive disease with severe lameness, swelling and localized pain. In contrast to DJD, the animal may be anorexic and milk yield can drop abruptly in dairy cattle. Crepitus is not usually apparent. Arthrocentesis reveals a flocculent or purulent fluid that clots. It has a high leucocyte count of which over 90 per cent are polymorphs. The protein content often exceeds 8 g/dl and the mucin precipitate is abnormally flocculent.

A category ‘suspect septic’ refers to an early septic process associated with obvious lameness but apparently normal yellow synovia. The presence again of a high percentage of neutrophils in a dense leucocyte population is confirmation of early septic arthritis. Radiography in early (<10 days duration) septic arthritis is usually unhelpful. Ultrasound, on the other hand, can delineate the limits and physical nature of the fluid. From 14 days onwards, subchondral bone destruction and a peripheral periostitis are suggestive of joint sepsis.

Culture of synovial fluid is frequently negative in terms of isolation of pathogens, especially if antimicrobial therapy has already started. It is helpful if synovia is immediately inoculated into a diphasic culture bottle with sodium polyanetholsulphonate to enhance recovery of the organism. Culture of synovial biopsy material is usually more rewarding but is frequently impractical.

Treatment and prevention

The prognosis for septic arthritis is guarded or poor. Early aggressive treatment is essential. Parenteral antibiotic therapy should be initiated as soon as possible. Until sensitivity, based on synovial cultures, is available 48 hours after sampling, penicillin or

Fig. 32.13 Massive periosteal proliferation of fetlock region (metatarsophalangeal joint) of a four-year-old Holstein cow resulting from sepsis of the joint originating from an ascending septic tenosynovitis.

ampicillin is the drug of choice for most pathogens. Penicillin is most likely to be effective *in vivo* against all common pathogens except *Staphylococcus aureus* (where erythromycin, lincomycin, gentamicin, or cephalosporin may be better) and coliforms (gentamicin or trimethoprim-sulphadiazine).

The joint should be irrigated and drained (through-and-through lavage) through two wide-bore inflow-outflow portals produced by 14 gauge needles. Alternatively, small arthrotomy incisions may be made for the same purpose. Irrigation should be done with large volumes (>5l) of polyionic solutions, physiological saline, or with dilute (0.1 per cent) povidone-iodine solution.

Radical surgery also has a place if suitable facilities exist for the maintenance of asepsis and for general anaesthesia. Radical surgery comprises opening the joint following section of collateral ligaments and incision of joint capsule, evacuation of purulent material, curettage of infected cartilaginous surfaces, restoration of joint stability by suturing capsule and ligaments, and immobilization of the area, if in the distal limb, to prevent ankylosis. Such surgery appears more successful in the fetlock, carpus and tarsus than in the stifle, elbow, or shoulder joints.

Idiopathic gonitis (p. 1014) carries a good prognosis for recovery, regardless of the method of treatment. Heifers were treated successfully with a variety of antimicrobials, including procaine penicillin G, neomycin and ampicillin, and, in some cases, with through-and-through needle lavage with a polyionic solution. Lateral patellar arthrotomy with curettage of lytic areas on the lateral tibial plateau may be useful adjunct therapy.

There is no place for intra-articular antibiotics. Drainage of infective material from a poorly vascularized area is important, whereas systemic antibiotics adequately penetrate the well-vascularized joint capsule. Antibiotics should be given for at least two weeks. Preferred antibiotics are usually penicillin G, ampicillin, ceftiofur and gentamicin. Non-steroidal anti-inflammatory drugs should be given if pain is severe and persistent. The dosage is as for cases of DJD (see p. 455).

Miscellaneous neuromuscular diseases

Spastic paresis (see also p. 179)

Aetiology and pathology

Spastic paresis is a progressive condition of the hind-limbs of unknown origin. It is characterized by contraction of the gastrocnemius muscle and tendon and of other associated calcanean tendons and muscle bellies.

This spasm leads to severe extension of the hock. The condition has been observed in numerous breeds, but the highest incidence in dairy and beef cattle respectively is probably in the German and Dutch Friesian and the Aberdeen Angus.

It is hypothesized that an overactive stretch reflex is the major mechanism (De Ley & De Moor, 1977). Selective deafferentation of the gastrocnemius muscle by resection of the dorsal root fibres containing afferent nerve fibres (L5–6) abolished clinical signs. Plasma SGOT is reduced, and alkaline phosphatase is increased in affected calves, which also show a decreased P, Ca, and homovanillic acid concentration in CSF. The last-named effect indicates a lowered metabolic rate of CNS dopamine (De Ley & De Moor, 1975).

Gross and histopathological CNS lesions have generally been absent.

Clinical signs and diagnosis

The typical clinical signs are characteristic, and difficulty arises only in very early cases. Signs may start at six weeks to six months, rarely later. Cases encountered in adult cattle are best considered to be forms of progressive hindlimb paralysis, likely to involve spinal cord pressure resulting from vertebral exostoses.

The affected hindlimb is extended so that the hock angle is approximately 180° (normal is about 140°). The calf walks with a tendency to drag the toes. The limb may jerk intermittently at rest. It is advanced in a pendulum-like style. Later, less weight is taken and the calf may hop forward. Palpation reveals a very firm gastrocnemius muscle and tendon. The hock can be flexed manually without causing pain. On release the hock immediately adopts the original extended position (Fig. 32.14).

Lateral radiographs of the hock of calves affected for several weeks show several features indicative of the chronic overextension. The distal part of the tibial metaphysis is abnormally curved caudally; the distal tibial and tuber calcanei growth plates are widened; exostoses are present around the distal tibial growth plate, along with some osteoporosis. Often the most striking feature is a cranial curvature of the proximal part of the calcaneus.

In early cases, differential diagnosis includes dorsal patellar luxation, septic or non-infectious gonitis or tar-sitis, fracture dislocation of the calcaneus, joint ill and luxation of the biceps femoris muscle.

Treatment and prevention

Since spastic paresis has a hereditary predisposition, breeding animals should be salvaged. Surgery can successfully alleviate the condition by either tenotomy or neurectomy.

Fig. 32.14 Severe spastic paresis of left hindlimb of a four-month-old Friesian heifer, showing overextension of hock joint. Note spasm and elevation of the tail, and arched back as calf attempts to put more weight on the forelimbs.

Tenotomy has traditionally involved section of the gastrocnemius tendon and partial section of the superficial flexor tendon a little proximal to the point of the hock in the standing animal under local anaesthetic infiltration. A 6cm (2½ inch) vertical skin incision is made caudally over the Achilles tendon to expose the two tendons. After section, the skin is sutured and the immediate surgical effect is usually pronounced hock flexion, with the joint initially close to the ground. Initial results have been consistently favourable, but a gradual recurrence of the abnormal posture is frequently seen, especially in older (six to ten-month-old) calves. Bilaterally affected calves should have the second leg operated four weeks following initial surgery.

It has been claimed that this classical operation ignores the fact that a second, deeply situated, tendon of insertion of the gastrocnemius muscle is left untouched. A modified operation, therefore, involves a lateral approach just cranial to the Achilles tendon, which is dissected to isolate the caudal component of the gastrocnemius tendon, from which a 2cm (1 inch) length is resected. The superficial flexor tendon is left untouched. The cranial tendon of the gastrocnemius is identified and a similar tenectomy performed. In some cases, the dense fascia caudal to the distal end of the tibia is transected (Pavaux *et al.*, 1985).

Neurectomy of the tibial nerve or of its gastrocnemius branches is the alternative to tenotomy. Clinical results have been better than with tenotomy. Since identification of the multiple (seven or more) branches of the tibial nerve innervating the gastrocnemius

muscle is awkward, complete tibial neurectomy has been advocated (Boyd & Weaver, 1967). Surgery is performed under sedation and epidural block, or general anaesthesia. The site is the lateral thigh, between the two heads of the biceps femoris muscle. The tibial and peroneal nerves are identified by stimulation by forceps or by electrical means. Tibial nerve stimulation causes hock extension and fetlock and digital flexion. The tibial nerve should have a 2cm (1 inch) portion removed at its most proximal point. Complications following this surgery are uncommon.

Spastic syndrome

Aetiology and pathogenesis

This chronic progressive disease, which is initially characterized by clonic-tonic spasms of the hindlimb musculature, is also known as 'crampy', 'stretches' or progressive hindlimb paralysis. The aetiology is unknown despite several attempts to find significant pathological lesions in the brain or spinal cord. Idiopathic muscular cramps is one current proposed explanation for the signs (Wells *et al.*, 1987).

The condition occurs in mature cattle of many breeds, both dairy (e.g. Holstein, Friesian and Guernsey) and beef (Hereford, Angus). The incidence in at least one breed (Danish Red) is significantly higher in bulls than cows. Many affected cattle have straight rear legs and poor hock conformation. Many bulls with spastic syndrome have spinal spondylosis. A single recessive gene with incomplete penetrance may be the mode of inheritance.

Clinical signs and diagnosis

Sudden episodic spasmodic contractions affect the muscles of both hindlegs, and sometimes also the back, neck and forelegs. The animal appears to be normal during recumbency. Signs are evident soon after rising.

The onset of the syndrome is slow, and signs may appear for a few months only to disappear for several weeks. The hindlimbs are hyperextended caudally in a fixed manner that may persist for several minutes. Spasms may extend forward to the forelimbs and neck muscles. The head is extended and the forefeet advanced with the back arched. If then forced to move, the gait is stiff and ungainly, and episodic lifting of the hindlimbs may also be seen during forward movement.

Animals generally spend considerable periods recumbent when the condition is advanced.

Other conditions that may confuse an initial diagnosis are relatively few but include bilateral DJD affecting the stifle or hock, and severe spinal spondylosis.

Treatment and prevention

The spastic syndrome is incurable. Palliative treatment has included vitamin D, bone meal (not available in many countries) and sedatives. Phenylbutazone has provided temporary relief in some cases. Affected bulls and apparently normal bulls that sire affected progeny should be culled from any breeding programme.

Diseases of skin and subcutis

Skin wounds are more liable around the limbs than the trunk and head. Their nature and treatment are adequately discussed in textbooks of general surgery. One unusual bovine problem is the constricting foreign body, usually rubber or wire, which slides over the foot to the level of pastern or metacarpus or metatarsus where it slowly becomes embedded in a mass of granulation tissue to present as a circumferential wound (Fig. 32.15). Such wounds require careful investigation because the band may be very deep and contacting bone.

Two specific disorders are discussed below. Generally, damage to skin and subcutis is more liable over pressure points such as the lateral aspect of the stifle, elbow and hock. Loss of the integument permits low-grade infection to become established. In a very contaminated environment such damage, arising from

Fig. 32.15 Circumferential wound of metatarsal soft tissues. This two-year-old crossbred Hereford steer had a wire embedded deep to the soft tissues, resulting in mild lameness. Wound healed in four weeks following removal of foreign body.

pressure points and poor vascularity, may result in localized abscessation and pyaemic spread to the lungs, liver, kidneys and heart. The common organism is *A. pyogenes*.

Affected cattle should be put out on soft bedding, the wounds should be cleansed with chlorhexidine hydrochloride, and systemic antibiotics should be injected for five to seven days to prevent systemic spread. The prognosis for healing is good if appetite is maintained unless clinical signs of involvement of other organs (e.g. heart) are apparent, and suggestive of septicæmic spread.

Tarsal cellulitis

Aetiology and pathology

Almost all cases of hock enlargement result from repeated trauma against concrete surfaces in stanchions or loose housing. Typically, soft tissue swelling over the lateral aspect of the tarsus may be a false or acquired bursitis. Medial swelling of the joint is minimal unless the lateral enlargement is pronounced. Lameness is rare unless the fluid distension becomes massive, when mechanical restriction of joint flexion causes stiffness, or a low-grade infection arises. Radiographs have repeatedly shown the absence of bone changes.

The swelling is usually symmetrical. Hair loss and skin excoriation are evident. Usually the skin is not broken. Occasionally, a central area of skin sloughs, permitting a dirty red-brown material to escape. At this time, septic infection can supervene and a purulent discharge may be noted for several days before granulation tissue fills the cavity of the false bursa.

Clinical signs and diagnosis

The distribution of the swelling and absence of lameness are almost characteristic (Fig. 32.16). An infectious tarsitis causes a more diffuse swelling and obvious lameness, as will a tarsal bone fracture. Tarsal hydrarthrosis first causes synovial distension of the joint capsule cranially and medially, then both medial and lateral to the caudal border of the tibiotarsal bone, and cranial to the base of the calcaneus. Tarsal hydrarthrosis is a cosmetic blemish and causes no lameness.

Treatment and prevention

The seasonal occurrence of tarsal bursitis, becoming increasingly severe during the housed period and disappearing in the summer grazing months, is evidence that tarsal bursitis is related to the specific environment. Errors and deficiencies usually can be found in the lying-in areas of loose-housed herds. Some cows may

Fig. 32.16 Right tarsal bursitis in a five-year-old Holstein cow with digital problems resulting in prolonged recumbency. Left supratarsal skin shows evidence of previous injury.

Fig. 32.17 Severe bilateral carpal bursitis in an eight-year-old Friesian cow associated with *Br. abortus* infection (Czechoslovakia).

refuse to use cubicles and remain out on the slurry-covered concrete. They often have problems rising from the slippery surface, during which the wet skin of the lateral part of the hock is repeatedly abraded. Other cows suffer injury when they rise awkwardly in poorly designed or badly bedded cubicles. Standings that are up to 30cm (12 inches) too short for the particular breed and neck rails placed 5cm (2 inches) too low may force cows to stand with the hind feet in the passageway. Careful observation (e.g. during oestrous detection) will usually disclose the specific problem.

Treatment should be conservative and medical. It should never involve a long incision to drain fluid from the false bursa, neither should one attempt radically to dissect out this bursa. Most cases are best left untreated in the absence of lameness. If lameness eventually occurs as a result of a low-grade tarsal infection, systemic antibiotics (oxytetracyclines) rapidly reduce the size of the swelling. Corticosteroids are usually ineffective. Infected cases may be bandaged daily and be irrigated with warm water, but the response tends to be incomplete. A cluster of cases indicates a need to check the loafing areas and cubicles (Hughes, 2000).

Carpal bursitis

Aetiology and pathology

Carpal bursitis or carpal hygroma involves the skin, subcutaneous precarpal bursa and adjacent soft tissues. Very rarely does infection extend into the joint. Repeated contusion from contact points of the stanchions, stalls, or floor in housed cattle is the main predisposing factor. The condition is similar to tarsal

cellulitis in that the swelling resolves in cattle when at pasture. Some cases have been associated with *Br. abortus* infection (Fig. 32.17; see also p. 580).

Clinical signs and diagnosis

A soft and painless swelling develops on the dorsal aspect of the carpus, usually with evidence of skin contusion. It tends to be symmetrical and no breed or age predilection is recognized. Minor swellings are merely a cosmetic blemish. The exceptional large grapefruit or melon-sized mass may cause slight mechanical lameness but is painless. The fluid appears to be synovia-like, yellow and clear, but less tenacious. It is produced by the bursal lining. The cavity tends to be multilocular. Differential diagnosis from a precarpal abscess or septic carpititis, both of which are painful and cause lameness, is simple.

Treatment and prevention

Surgical drainage is rarely necessary. Such drainage (as in tarsal bursitis, p. 460) is fraught with the risk of introducing infection into a sterile site. The skin is more liable to contamination every time the animal lies down. It is hard to protect the area with a bandage. Most cases respond if placed in a well-bedded straw yard (winter) or put to pasture (summer), i.e. into surroundings where predisposing trauma can be avoided.

Drainage is needed only when gait, feed intake and production are affected. The drainage should be done as an aseptic procedure. A mixture of antibiotic and corticosteroid solution should be instilled into various

sections of the collapsed cavity and such injection should be repeated at weekly intervals.

Radical surgical removal of the bursa and excessive skin is possible, but is a haemorrhagic and time-consuming process despite the presence of a tourniquet proximal to the carpus. General anaesthesia is usually required as adequate local infiltration of the bursal wall is impractical.

Destruction of the bursal lining with an astringent (copper sulphate) or irritant disinfectant (tincture of iodine) is not advisable, as a severe local reaction is produced, and dissection, curettage and repeated irrigation of the wound are essential steps before secondary healing eventually occurs.

Prevention involves careful attention to the housing system for the existing herd. Problem cows should be put into straw yards before the swellings cause a clinical problem.

Ankylosing spondylitis

Aetiology and pathology

Generally confined to old bulls and defined as an acquired fusion of the ventral aspects of the bodies of the caudal thoracic and lumbar vertebrae, sufficient pressure may be exerted on the ventral and lateral spinal cord tracts or the ventral nerve roots to cause some hindlimb weakness, ataxia or paralysis. Exostoses first develop on the ligaments of the caudal 2–3 thoracic and cranial 2–3 lumbar spinal bodies (T11–L3). Degenerative changes in the intervertebral discs may predispose to exostosis formation. The new bone may extend into the spinal canal as ‘replacement bone’. Sometimes, possibly resulting from a fall or a violent ejaculation, part of the exostosis may fracture, the fracture line extending through the vertebral body. Fluid exudate (blood, oedema) from the fracture may cause pressure on the spinal cord.

Clinical signs and diagnosis

An early sign may be a reluctance or difficulty in mounting cows, attributable to the mechanical effects of a relatively inflexible thoracolumbar spine. Usually there are no premonitory signs and the bull suddenly has difficulty in rising and may adopt a ‘dog-sitting’ position or may be completely paraplegic, dragging the digits caudally. Sometimes marked ataxia suddenly develops.

The site of trauma can rarely be accurately defined due to problems of size. Crepitus is rarely elicited. Swelling of the back musculature is not seen. On rectal examination, exostoses may be palpable dorsal to the aortic bifurcation, but such exostoses are a normal

feature of mature and older bulls. In one extensive series of bulls followed to slaughter, severe signs of tail and hindlimb paralysis were only seen in two cases, though all bulls had varying degrees of ankylosing spondylitis.

Differential diagnosis includes other causes of spinal cord compression such as aberrant migrating larvae and infiltrating neoplasms such as lymphosarcoma as well as hindlimb degenerative joint disease.

Treatment and prevention

The prognosis depends on the degree and extent of nerve damage. In the progressive ataxic or paraplegic case, it is poor. Mild cases may improve following rest and use of corticosteroids and diuretics to reduce the oedema. Animals should be bedded on deep straw to prevent the development of decubital lesions. Many mild cases relapse following partial recovery. Slaughter on humane grounds is often the action of choice.

Mineral imbalance-related lameness: rickets, osteomalacia (see also p. 253)

Aetiology and pathology

Mineral, indeed nutrient, imbalance can result in lameness from calfhood through the growing yearling stage to maturity and old age. The pattern almost invariably involves an imbalance or deficiency of two or more factors.

During growth the important elements in normal development of healthy bone collagen, which is the framework for provisional calcification of the zone of hypertrophied cartilage, are vitamin D, copper, protein and energy. Mineralization of the cartilaginous matrix results in deposition of much calcium, phosphorus and carbonate, with lesser amounts of sodium, magnesium and fluoride. Vitamin D, calcium and phosphorus are essential to the formation of this bone mineral.

In the prenatal period, identified deficiency diseases resulting in abortion or the birth of progeny with skeletal defects include lupinosis (congenital arthrogryposis), manganese (contracted tendons), and zinc and vitamin A deficiencies (multiple defects).

Vitamin D deficiency in calves leads by a complex pathway involving the parathyroid gland, kidney and intestine to deficient calcification of long bones and of the cartilaginous matrix. The result in calves is rickets. The zone of provisional calcification is widened but the new osteoid is not mineralized. In adults, the same deficiency causes osteomalacia, which is rare except in northern Australia and South Africa. Usually a calcium: phosphorus imbalance is also involved. Vitamin

D-deficient diets may be identified on some farms where feed is home-mixed.

Clinical signs and diagnosis of rickets

Calves have enlarged metaphyses and growth plates of the long bones, especially the distal metatarsus and metacarpus, fetlock and pastern. The swellings are rather painful to pressure. The costochondral junction exhibits the classical 'ricketty rosary' in calves. Radiographic changes include a widened area of radiolucency at the growth plate with flaring of the distal metaphyses, usually in the carpus, pastern and fetlock.

The diagnosis rests on the soft tissue swelling at characteristic sites, lameness, and in cases of doubt, feed analysis. Serum or plasma may reveal depressed levels of calcium, phosphorus and an elevated alkaline phosphatase.

Differential diagnosis includes physeal dysplasia and joint ill (polyarthritis).

Clinical signs and diagnosis of osteomalacia

The relative or absolute phosphorus deficiency, usually acquired from low phosphorus pastures, is classically associated with the development of pica and osteophagia, variable degrees of lameness including pathological fractures of long bones, weight loss, stiffness and recumbency. Deficiency tends to be exaggerated in cows due to the demands of pregnancy and lactation. Fertility may be severely reduced. Hypophosphataemia is accompanied by normal blood levels of calcium. The condition must be distinguished from DJD.

Vitamin D-deficient osteomalacia in grazing animals is seen in temperate climates with a shortage of sun-cured hay and affects cattle stressed by the demands of pregnancy and lactation. The clinical manifestation resembles the phosphorus-deficient form.

Treatment and prevention

In rickets, increased vitamin D in the ration along with restoration of a normal Ca:P ratio with adequate intake brings a rapid response.

Osteomalacia in adult cattle is treated by dietary supplementation with rations high in phosphorus.

Osteomyelitis

Aetiology and pathogenesis

Osteomyelitis of the limb bones in cattle occurs in two forms: one in growing cattle, the other in adults.

Fig. 32.18 Distal right radial septic physitis in two-year-old Holstein heifer. Weight bearing is minimal due to severe pain and soft tissue swelling. The aetiology, in the absence of penetration, was probably haematogenous.

A haematogenous form is seen in calves six to twelve months old as a result of *Salmonella* infection, which localizes in the metaphysis, physis and epiphysis of long bones such as the metacarpus as well as the upper limb where an embolic process may be responsible (Kersjes *et al.*, 1966; Gitter *et al.*, 1978). Blood flow through the metaphyseal sinusoids is slow, facilitating easy bacterial deposition and proliferation. Many clinical cases are multifocal and cause rapid destruction of bone. Other organisms in calves include *A. pyogenes* and *E. coli*. In older, growing cattle, less than two years old, a growth plate osteomyelitis may involve the distal metatarsus or distal tibia. Common bacterial isolates are *A. pyogenes* and *Salmonella* spp. (De Kessel *et al.*, 1982). Periarticular soft tissue swelling is prominent (Fig. 32.18). The radiographic extent of bone destruction is very variable and appears to be unrelated to the involvement of epiphysis and metaphysis, which are equally likely to be affected. Many cases have infected sequestra in the osteomyelitic focus.

In adult cattle, osteomyelitis of long bones is a sporadic isolated phenomenon. The aetiology may again involve haematogenous spread, or may arise following direct trauma. Open long bone fractures are an obvious example (see p. 441). Less obviously, saucer fractures of the diaphysis may lead to formation of a sequestrum. Sequestra in long bones of cattle are related to common sites of lacerating wounds, notably the proximal half of the dorsal aspect of the metatarsus (Firth, 1987). This author hypothesizes that severe contusion alone may produce sufficient subcutaneous soft tissue damage to render the area susceptible to infection and subsequent adjacent bone sequestration.

A chronic sequestrum in a long bone may develop a fistulous tract, which permits easier delineation of the bone by insertion of a positive contrast agent for a fistulogram.

A specific form of osteomyelitis is Brodie's abscess, which is a circumscribed abscess lined with a granular membrane surrounded by sclerotic bone. Synonyms are chronic fibrous osteomyelitis and chronic bone abscess. Though the lining is histologically a definite pyogenic membrane, bacteriological culture may be sterile. Both *F. necrophorum* and *A. pyogenes* have been involved in cases of Brodie's abscess in three and six-months-old calves (Weaver, 1972).

Clinical signs and diagnosis

Osteomyelitis usually causes severe, continuing pain with local swelling. These signs relate to the active process such as long bone infection following an open fracture when, if left untreated, purulent material, sometimes with bone spicules, is discharged to the exterior. Cellulitis may be severe and additional sinuses may form.

Osteomyelitis in calves where infection is within and surrounding the epiphysis presents differently. Localization of the lameness may be difficult due to the absence of local swelling but pain is usually evident.

Chronic osteomyelitis may not cause lameness when the infected focus is effectively walled off by dense sclerosed bone (involucrum). Sometimes, in such cases, lameness suddenly develops as infection flares up once more.

Osteomyelitis rarely extends to involve joints except in the digit and any resentment to joint flexion is usually due to extension from the diaphyseal or metaphyseal focus.

Systemic effects of osteomyelitis include lassitude, mild fever and a reduced appetite. Radiology is indicated in most cases to confirm the diagnosis, to determine the extent of the pathological process, and to assess the possibility of useful surgical intervention. Osteoporosis results from the loss of bone by erosion and its replacement by infected granulation tissue. Periosteal new bone is often evident and is variable in amount. Initially, the periosteum is elevated over an osteomyelitic focus with an underlying loss of cortical density. Later, in animals where a sequestrum forms, new subperiosteal bone is deposited while sclerosis is evident around the sequestrum.

Differential diagnosis of osteomyelitis with an open wound involves determining the primary lesion. Some cases of wounds may not involve the periosteum and lameness may reflect pain due to subcutaneous absces-

sation, septic myositis or extensive intramuscular abscessation. Open wounds should, therefore, be explored with a sterile probe.

Osteomyelitis of long bones without evidence of skin trauma must be differentiated from fissure fractures, subperiosteal haematoma, subcutaneous abscesses and rare bone tumours. In calves, haematogenous bacterial infection of metaphysis, growth plate and epiphysis must be distinguished from joint ill, epiphyseal separation and metaphyseal fractures.

Treatment and prognosis

Cattle with systemic involvement (pyrexia, anorexia) should be given parenteral antibiotics for three to five days. Many cases respond to this therapy. Non-responsive cases should be considered for surgery. This applies particularly to cases of Brodie's abscess and incision should be made over the metaphysis to attempt aspiration of the contents of the abscess if subperiosteal in position. In other cases a sinus tract through the cortex may be enlarged to evacuate the contents and to permit curettage of the adjacent necrotic bone and pyogenic membrane.

Cattle with open long bone fractures and osteomyelitis should have sequestra removed and check radiographic films taken. Treatment then depends on the type of fracture and extent of osteomyelitis. The options are discussed elsewhere (p. 442).

Calves with bacterial infection of the metaphysis sometimes respond to parenteral antibiotics alone, otherwise local debridement and irrigation of the focus is justified.

Physeal dysplasia

Aetiology and pathology

Physeal dysplasia, also loosely termed epiphysitis (though the epiphysis is not involved in an inflammatory process), is primarily a defective development of one or more growth plates, which later may become necrotic and inflammatory and later still may be purulent. The problem usually affects the lower limb, especially the carpal and fetlock joints. The pathogenesis apparently involves a reduced blood supply to the growth plate as a result of uneven or excessive mechanical pressure. The metaphyseal side, dependent on an adequate blood supply for calcification and ossification, is more affected than the epiphyseal surface. The pathological process has not been thoroughly investigated in cattle, but necrosis of the ground substance, resulting

from folding of the cell columns and loss of continuity, has been noted histologically in housed fattening cattle. Poor-quality, uncomfortable floor surfaces predispose rapidly fattening cattle with limited exercise space to physeal dysplasia.

Gross pathology reveals some subcutaneous oedema and red or red-grey discolouration around the growth plate, which is either necrotic or, in severe cases, purulent. In its most severe form the growth plate undergoes separation.

Copper deficiency or a combined copper–molybdenum deficiency (see pp. 254, 298) has also been associated with physeal dysplasia as a result of defective collagen formation. The abnormal collagen does not permit normal mineralization. The result is stiffness and lameness in calves with a characteristic distal metatarsal swelling. Another result is an increased incidence of long bone fractures.

Clinical signs and diagnosis

The swellings are usually symmetrical, and hindlimbs are affected more often. The enlarged area in the lame calf or yearling is painful. Weight loss is rapid in beef cattle aged nine to eighteen months. Occasionally, several animals in a group of cattle are affected simultaneously following violent exercise, for example at turning out to pasture from confined housing. Isolated cases may result from trauma on slats.

In the copper-related form the limbs may be bowed either laterally or medially, the gait is stilted, and the swellings tend to be symmetrical. However, other signs of copper deficiency are present, including unthriftiness, a rough discoloured hair coat and diarrhoea.

Radiographic features include rarefying lesions with an increased width of the growth plate with irregularity and fragmentation, but with an absence of reactive change around the metaphyseal margin. The radiographic changes are more severe in cattle with physeal separation and secondary repair. Milder radiographic changes are evident in many cattle of the same group that do not show lameness.

The list of differential diagnoses includes rickets, traumatic separation of the growth plate, bacterial osteitis, septic arthritis and fractures. Radiography is necessary to permit this differentiation.

Treatment and prevention

Only the copper-related syndrome is responsive to treatment by an appropriate diet change. Mild non-copper-related cases respond to rest and external support by lightweight casting. Most cases of such

Fig. 32.19 Massive septic myositis in right hindquarters of two-year-old Saler bull. The light area (shaved) shows the site of exploratory needle puncture. Abscess cavity contained 12 litres of pus. *Actinomyces pyogenes* was recovered in pure culture. Severe oedema extends down to the hock. Recovery followed drainage and irrigation.

lameness should be salvaged before there is further weight loss.

Lameness of iatrogenic origin

Some forms of upper limb lameness may be the result of treatment for disease or injury. Various entities have been discussed elsewhere: radial paralysis from prolonged lateral recumbency during anaesthesia (p. 436), neonatal long bone fractures and physeal separations resulting from excessive traction in dystokia (p. 444), and traumatic injury and transection of the gastrocnemius tendon (p. 451). Another form of iatrogenic damage is that following intramuscular injections. Occasionally, particularly in calves, the sciatic nerve may be injured. More frequent is the development of an abscess following a subcutaneous injection, which rarely causes lameness but remains a cosmetic blemish. When a non-sterile preparation, or a dirty syringe and needle are used for an intramuscular injection, the results may be more serious. As a rule, infection is sealed off by fibrous tissue with no ill-effects. Sometimes the result is a massive abscess, which causes lameness and requires prompt surgical drainage and daily irrigation to prevent recurrence (Fig. 32.19).

Introduction

Reproductive efficiency in a cattle enterprise is a function of good management. Therefore, it is important that the help and advice provided to management by the veterinarian should be based upon a sound appreciation of the physiological mechanisms that control the principal reproductive events.

The essential numerical data on reproduction in cattle are well known: puberty in bulls and heifers at 10–15 months of age; normal oestrous cycles of 18–24 days (mean = 21 days); normal oestrus lasts 12–24 hours (mean = 18 hours); ovulation occurs about 24 hours after the LH peak at the beginning of oestrus; normal gestation lasts 278–293 days; the interval from parturition to first ovulation can be as short as 15 days. The physiological control of each of these events is exerted by a system of interdependent endocrine organs that form the hypothalamic–pituitary–gonadal (HPG) axis, an important limb of the neuroendocrine system.

The primary purpose of this chapter is to provide a succinct outline of the salient features of the neuroendocrine system as it affects reproduction. Why is it con-

sidered necessary to do this in a text addressed primarily to clinicians? Essentially, because we believe that it will enhance the reader's understanding of the pathogenesis of many of the reproductive problems encountered in practice and, as a consequence, it will foster a more methodical and perceptive approach to diagnosis and treatment. Underpinning that belief is the knowledge that efficient reproductive performance in the female is dependent on an integrated and precisely timed sequence of hormonal changes that are regulated by the hypothalamus in response to changes in the external and internal environments. Of course, this means that the sequence and timing of the hormonal changes are vulnerable to a great variety of stressors and noxious agents. Many of these deleterious factors have been recognized – and will be mentioned later in the relevant sections – but it is likely that many more remain to be discovered, in particular subtle but significant stressors associated with modern developments in cattle husbandry. The individual best placed to identify 'new causes' of reproductive inefficiency is the informed clinician working with problem herds; however, such insights are less likely if the investigator is not fully alert to the central role of the neuroendocrine mechanisms and their sensitivity to the effects of dietary and metabolic factors, hormone imbalances, stressors, drugs, age and many other influences.

The hypothalamus

In the neuroendocrine system the dominant role is played by the hypothalamus, which acts as a relay station where neural and hormonal messages are decoded and translated into appropriate signals to ensure the cooperation of the endocrine system with the nervous system in regulatory activities. It is able to do so because it contains many neurones that are capable of forming and releasing peptide hormones (neurohormones) that regulate the functions of various organs, principally via the pituitary gland.

These regulatory peptides are synthesized and packaged into granules in the cell body of the neurone

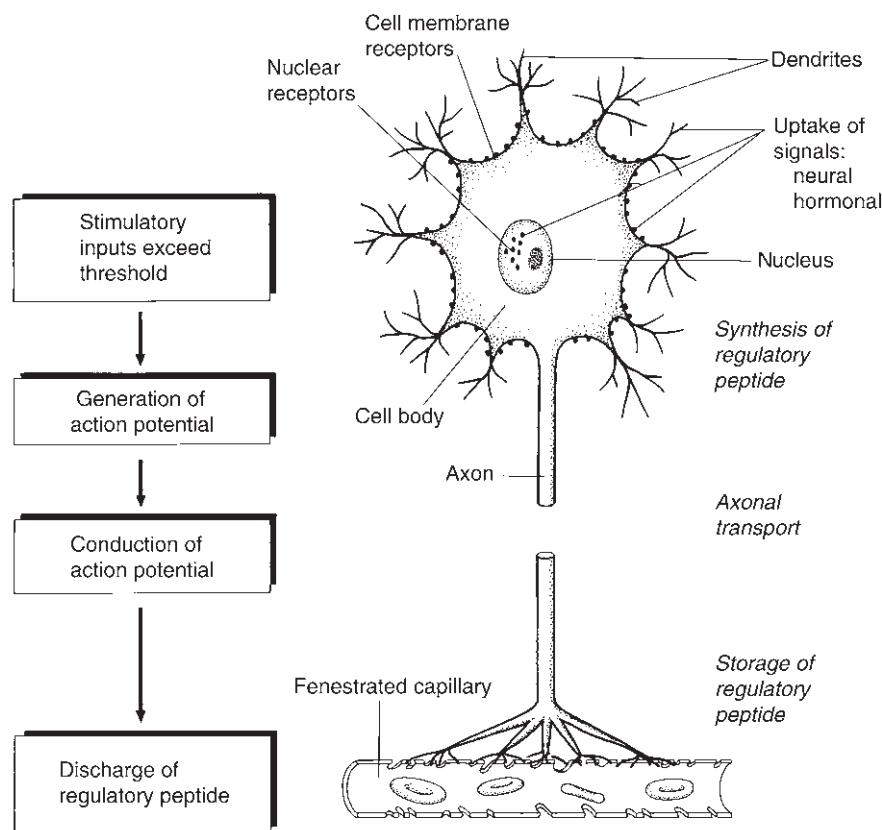

Fig. 33.1 This diagrammatic representation of a typical peptidergic neurone depicts: (i) the uptake of neural signals by dendrites; (ii) the uptake of endocrine signals by specific receptors located either in the cell membrane (for water-soluble hormones: peptides, proteins) or in the nucleus (for lipid-soluble hormones: steroids, thyroid hormones); (iii) the endocrine response to signals (synthesis, transport and storage of regulatory peptide); (iv) the neural response to signals (generation and conduction of action potential, which is responsible for the discharge of the regulatory peptide).

before they are transported down the axon to the nerve terminals where they are stored pending release. The peptidergic neurones retain the electrophysiological properties of nervous tissue and they use their electrical activity to release the peptides.

A typical peptidergic neurone (Fig. 33.1) has many hundreds of synapses and through these it receives neural inputs (information) from most parts of the brain. (It also receives information from humoral inputs; we shall return to this topic later.) The neural and humoral inputs may be stimulatory or inhibitory; at any one moment the response of the peptidergic neurone will reflect its assessment of the current interplay between the synergistic and conflicting stimuli. When the stimulatory inputs exceed a critical threshold an action potential is generated, the nerve impulse passes down the axon and it causes the release of the (stored) peptide at the nerve terminals. Usually, the nerve terminals are in close apposition to capillaries with highly fenestrated walls that allow the peptide molecules to enter the vascular circulation promptly on release.

A simple example to illustrate the physiological phenomena just described is the milk ejection reflex (Fig. 33.2). This reflex depends on a suckling-induced release of oxytocin. Oxytocin is produced by peptidergic

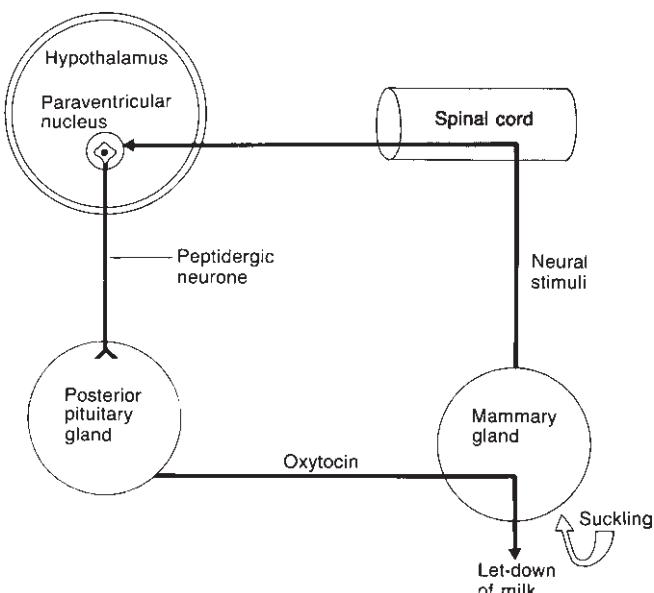

Fig. 33.2 Diagrammatic representation of the suckling reflex, in which neural stimuli elicit an endocrine response.

neurones whose cell bodies are located (principally) in the paired paraventricular nuclei in the hypothalamus and whose axons pass through the pituitary stalk into the posterior pituitary gland. Suckling evokes sensory

impulses that travel via the spinal cord to the brain where they converge on the paraventricular nuclei and generate the impulses in the peptidergic neurones that lead to the release of oxytocin from the nerve endings in the posterior pituitary gland. The reflex is completed when the oxytocin in the blood perfusing the mammary gland induces 'let down' of milk. Conceptually, this is neuroendocrine regulation at its simplest: the neurone that 'reads' the afferent sensory message also produces and releases the effector hormone. This is possible only because the posterior pituitary gland, which arises as a downgrowth of neural tissue from the floor of the third ventricle, retains a direct neural link with the hypothalamus.

The anterior pituitary gland

The anterior pituitary gland (adenohypophysis) arises as an upgrowth from the roof of the primitive mouth and, therefore, it does not have a direct neural link with the hypothalamus. A vascular route has to be used to bring the regulatory peptides from the hypothalamus to the adenohypophysis. A specialized arrangement of the vasculature, the hypothalmo-hypophyseal portal system, has evolved for that purpose. In contrast to the normal sequence of arterioles, capillaries and venules, a portal system begins and ends with capillaries. In this instance, the superior hypophyseal artery gives rise to a plexus of capillaries (the primary plexus) in the region of the median eminence at the top of the pituitary stalk. From this the blood is drained by the hypophyseal portal veins, which pass down the pituitary stalk to end in a secondary plexus (the sinusoidal capillaries) within the anterior pituitary gland (Fig. 33.3). From there the blood returns to the general circulation via the anterior hypophyseal vein.

In contrast to the posterior pituitary gland, which does not produce the hormones it releases, the anterior lobe actually synthesizes the trophic hormones it releases into the circulation, including the gonadotrophins: follicle stimulating hormone (FSH) and luteinizing hormone (LH). However, the release of the trophic hormones is governed by stimulatory or inhibitory peptides produced in the hypothalamus. For instance, the secretion of FSH and LH is controlled by a gonadotrophin-releasing hormone (GnRH), which is synthesized by peptidergic neurones in the hypothalamus and is brought to the anterior pituitary gland via the hypothalmo-hypophyseal portal system. The axons of the neurones that produce GnRH end in the median eminence, in close apposition to the fenestrated capillaries of the primary plexus. When a nerve impulse induces a discharge of GnRH from the nerve terminals, this hypothalamic factor is transported via the primary

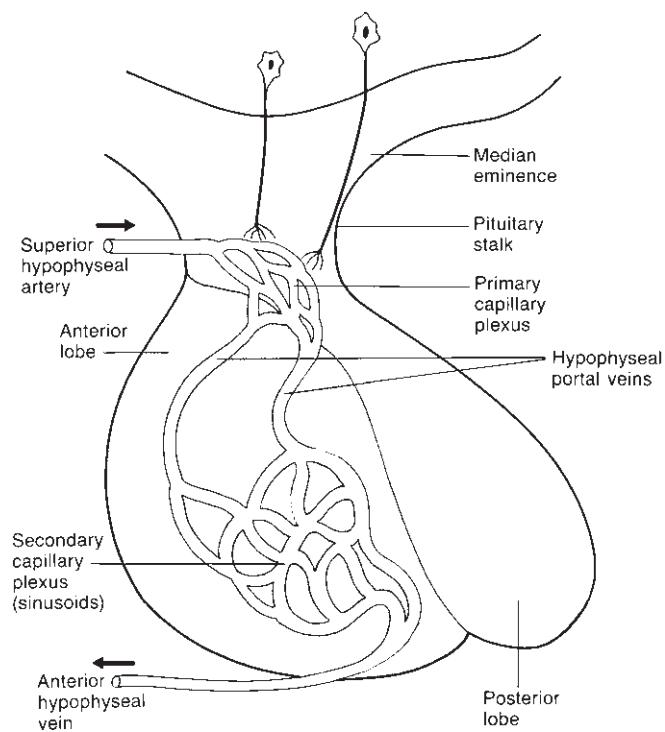

Fig. 33.3 The primary capillary plexus, the hypophyseal portal veins and the secondary capillary plexus form the hypothalmo-hypophyseal portal system that intervenes between the superior hypophyseal artery and the anterior hypophyseal vein. This is the route taken by GnRH which is synthesized by neurones whose cell bodies lie within the arcuate nucleus of the hypothalamus and whose axons abut onto the external walls of the capillaries in the primary plexus.

plexus, the hypophyseal portal veins and the secondary plexus to the secretory cells of the anterior lobe. It stimulates the release of the gonadotrophins, which enter the general circulation via the draining anterior hypophyseal vein. Other hypothalamic factors may exert inhibitory actions in the anterior pituitary gland, e.g. prolactin inhibitory factor (dopamine).

Neuroendocrine links

Since the peptidergic neurones form the functional links between the neural and endocrine systems, they need to be able to receive, decipher and react to signals generated by either system in response to changes in the internal and external environments. Neural signals from other regions of the brain converge on the hypothalamus bringing important cues from the special senses (sight, sound, smell), various exteroceptors (suckling, mating, pain), interoceptors (stimulation of

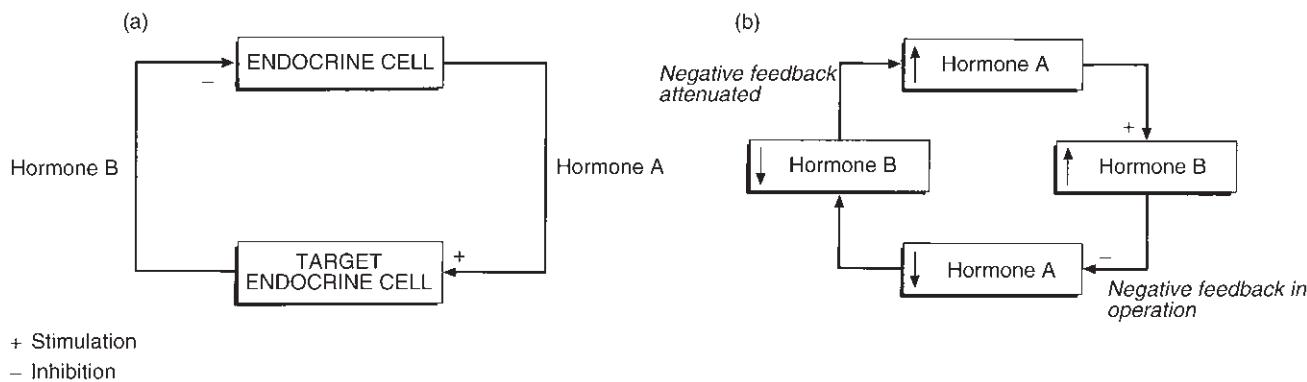

Fig. 33.4 Negative feedback. Example: hormone A, FSH; hormone B, oestrogen. FSH stimulates the production of oestrogen by the granulosa cells of the ovarian follicle. The oestrogen exerts an inhibitory effect on the release of FSH by the pituitary gland. When the oestrogen declines the negative feedback is attenuated and secretion of FSH is increased.

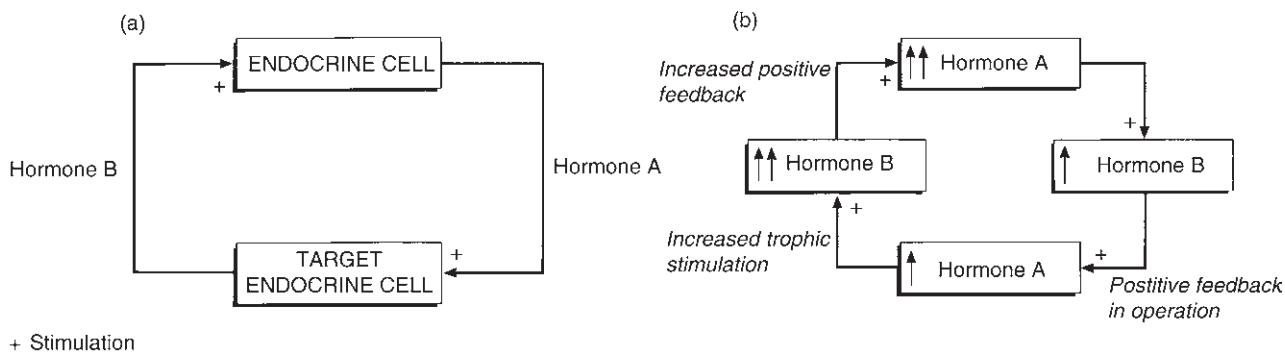

Fig. 33.5 Positive feedback. Example: the gonadotrophins FSH and LH (hormone A) stimulate the secretion of oestrogen (hormone B) by the granulosa cells of the preovulatory ovarian follicle (see Fig. 33.24). The rapidly rising concentration of oestrogen (the 'oestrogen surge') stimulates the hypothalamus and the pituitary gland to release a surge of gonadotrophins that is responsible for ovulation. Dilution abolishes the positive feedback at source.

the cervix and uterus) and stressors (physical, emotional, overcrowding). The peptidergic neurones also respond to humoral signals, especially to hormones acting through feedback loops. Again, the input may be stimulatory (positive feedback) or inhibitory (negative feedback). Although there are some important positive feedbacks, e.g. oestrogen prior to ovulation, the majority of feedback loops are negative.

Feedback

In its simplest form, a negative feedback loop (Fig. 33.4a) is a closed system in which hormone A stimulates the production and release of hormone B which, in turn, has an inhibitory effect on the cells that produce hormone A. Such a loop provides a very efficient mechanism by which circulating hormones are maintained

within stable normal limits while retaining their responsiveness to the immediate needs of the body. For instance, when the concentration of hormone B in the circulation rises towards its upper normal limit it exerts negative feedback on its trophic hormone. Thus, hormone A is prevented from exceeding its upper normal limit; the concentration of A in the circulation declines and, of course, so does the activity of its target cells. The resultant decline in hormone B attenuates the negative feedback inhibition (Fig. 33.4b) and the secretion of hormone A is enhanced before it falls below its lower normal limit.

In a positive feedback loop (Fig. 33.5a) hormone B stimulates rather than inhibits the production of more hormone A. This is an inherently unstable system in that it is liable to generate ever-increasing quantities of each of the hormones (Fig. 33.5b); in other words, it lacks the checks and balances of a negative feedback system. However, it is ideal for situations that call for

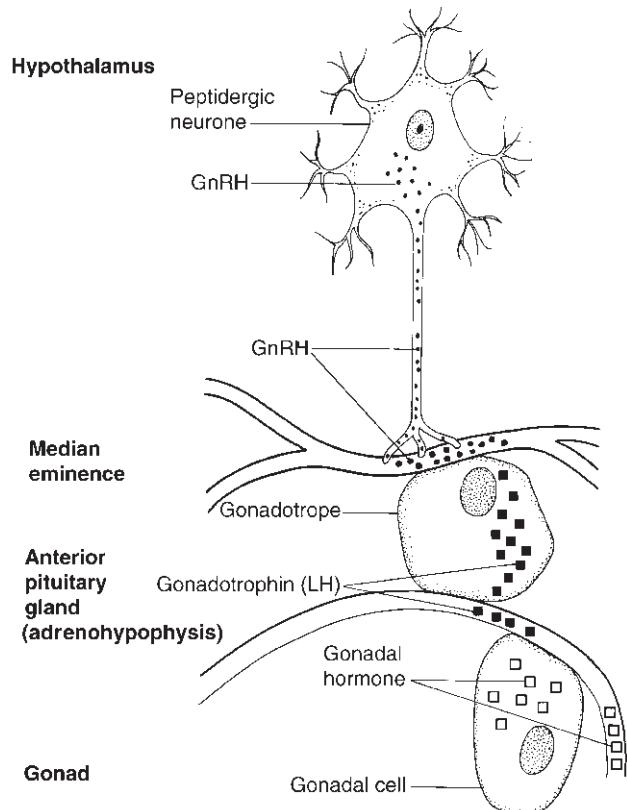

Fig. 33.6 Secretory cells in series: peptidergic neurone secretes GnRH; gonadotrope secretes LH, FSH; gonadal cell secretes testosterone, progesterone or oestrogen.

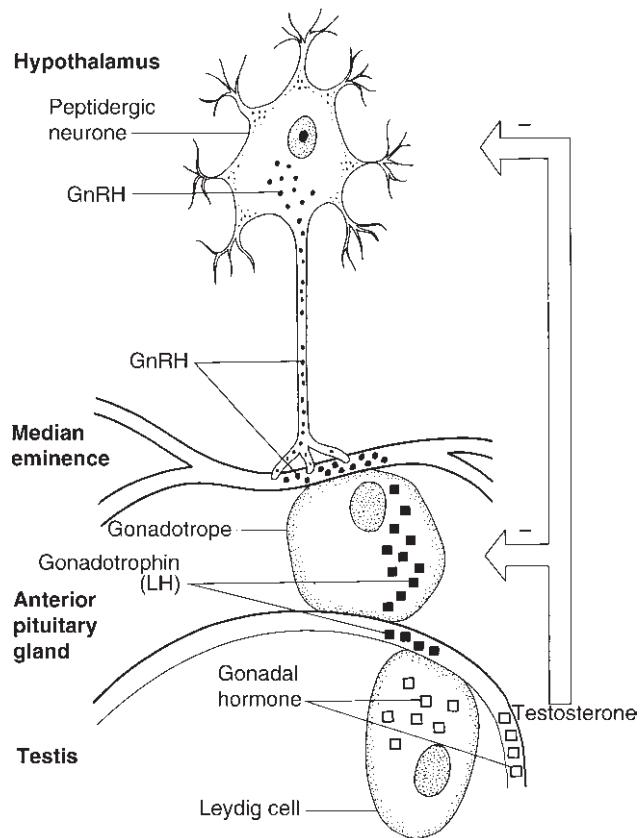

Fig. 33.7 Long loop negative feedback. LH induces Leydig cells to secrete testosterone; testosterone exerts so-called long loop feedback (i) on adrenohypophysis (suppressing secretion of LH) and (ii) on hypothalamus (suppressing secretion of GnRH).

short-term but self-limiting responses. The positive feedback loop may be a purely hormonal phenomenon; for example, the brief but highly significant period of positive feedback by oestrogen that elicits the preovulatory surge of LH. Other important positive feedback mechanisms are initiated by neural stimuli from exteroceptors, e.g. the suckling reflex, or interoceptors, e.g. stretch receptors in the cervix and vagina during the second stage of parturition, that induce reflex release of oxytocin. These two reflexes are excellent examples of self-limiting responses; removal of the physical stimulus terminates the reflex response almost at once.

The feedback mechanisms involved in the control of the reproductive tract are complex and involve several sets of secretory cells in series (Fig. 33.6). For descriptive purposes, three types of complex feedback loops are recognized:

- Long loop: for example, gonadal hormones acting at the level of the brain or pituitary gland (Fig. 33.7).

- Short loop: for example, pituitary gonadotrophins acting at the level of the hypothalamus (Fig. 33.8).
- Ultra-short loop: hypothalamic peptides acting at the level of the hypothalamus (Fig. 33.9).

The feedback effect of a particular hormone is not an intrinsic property of the molecule itself; for instance, although oestrogen is inhibitory (negative long loop feedback), during most of the oestrous cycle it exercises an essential stimulatory effect (positive long loop feedback) shortly before ovulation. Clearly, a single hormone can vary the message it conveys to the hypothalamus. This raises a crucial question: how do the gonadal steroids, the pituitary gonadotrophins and the hypothalamic peptides encode the signals that constitute the feedback messages? By definition, feedback depends on the ability of the target tissues to detect changes in hormone concentrations in the circulation, and to induce the appropriate re-adjustments (further changes). Hence, the system

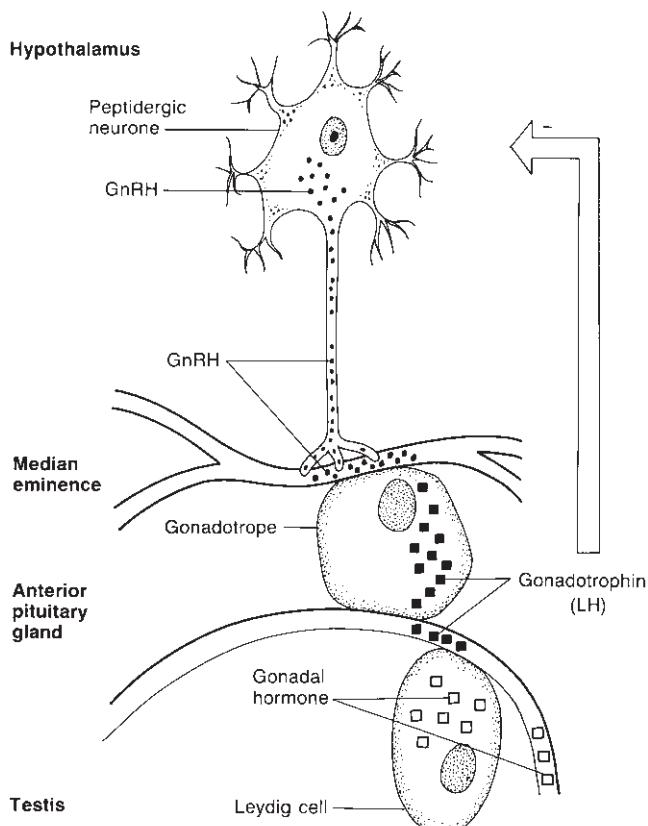

Fig. 33.8 Short loop negative feedback. GnRH induces the gonadotropes to secrete LH; LH exerts negative feedback on the release of GnRH by the hypothalamus.

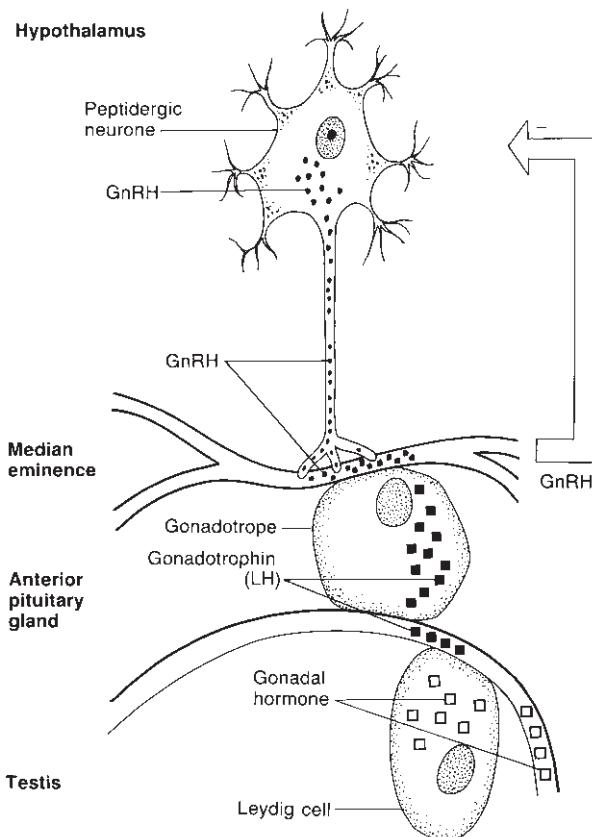

Fig. 33.9 Ultra-short loop negative feedback. The hypothalamic hormone (GnRH) regulates its own secretion.

depends on fluxes rather than constancy as the means of communication.

Endocrine signals: generation and reception

Two basic types of endocrine signals are used: pulses and surges (Fig. 33.10). A pulse of a particular hormone is a discrete burst of secretion of relatively short duration and modest amplitude. A surge occurs when a sequence of frequent pulses, often of high amplitude, produces a massive increase extending over a period of 12–24 hours.

Endocrine signals are detected only by cells that have specific receptors to which a particular hormone will bind. When the hormone interacts with the cells that produce it we refer to autocrine stimulation; when it interacts with another cell type located near the producer cell we call it paracrine stimulation; when it enters the blood stream and interacts with target cells elsewhere we call it endocrine stimulation. The recep-

tors may be located in the cell membrane or within the cell, mainly in the nucleus (see Figs 33.1 and 33.11). The polypeptide hormones, e.g. GnRH, and the glycoprotein hormones, e.g. LH, FSH, bind to receptors in the cell membrane (Fig. 33.11a), whereas the lipid-soluble gonadal steroids can diffuse through the cell membrane to react with intracellular receptors (Fig. 33.11b). The location of the specific receptors determines the mechanism by which the target cells express their characteristic responses to a hormone and, in turn, the different mechanisms determine the speed at which the final response is elicited.

When a gonadal hormone binds to its specific receptor in the nucleus of a target cell, it initiates a series of biochemical reactions that takes several hours to produce the new proteins that elicit the characteristic response to that hormone (Fig. 33.11b). By contrast, when a gonadotrophin binds to its receptor in the cell membrane, it elicits the final response much more rapidly because the resultant cascade of enzymatic activity utilizes enzymes that exist already within the cell. Binding of the hormone (the ‘first messenger’) to

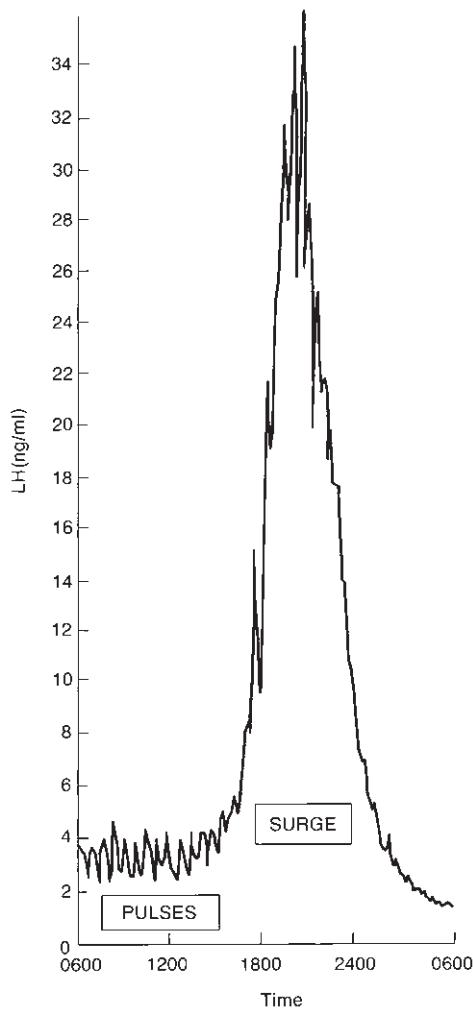

Fig. 33.10 Preovulatory surge of LH on day 18 of the oestrous cycle in a cow. (Redrawn from Rahe *et al.*, 1980).

the receptor activates an enzyme within the cell membrane that acts as a catalyst in a reaction that produces a 'second messenger', e.g. cyclic AMP, that, in turn, alters the activities of the enzymes that produce the final and characteristic response by the cell (Fig. 33.11a).

The sensitivity of a target tissue to a particular hormone will vary depending upon the number of specific receptors it has available for binding that hormone. At any time, the number of receptors depends on the balance between degradation and synthesis of receptors. A hormonal stimulus may increase the sensitivity of a target tissue by increasing the rate of synthesis of the specific receptors; a good example of this 'up regulation' is the increase in LH receptors induced in the granulosa cells of the preovulatory follicle by FSH

(see p. 492). Alternatively, the hormone stimulus may decrease the sensitivity of the target tissue because it increases the degradation and/or decreases the synthesis of receptors; for instance, GnRH can 'down regulate' its own receptors in the adenohypophysis, especially when the gonadotropes are subjected to constant stimulation rather than pulsatile stimulation by the releasing hormone (see p. 497).

The inherent mode of secretion of hormones in the neuroendocrine system is pulsatile and it is controlled by an oscillator or pulse generator in the hypothalamus. The activity of the pulse generator can be modulated both by neural inputs and by feedback signals from the median eminence, the pituitary gland and the gonads. In turn, the pulse generator will seek to ensure that the characteristics of the signals emanating from the pituitary gland and the gonads are altered so as to elicit the appropriate responses from target tissues in the reproductive tract. In that way the hypothalamus exercises fine tuning as well as gross control over reproductive events such as puberty, gametogenesis, oestrus, pregnancy, parturition and lactation.

Before we deal with the neuroendocrine regulation of those processes, it is appropriate to mention three systemic conditions that can constrain the reproductive system: energy balance, stress and neural-immune interactions.

Systemic constraints on reproduction

Energy balance

Although reproduction is critical for the survival of the species, processes that are of more immediate importance for the survival of the individual take top priority when an animal allocates available metabolic fuels among various energy-consuming activities (Fig. 33.12). Hence, changes in the availability of metabolic fuels affect reproductive functions, through actions at multiple sites in the central nervous system, pituitary gland, gonads and other peripheral organs (e.g. liver, skeletal muscles, adipose tissue). Negative energy balance leads to metabolic trade-off in which reproductive activity is curtailed, sometimes suspended. The suspension leaves the regulatory neuroendocrine apparatus intact; reproductive efforts can be resumed when the energy deficit has been repaired.

In many simple-stomach species the neural mechanisms that control the pulsatile release of GnRH (and, consequently, LH secretion and ovarian function) appear to respond to minute-by-minute changes in the availability of metabolic fuels (Bronson, 1989; Wade & Schneider, 1992). The response in ruminants may not be as immediate but it is significant, nonetheless. According to Roche *et al.* (2000), cattle are very sensitive to

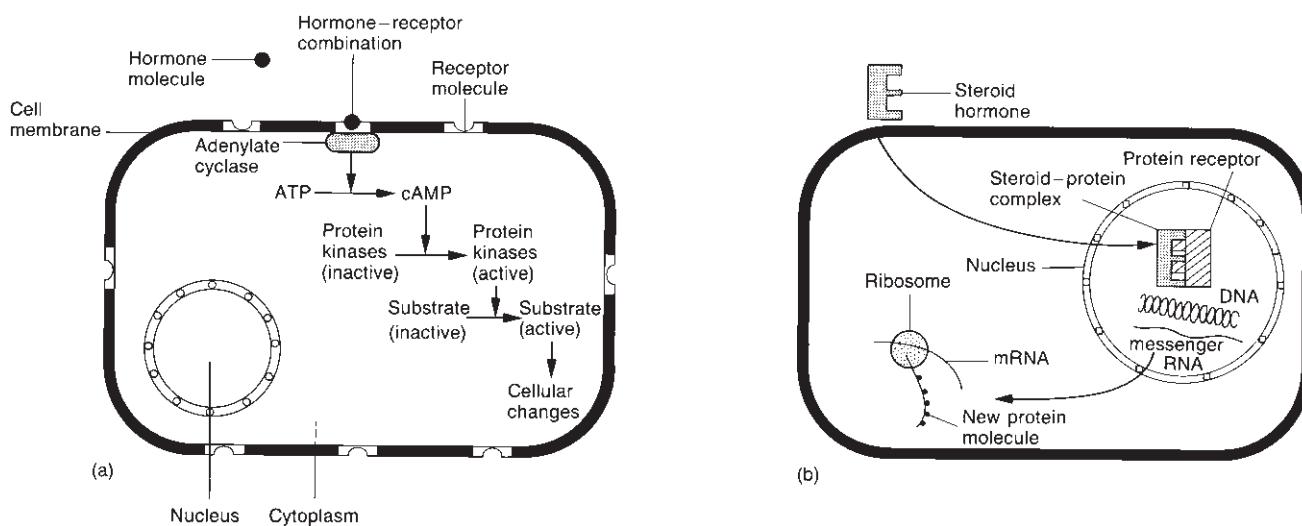

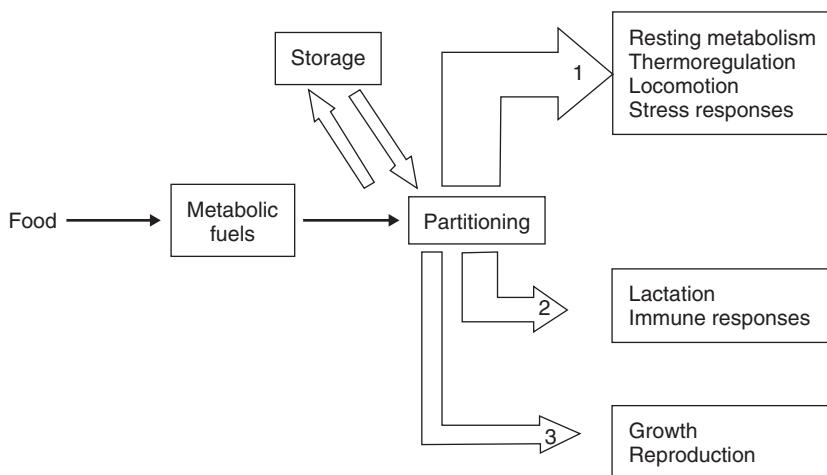

Fig. 33.11 Interaction of hormones with target cells. In (a) a glycoprotein (the ‘first messenger’) binds with receptors in the cell membrane and activates adenylate cyclase in the membrane. Adenylate cyclase converts ATP to cyclic AMP (the ‘second messenger’) which, in turn, activates various protein kinases. The resultant cascade of enzymatic activity produces the characteristic cell response to the endocrine signal. In (b) a steroid hormone enters the nucleus where it binds to its receptor. The receptor–hormone complex binds to a particular region of DNA and activates particular genes. The activated genes promote the synthesis of particular messenger RNA molecules that pass from the nucleus to the cytoplasm where they induce the synthesis of proteins (mainly enzymes) that are responsible for the characteristic actions of that hormone in that cell type.

acute nutritional deprivation: after a lapse of three to five days, follicular growth is impeded and ovulatory ability is reduced. Chronic nutritional deprivation results in delayed puberty and, in adult females, it causes extended postpartum anoestrus and prolonged calving intervals.

Stress (see Chapter 67)

The effects of stress on reproductive functions are complex: during the stress response increased activity

of the sympathetic nervous system induces catabolic responses that mobilize energy, promote its expenditure, and leave less available for use by the HPG axis; concurrently, cortisol released by the hypothalamic–pituitary–adrenal (HPA) axis acts as a counter-regulatory signal at all critical points in the HPG axis and at target tissues for the gonadal steroids (see Fig 67.6). Short-term acute stressors active at critical times in the reproductive cycle of a female can disrupt the orderly timed sequence of hormonal changes on which reproductive success is predicated. In

Fig. 33.12 Partitioning of energy by a lactating cow. The sizes of the arrows indicate the order of priorities rather than the quantities of metabolic fuels allocated to the different activities.

such circumstances, failure to establish a pregnancy may be a ‘one-off’ eventuality without residual effects on the next attempt. On the other hand, stressors that generate allostatic load (see Chapter 67) may lead to attenuation or suspension of reproductive activities for periods of weeks or months until the counter-regulatory signals are quenched. In such cases, inhibition of the pulsatile release of GnRH may be the most significant action in the context of self-preservation of the organism, but inhibition at other critical points in the HPG axis may be responsible for more persistent carry-over effects during the recovery phase. Recovery of reproductive efficiency requires that the appropriate biochemical features (receptors, G-proteins, transcription factors, other signalling proteins, enzymes, metabolic cascades) be restored and functional at each of the critical points in the HPG axis. As happens at puberty and, again, in the early postpartum period, it may require more than one attempt to fully up-regulate the normal cascade of the HPG axis and reinstate the ability to reproduce.

Neuro-immune interactions

In recent years it has become increasingly evident that the interactions *between* behavioural, neural, endocrine and immune processes are as important to our understanding of homeostasis as are the interactions *within* each of the individual disciplines. In the present context, we focus on the bidirectional network through which the CNS and the immune system exert profound effects on each other. The nervous system impacts upon the immune system through several routes, systemic and local, including neuroendocrine pathways (e.g. the HPA axis), autonomic nerves and systemic nerves. In the reciprocal relationship, cytokines (see Box 33.1)

Box 33.1. Cytokines

Molecules, proteins or glycoproteins, produced by one or more cell types that regulate the activities of other cells. They bind to specific receptors on the cell membranes of target cells and, like hormones, they may act locally in autocrine or paracrine fashion, or they may be released into the bloodstream and interact with target cells elsewhere in the body. More than 100 cytokines have been identified; they are classified into several categories: interferons, insulin-like growth factors, interleukins, tumour necrosis factors, growth factors, transforming growth factors, and so on. Amongst a vast range of activities, they participate in haematopoiesis, cell proliferation, immune responses, inflammation, wound healing, modulation of cell metabolism. The nervous system can produce cytokines and it can respond to cytokines released peripherally; for instance, in fever, in sickness behaviour and in modulating neuroendocrine responses – which is the context in which we have introduced the term.

from activated immunocompetent cells can evoke a variety of neural, neuroendocrine, metabolic and behavioural responses regulated by the CNS; the effect is akin to activation of the central neural and hormonal components of the stress response (see Chapter 67): the main routes of communication are via the sympathetic nervous system and the HPA axis. The noradrenaline and glucocorticoids released by the counter-regulatory loops invoked by the cytokines can have profound biological effects in terms of the expenditure of energy, immunosuppression and interference with the functions of the HPG axis. Thus, for instance, the cross-talk between the brain and the immune system evoked by a severe bout of mastitis in early lactation can have a seriously negative impact on the restoration of cyclic ovarian activity and fertility.

Puberty (see also Chapter 5)

Puberty, the process by which animals become capable of producing offspring, is often given a very restricted definition. According to Short (1984), ‘we generally refer to puberty as that moment at which the female first comes into oestrus and ovulates, or the male first produces spermatozoa in his ejaculate’. The trouble with this widely-held perception of puberty is that it concentrates exclusively on the apparent end-point of a protracted and complex physiological process and suggests that puberty is a discrete event that can be assigned to a particular day (or moment!). There is the additional problem that the apparent end-point (first release of the gametes) is not necessarily conclusive evidence that the animal has now reached the stage at which it can reproduce itself; for instance, it is clear that many heifers may not be capable of doing so until well after first ovulation.

In fact, the onset of puberty is a gradual process that is in train for several months during which there are significant morphological, physiological and behavioural responses to the progressive expression of both the steroidogenic and gametogenic activities of the gonads. The essential feature of the process is the maturation of the brain–hypothalamic–pituitary–gonadal axis, which culminates in the adult pattern of reproductive activity. The components of the hypothalamic–pituitary–gonadal axis are present before birth and, even at that stage, each component is capable of responding to appropriate hormonal signals. During gestation, steroid hormones released from the placenta have an inhibitory effect on the fetal hypothalamus that suppresses the activities of the axis. After birth the axis becomes an independent regulatory system that secretes increased amounts of gonadotrophins and gonadal steroids. However, the system is restricted to a

relatively low level of activity (juvenile level); for instance, in the female the level of activity is well below that required for ovulation or cyclic ovarian activity. The restraint is due partly to fine sensitivity of the GnRH pulse generator to negative feedback by gonadal steroids and partly to inhibitory inputs from the neural circuits that modulate the activities of the hypothalamus.

The transition to sexual maturity is brought about by progressive changes in the neuroendocrine activities of the axis in response to a variety of internal and environmental factors. The 'gonadostat' hypothesis postulates that the essential change during the transition to sexual maturity is a progressive decrease in sensitivity of the hypothalamus to the negative feedback effects of gonadal steroids (Fig. 33.13) so that the frequency of GnRH pulses is increased progressively. This leads to an increase in the sensitivity of the pituitary

gonadotropes to GnRH and to an increase in the responsiveness of the gonads to the gonadotrophins (Fig. 33.14). Greater quantities of gonadotrophins are released from the pituitary gland and, in turn, greater quantities of steroids are released by the gonads. For instance, in the female the sensitivity of the hypothalamus to the negative feedback effect of oestrogen declines progressively and, as it does so, the increasing quantities of oestrogen from the ovaries can no longer hold the axis within the juvenile pattern of activity. There is a gradual movement of the regulatory system towards the adult pattern (Figs 33.13 and 33.14). Eventually, the ovaries produce a surge of oestrogen that exerts a positive feedback effect on the pulse generator in the hypothalamus (Fig. 33.14) and this induces a surge of LH that leads to ovulation.

As our knowledge of these changes expands, there is increasing evidence that sexual maturity is regulated to

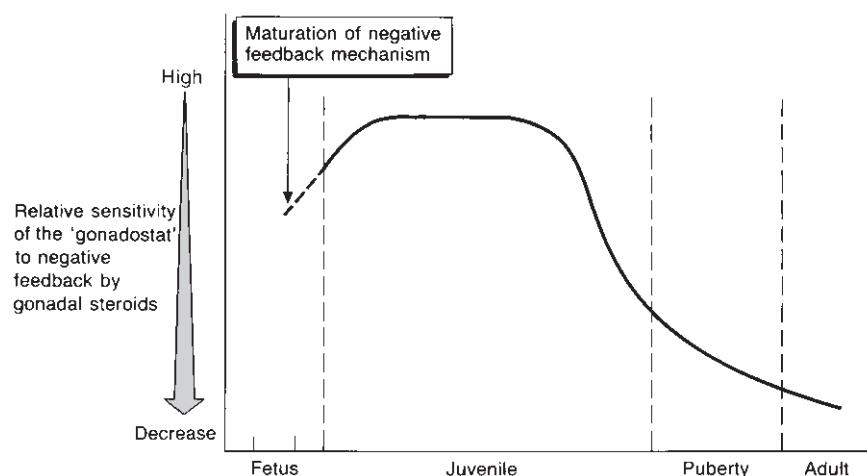

Fig. 33.13 Maturation of the negative feedback system and changes in set point of the hypothalamic gonadostat extending from fetal life through puberty to adulthood (modified from Grumbach *et al.*, 1974).

a considerable extent by changing patterns of neural control over the hypothalamus. These alterations in intrinsic neural activity do not appear to be dependent on gonadal hormones; however, they play a crucial role in that they gradually release the GnRH pulse generator from the restraints exercised by the central nervous system during the juvenile period, thus enabling it to respond to the gonadal steroids in the adult manner. It is evident that the classical 'gonadostat' hypothesis does not furnish an entirely satisfactory explanation of the onset of puberty in all its details. Nevertheless, it does provide a conceptual framework that is adequate for the purposes of this text.

The first ovulation is likely to be silent; it appears that the hormonal requirements for the expression of oestrus are small quantities of progesterone from a regressing corpus luteum followed by a surge of oestrogen from the preovulatory follicle – a sequence that is absent at the time of first ovulation. Thus, the first oestrus observed by the stockperson indicates that the process of puberty is well advanced but it does not provide a precise date for the 'moment' of puberty.

The earliest possible maturation of the individual components of the reproductive axis (and, therefore, of the axis itself) is determined by genes, i.e. there are inherent breed variations in the onset of puberty. However, in all breeds this process is subject to delays caused by a variety of endogenous and exogenous influences, some of which can be manipulated by the stockperson to ensure that the heifer is ready for breeding at the desired time. The principal environmental factors that influence the onset of puberty are: season of birth, level of nutrition, growth rate, photoperiod, high ambient temperatures, intercurrent diseases and presence of the male.

Specific reference to these factors will be made in the clinical segment of the text. For the moment, suffice it to say that, as a general guideline, the stockperson should devise a management strategy in the knowledge that the onset of puberty is a labile process that is conditioned by competition between the reproductive system and the other body systems of the growing animal for energy and specific nutrients. Reproduction, particularly in the female where it involves pregnancy followed by lactation, is an energy-consuming process to which Nature assigns a relatively low priority for the prepubertal animal. Evidence is accumulating from work on a number of species that inadequate intake of energy or nutrients can depress or abolish the activities of the GnRH pulse generator in the juvenile animal. This has been attributed, variously, to deficiencies in body weight, in rate of growth, in fat content or in fat:lean ratio. There is no agreement on the particular cue(s) that inhibit(s) the pulse generator but there is general acceptance of the thesis that the function of the

generator is closely coupled with energy balance and that it is allowed to progress from the juvenile to the adult level of activity in the female only when the energetic status appears to be adequate to sustain pregnancy and lactation. It was anticipated that the hormone leptin, produced by adipose tissues, might prove to be the signal that triggers the onset of puberty: current evidence is that leptin is just one of many permissive metabolic factors that allow pubertal development to proceed; it may act as a permissive signal to increase GnRH secretion after the pulse generator has been sensitized to energy balance by other developmental or metabolic cues; it is not the trigger for the beginning of puberty (Urbanski, 2001; Smith *et al.*, 2002).

Selective culling is an integral part of efficient management of the dairy herd. It can be practised successfully only when the stockperson has available an adequate number of high-quality heifers due to calve down at the appropriate time. This requires careful management of the prepubertal animal to ensure that the reactivation of the hypothalamic pulse generator is not delayed unduly by environmental influences, principally nutritional factors and subclinical diseases.

Similarly, young bulls intended for breeding purposes require careful management during the juvenile period because the onset of puberty in the male is also influenced by a variety of factors (including breed, season of birth, energy intake and liveweight gain) that affect the reactivation of the hypothalamic GnRH pulse generator.

Male physiology

In the male, puberty is associated with changes in the pattern of LH secretion, a gradual increase in the concentration of testosterone in the blood, rapid growth of the testes and the initiation of spermatogenesis. In essence, the adult pattern of GnRH release is attained and the testes proceed to fulfil two primary functions: the synthesis and release of androgens (steroidogenesis) and the production of spermatozoa (gametogenesis). In most male mammals, these functions are performed best at temperatures somewhat lower than body core temperature.

In the bull the testes are located in the pendulous scrotum, where they are attuned to function at 3–4°C below core temperature. The three principal mechanisms by which the scrotal temperature is reduced are as follows:

- (1) Precooling of the arterial blood supply as it passes through the vascular cone in the spermatic cord. The vascular cone consists of a coiled segment of the spermatic artery that is surrounded by the

pampiniform plexus of the spermatic vein. Because of this anatomical arrangement the arterial blood and the venous blood are flowing in parallel but in opposite directions; this allows for an efficient countercurrent exchange of heat between the two vessels. The net result is that the arterial blood delivered to the testes is several degrees below body core temperature.

- (2) Sweating from the many sweat glands in the scrotal skin.
- (3) Physical contact with cold ground or other cold objects.

In very cold weather, the temperature at the base of the scrotum may be up to 7°C below core values but the bull can attempt to curtail the drop in temperature by drawing the scrotum closer to the (relatively) warm body wall by contracting the cremaster and dartos muscles.

The gametogenic function of the testes is much more heat sensitive than the steroidogenic function; for instance, a retained testicle in a cryptorchid animal ('rig') may secrete androgens but the seminiferous tubules will remain infantile in structure and they will not produce spermatozoa. The retained testicle has a propensity to develop neoplasms (see p. 182).

Morphology of the testis

The testis is surrounded by a thick fibrous capsule, the tunica albuginea, from which septa project inwards to divide the substance of the testis into lobules (Fig. 33.15). Each lobule contains one to four highly convoluted seminiferous tubules and interstitial tissue that fills the spaces between the convolutions.

The interstitial tissue contains blood vessels, lymphatic vessels, nerves and the steroid-secreting Leydig cells.

The seminiferous tubules are about 200 µm in diameter and they may be up to 70 cm long; they open at both ends into the rete testis (Fig. 33.15). The tubules contain two populations of cells: (i) a fixed population of non-proliferating somatic cells, the Sertoli cells, and (ii) a migratory population of proliferating, differentiating germ cells (Fig. 33.16).

Sertoli cells

The Sertoli cells have been described as the 'backbone' of the tubule. They are columnar cells that rest on the basement membrane and extend the full depth of the epithelial layer; they envelop the developing germ cells in deep recesses in their lateral walls and, ultimately, in their luminal surfaces. The Sertoli cells continually alter shape to accommodate the morphological changes in

the germ cells during their migration from the base to the luminal surface. The plasma membranes of adjacent Sertoli cells form specialized interepithelial tight junctions that extend entirely around the circumference of each cell (Fig. 33.17). These junctions constitute the epithelial component of the blood-testis barrier that precludes the passage of many substances from the blood or interstitial fluid into the lumen of the seminiferous tubule. They also divide the intercellular spaces into two compartments: the basal compartment that contains the undifferentiated germ cells and the adluminal compartment that provides the appropriate microenvironment for the more differentiated germ cells (see below).

The basal surface of the Sertoli cell has specific receptors for FSH. The cells respond to the gonadotrophin by secreting (i) a nutrient fluid that sustains the germ cells in the intercellular spaces, (ii) androgen-binding protein that binds and transports testosterone to the epididymis and (iii) inhibin that modulates the secretion of FSH by negative feedback at the pituitary gland (Fig. 33.18). Sertoli cells also have receptors for androgens; it is known that testosterone can maintain the functional integrity of the Sertoli cell when FSH is withdrawn.

Sertoli cells are resistant to relatively high levels of heat, ionizing radiation and many toxins (e.g. cadmium, nitrofurans, cytotoxins) that destroy differentiating germ cells.

Germ cells

A detailed description of the process of spermatogenesis (see Table 33.1) is beyond the scope of this text. Suffice it to say that the spermatogonia are the stem cells and that they begin the process by undergoing a number of mitotic divisions in the basal compartment. These divisions produce a pool of cells that are joined to each other by intercellular bridges (Fig. 33.19).

Cohorts of spermatogonia from this pool are moved to the adluminal compartment while one spermatogonium from the group remains behind in the basal compartment. It enters a resting phase during which it is highly resistant to ionizing radiation and toxic agents. This will be the stem cell from which the next cycle of spermatogenesis will begin (two weeks later). In the meantime, the newly arrived cells at the base of the adluminal compartment proceed to undergo meiosis as primary spermatocytes (first meiotic division) and secondary spermatocytes (second meiotic division). The haploid secondary spermatocytes are still attached to each other by intercellular bridges and after a short period each of them divides to yield two spermatids. As the process of spermatogenesis proceeds the germ cells move progressively towards the lumen of the tubule,

still attached to the Sertoli cell; the final stages take place at the luminal surface. The conversion of the spermatid to the spermatozoon does not involve cell division, merely morphological reorganization (referred to as spermiogenesis). The principal changes are condensation of the nucleus and acquisition of the acrosome in the head region, reorganization of the mitochondria in the middle piece, development of the tail and loss of excess cytoplasm that moves caudally and is shed as the residual body, which is phagocytosed by the Sertoli cell. The intercellular bridges are lost with the residual bodies and each spermatozoon now is a separate cell, that soon escapes from the luminal surface of the Sertoli cell (spermiation). When the fully developed spermatozoon is released into the lumen of the seminiferous tubule it is non-motile. It is transported passively from the tubule into the rete testis and thence to the epididymis. Motility is acquired during passage through the epididymis.

In summary, during spermatogenesis the germ cells advance through three major processes:

- (1) Proliferation of stem cells by mitosis in the basal compartment.
- (2) Reduction of the chromosome number by meiosis in the adluminal compartment.

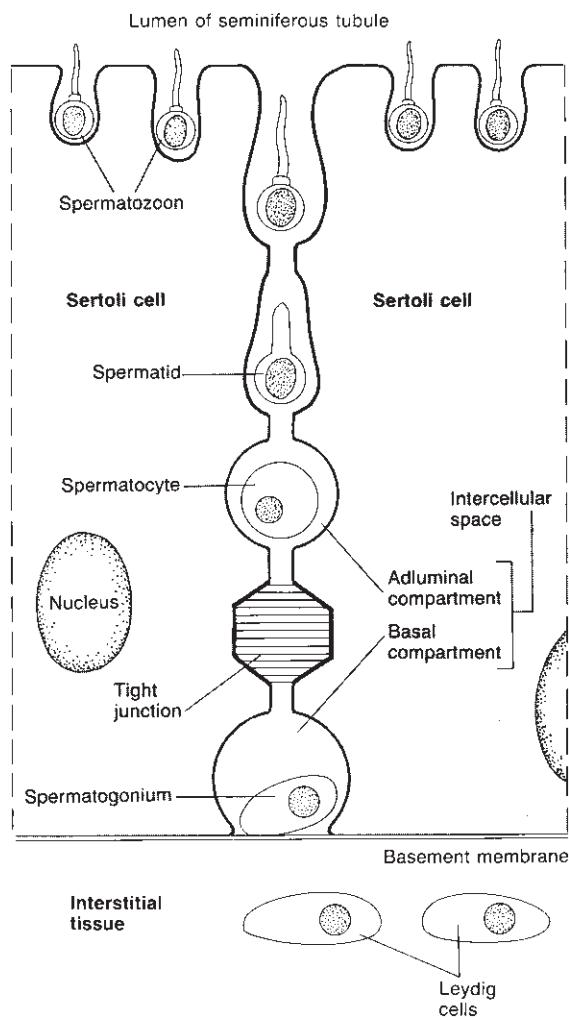

Fig. 33.17 The relationship between the germ cells and Sertoli cells during spermatogenesis.

- (3) Morphological transformation of a conventional cell (the spermatid) into the very specialized structure of the spermatozoon (spermiogenesis) in the adluminal compartment.

This sequence of mitotic, meiotic and packaging events requires 56 days for completion in the bull. It is a very orderly sequence in which each of the component cells has a fixed lifespan so that cellular differentiation proceeds at a fixed rate. The spermatogonium that reverts to the resting phase remains quiescent in the basal compartment for 14 days (equivalent to 25 per cent of the entire cycle) before it enters mitosis and begins the next spermatogenic cycle. The cells derived from the new cycle advance in a similar orderly fashion behind the cells from the previous cycle as they move progressively towards the luminal surface. In fact, this arrangement means that four successive cycles of spermatogenesis

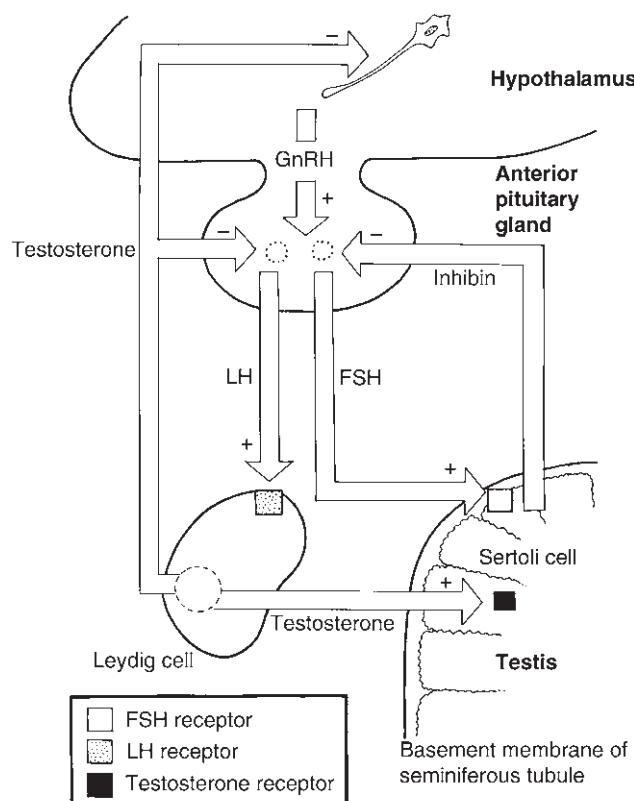

Fig. 33.18 Hormonal interactions in the hypothalamic–pituitary–testicular axis.

Table 33.1 Principal stages in the development of spermatozoa (spermatogenesis).

| Cell type | Number of chromosomes |
|------------------------|-----------------------|
| Spermatogonium | 2n |
| Primary spermatocyte | 2n |
| Secondary spermatocyte | n |
| Spermatid | n |
| Spermatozoon | n |

will be in train in the seminiferous epithelium at any moment. Furthermore, since both the intervals between the commencement of the cycles and the rates of progress of the cells through spermatogenesis are constant, a histological examination of a cross-section of a seminiferous tubule will reveal a characteristic set of cell associations at any one time. In most mammals the same set of cell associations is seen at all points in the circumference of the tubule (this represents the ‘cycle of spermatogenesis’); however, adjacent segments of the tubule tend to have a different set of cell

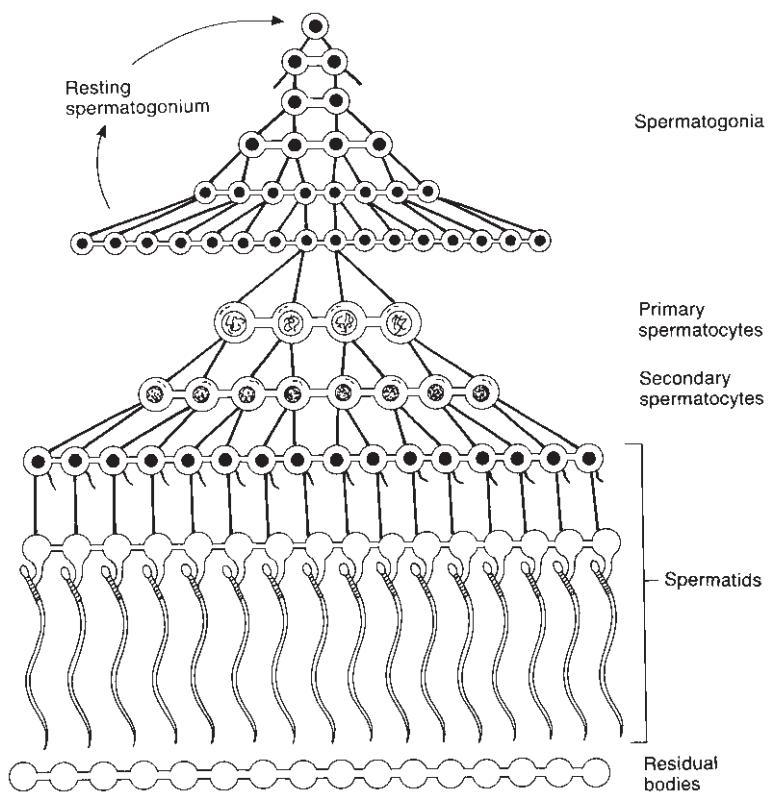

Fig. 33.19 The process of spermatogenesis.
(Reproduced from Fawcett, 1994.)

associations, each either in advance of or behind its neighbours (this constitutes the 'wave of spermatogenesis').

Some of the progeny of the original spermatogonia do not complete the full course; large numbers (perhaps 20 per cent) of differentiating germ cells die without reaching maturity and these are removed by the Sertoli cells.

The spermatozoon

The essential features of the mammalian spermatozoon are depicted in Fig. 33.20. Only one structure warrants further comment at this juncture: the acrosome, an organelle that undergoes significant morphological change as an essential prelude to fertilization. The acrosome contains a number of lytic enzymes (particularly hyaluronidase, neuraminidase and acrosin); it has been described as a modified lysosome and, like all lysosomes, it has a bilaminar structure. The inner acrosomal membrane is adherent to the nuclear membrane, while the outer acrosomal membrane underlies the cell membrane. When the ejaculated spermatozoon undergoes the acrosome reaction in the female genital tract, the outer acrosomal membrane forms point fusions with the cell membrane creating a sequence of vesicles over

the head of the sperm and allowing the lytic enzymes to escape through the resultant pores (see p. 499).

Neuroendocrine control

The steroidogenic functions and the gametogenic functions are segregated anatomically: androgen synthesis by the Leydig cells in the interstitial spaces and spermatogenesis within the seminiferous tubules (Fig. 33.17). Both functions are controlled by the pituitary gland through the secretion of the gonadotrophins. Luteinizing hormone binds to specific receptors on the cell membranes of Leydig cells and they respond by secreting androgens (principally testosterone), which in turn inhibit LH secretion by negative feedback. When the concentration of testosterone in the blood declines sufficiently the 'brake' on LH secretion is released and the resultant rise in LH in the circulation induces the Leydig cells to secrete testosterone (Figs 33.18 and 33.21). The negative feedback effect of testosterone on LH secretion is exercised at the level of the hypothalamus (influencing the secretion of GnRH) and at the pituitary gland (modulating the responsiveness of the gonadotropes to GnRH). In this manner the hypothalamic–pituitary–Leydig cell axis maintains the

concentration of testosterone in the general circulation within normal limits.
